Effects of early versus delayed umbilical cord clamping during antepartum lower segment caesarean section on placental delivery and postoperative haemorrhage: a randomised controlled trial

M Withanathantrige[1], I M R Goonewardene[1]

(Index words: cesarean section, delayed clamping, umbilical cord, postoperative hemorrhage)

Abstract

Introduction Although recommended, delayed cord clamping (DCC) is not frequently practised during lower segment caesarean section (LSCS).

Objective To assess the effects of DCC during antepartum LSCS on placental delivery and postoperative hemorrhage.

Methods A randomised controlled trial was carried out on 156 women undergoing antepartum LSCS between 37-39 weeks gestation at the Academic Obstetric Unit, Teaching Hospital Mahamodara, Galle from 21st January to 30th April 2013. One surgeon carried out the LSCS and the same operative technique was used on all. The umbilical cord of the baby was clamped at <15 seconds (n=52) or between 60 - 75 seconds (n=52) or between 120 - 135 seconds (n=52) according to a predetermined randomised allocation sequence. Postoperative hemorrhage, time taken for delivery of placenta, requirement of manual removal of placenta and additional uterotonics, and reduction of maternal haemoglobin and haemotocrit 48 - 60 hours after LSCS, were measured. The neonate was monitored for 72 hours.

Results There were no significant differences in post-operative haemorrhage or neonatal morbidity between the groups. There was a clinically non-significant increase in the time taken for placental delivery. The trend of reduction in the need for manual removal of placentae and additional uterotonics with DCC was not significant. The trend of increased requirement of phototherapy for neonatal jaundice with DCC was not significant.

Conclusion There were no significant differences in the risk of postoperative haemorrhage, manual removal of placenta, or maternal or neonatal morbidity between early cord clamping and DCC during antepartum LSCS.

Introduction

Delayed cord clamping (DCC), an inexpensive method which allows physiological placental transfusion has been described since the 1950s [1,2]. DCC is associated with increased birth weight, (mean difference 101g; 95% CI 45-157), increased new born haemoglobin (mean difference 2.2 g/dl; 95% CI 0.3-4.0 g/dl), increased new born haematocrit >45% (RR 16.2; 95% CI 2-127.4) persisting up to 48 hours, and a reduction of the risk of iron deficiency at three to six months of age (RR 2.7; 95% CI 1.0-6.7) [3]. The requirement of phototherapy for neonatal jaundice is reduced by early cord clamping (RR 0. 62; 95% CI 0.41-0.96) compared to DCC [3]. However DCC is not associated with lower Apgar Scores at 5 minutes, increased admission to special care baby units, respiratory distress, severe jaundice or long term adverse effects [3-7]. DCC is also not associated with increased risk of postpartum haemorrhage, blood transfusion, manual removal of placenta or increased duration of third stage of labour [3, 6-8]. DCC improves blood pressure, reduces the need for blood transfusions and the risk of intra-ventricular haemorrhage and necro-tizing enterocolitis in preterm infants [9]. Furthermore, DCC maintains oxygenation by sustained placental circulation and is beneficial if spontaneous pulmonary respiration is delayed or impaired [10-13]. Recently the use of the term 'deferred' cord clamping has been recommended as this suggests a planned policy in contrast to the term 'delayed' cord clamping which may imply that the cord is clamped later than the ideal time [14].

Although evidence based guidelines have recom-mended that DCC should be practiced for all births, in

[1]*Academic Obstetrics and Gynaecology Unit, Teaching Hospital, Mahamodara, Galle, Sri Lanka.*

Correspondence: MG, *e-mail: <malikg@eureka.lk>. Received 2 June 2016 and revised version accepted 10 September 2016.*

many units it is practiced during vaginal deliveries but not during caesarean sections (CS) [15]. This is because most of the data regarding DCC has been obtained from vaginal deliveries and there is a fear of possible increased post-operative hemorrhage after DCC during CS. In the latest Cochrane Review on the subject, out of 15 rando-mised controlled trials involving 3911 women from 12 countries, only three studies included women who were delivered by CS [3]. Of these three studies, one study carried out in Argentina had 79 out of the 276 women delivered by CS [16]. The other two studies had very few delivering by CS [5,17]. Therefore the objective of this study was to assess the effects of DCC during ante partum LSCS on placental delivery, post-operative haemorrhage and neonatal complications.

Methods

A randomised controlled trial was conducted on 156 consecutive women with intact membranes and healthy foetuses, who underwent antepartum LSCS between 37-39 weeks gestation at the Academic Obstetric Unit, Teaching Hospital, Mahamodara, Galle, Sri Lanka, from 21st January to 30th April 2013. Exclusion criteria were women with increased risk of feto-maternal haemorrhage or post-operative haemorrhage, rhesus negative, multiple pregnancies, estimated fetal weight >3.5 kg, polyhy-dramnios, blood pressure >160/110mmHg, placenta praevia, abruptio placentae, pre-labor rupture of mem-branes and failed induction of labor. In Sri Lanka, the mean birth weight of a neonate at 40 weeks of gestation and the 90th centile are estimated to be approximately 3 kg and 3.5 kg respectively [18]. Audits carried out in the unit have indicated that neonatal birth weight of >3.5 kg and induction of labor have increased risks of postpartum haemorrhage (PPH).

The average post-operative blood loss after LSCS is estimated to range from 400-1000 ml and its variance is estimated to be approximately 500 ml [19-21]. To detect an increase of 300 ml or more blood loss after DCC, with 80% power and 95% significance, the minimum sample size was calculated as 43.5 per arm for a three arm randomised controlled trial [22]. Using computer generated random numbers and blocks of three (each block including groups 1, 2 and 3 in a random sequence), the second author prepared sequentially numbered and sealed opaque envelopes containing the code for the appropriate umbilical cord clamping regimen. The first author assessed all women admitted to hospital for scheduled (category 3) or elective (category 4) CS and obtained informed written consent from those eligible for inclusion. All the participants had their body mass index (BMI) documented on admission to the unit for CS. Just prior to the CS, the on call senior house officer opened the sealed opaque envelopes and assigned the participants to the appropriate umbilical cord clamping regimen and informed the first author. Fifty

two subjects were recruited to each arm, *ie.* a total of 156 to allow for post randomisation exclusions (Figure 1).

Lower segment CS (LSCS) was carried out by the first author and the same routine operative techniques were used on all. The preoperative haemoglobin concentration (Hb) and the haematocrit of the mother were measured using a sample of blood obtained when inserting the intravenous cannula prior to CS. Preloading with 500 ml of normal saline was carried out by the anaesthesiologist prior to spinal anesthesia. An intra-venous bolus dose of oxytocin 10 iu was administered to the mother following delivery of the baby. This was followed by an infusion of 10 iu oxytocin in 500 ml of normal saline over four hours. Additional doses of uterotonics were given only if there was significant bleeding.

The umbilical cord of the baby was clamped at <15 seconds (Group 1) or between 60-75 seconds (Group 2) or between 120-135 seconds (Group 3,) according to the predetermined randomised allocation sequence. Bleeding from the uterine cut edges were controlled by the routine use of three Green Armitage clamps, two for the lower cut edge and one for the upper cut edge. The baby was covered with a sterile, dry and warm cloth to prevent hypothermia, and placed on the mother's thighs, until the cord was clamped and divided, in the DCC groups. None of the neonates required resuscitation. After clamping the cord, controlled cord traction was applied to deliver the placenta. Time interval from delivery of the baby to the delivery of the placenta was documented. In groups 2 and 3 if the placenta separated before the stipulated time interval for the particular group, it was removed and time of such removal was documented. If there was a delay in placental separation and delivery, controlled cord traction was applied at 30 second intervals up to a maximum of five minutes. If the placenta was not delivered in five minutes, a manual removal of placenta was carried out. The uterine incision was sutured in two layers using No. 1 polyglactin. The visceral peritoneum of the uterus was not sutured.

The postoperative blood loss was calculated in all three arms of the study using the following methods. The surgical sucker was used only when the amniotic membranes were ruptured and up to the delivery of the placenta. Only gauze towels were used to mop up the blood during the balance time of the LSCS, up to closure of the abdomen. The amniotic fluid was carefully sucked into the sucker bottle avoiding spillage onto the gauze towels and the drapes. However some amount of blood mixing up with the liquor being sucked could not be prevented. As soon as the placenta was delivered, the total volume in the sucker bottle was measured by an assistant, the fluid in the sucker bottle was well shaken, and a 10 ml sample of the fluid was obtained into a BD Vacutainer plastic tube with ethylene diaminetetra acetic acid

(Becton, Dickinson and Company; Haryana, India). This sample was sent to the laboratory where it was kept at room temperature for 30 minutes and centrifuged at 3500 rpm (2000 g) for 10 minutes. The volume of blood in the sucker bottle was calculated using the following formula:

Volume of blood in sucker bottle = percentage of packed cells in the 10ml sample × total volume in sucker bottle ÷ preoperative hematocrit

All the towels and drapes prepared for the LSCS were weighed and the weight marked on each pack, prior to autoclaving. All of them (used and unused) were weighed again after use, and a difference of one gram was considered to be equivalent to one ml of blood. The volume of blood obtained by gravimetry was added to the volume of blood obtained by calculation from the sucker bottle solution to obtain the postoperative blood loss. Birth weights of the neonates were documented and the neonates were kept under close observation by the neonatology team for a minimum of 72 hours. Neonates were monitored for neonatal jaundice. The postoperative Hb and haematocrit of the mother were measured as per routine 48-60 hours after the CS. The Hb and haematocrit were measured using a Mindray BC-5800 Haematology Analyser (Mindray, Shenzen, China). The neonatology team was blinded to the timing of the umbilical cord clamping.

Normally distributed continuous variables were described as means and 95% confidence intervals and compared using ANOVA. Parity was described using medians and inter-quartile ranges and compared using the Mann-Whitney U test. Percentages were compared using Chi-square test. The data was analyzed using an intention to treat analysis. As the variances in the outcome measures were not significantly different between the 60-75 second group and the 120-135 second groups, comparisons were also carried after combining these two groups into one DCC group (60-135 second). A multiple regression analysis was carried out to study the association between mean postoperative blood loss and maternal age, parity, BMI, the number of previous CS, and the birth weight of the neonate, among the three groups. Using a receiver operating characteristics (ROC) curve with a post-operative haemorrhage of ≥500 ml as the outcome, optimum cut off levels were obtained for the variables maternal age, BMI, and the birth weight of the neonate. Using these cut off levels, the odds ratios (OR) and their 95% confidence intervals (95% CI) were calculated for the occurrence of post-operative haemorrhage of ≥ 500 ml with these variables. Analysis of results was carried out using Statistical Package for the Social Sciences (SPSS version 20).

Approval was obtained from the Ethical Review Committee, Faculty of Medicine, University of Ruhuna, Galle (3.7, 26 / 07 / 2012). Informed written consent was obtained from all participants. The study was registered in the Sri Lanka Clinical Trials Registry (SLCTR / 2013/003 on 20th January 2013, http://trials.slctr.lk/trials/108).
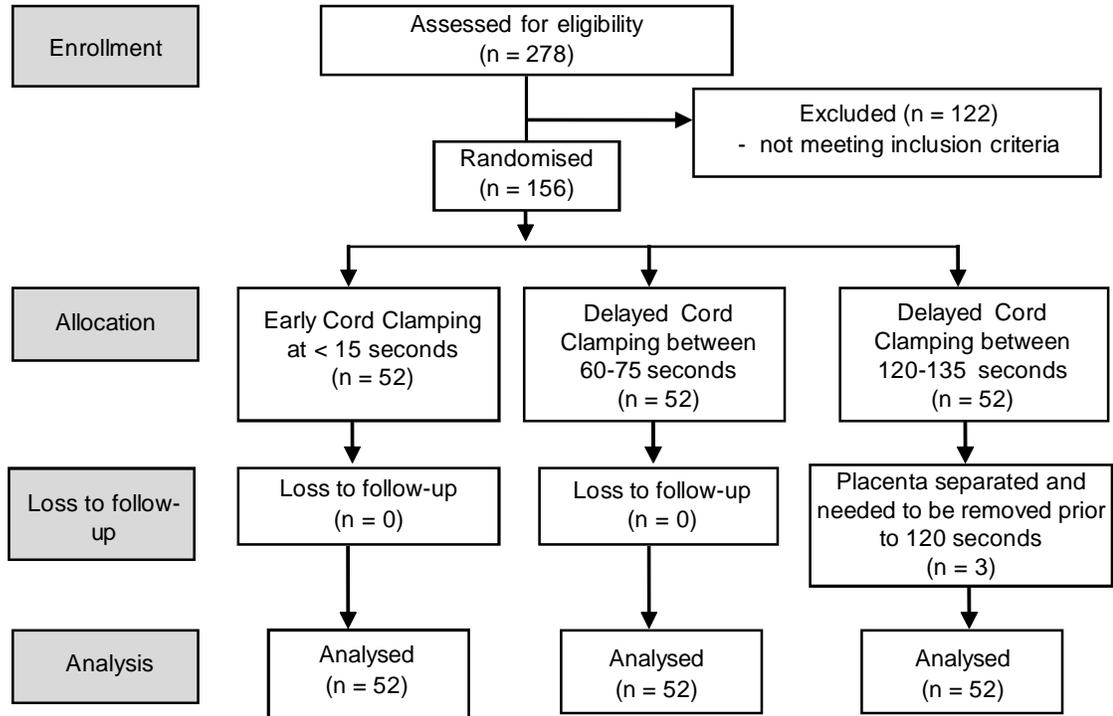

Results

From 21st January to 30th April 2013, there were 278 antepartum LSCS and of them 156, (52 for each arm) were recruited for the study. In the DCC groups there was no significant bleeding from the uterine incision which required additional clamps, abandoning the trial or need for early cord clamping. In three cases in the 120-135 second cord clamping group, the placenta separated before the determined time and therefore placenta was removed. An intention to treat analysis was carried out including these three cases (Figure 1).

There were no significant differences in maternal age, parity, gestational age and BMI among the three groups. Majority of the mothers were in the 30-39 years age group and para 2, 3 and 4 (Table 1). There were no significant differences in the mean postoperative blood loss between the three groups or between the early cord clamping (< 15 seconds) and the DCC (60-135 seconds) groups. Mean duration for placental delivery increased from 120 seconds (95% CI 92-148) to 195 seconds (95% CI 171-218, $p< 0.001$) but retained placentae were not increased. There were non-significant trends towards a reduced need for a manual removal of the placenta from 11.5% to 6.7% and a reduced need for additional uterotonics from 13.5% to 6.7% in the early cord clamping group compared to the combined DCC groups. The mean postoperative reductions in Hb and haematocrit were not significantly different between the three groups. The requirement of phototherapy for neonatal jaundice showed a non-significant increase from 7.7% in the early cord clamping group to 13.5% in the combined DCC groups (Table 2).

None of the subjects required colloids or other blood products and none of the neonates had Respiratory Distress Syndrome (RDS) or needed admission to the special care baby unit (SCBU). There were no significant differences in the requirement of additional crystalloids, between the three groups. A postoperative blood loss of ≥500 ml occurred in approximately 45% of the study population ranging from approximately 39% in the <15 seconds cord clamping group to 54% in the 60-75 second cord clamping group. However these differences were not statistically significant. The largest blood loss was approximately 856 ml. A postoperative blood loss of ≥750 ml occurred in approximately 3% of the study population. None had postoperative blood loss of ≥1000 ml (Table 3). There were no clinically significant differences in the risk of increased postoperative haemorrhage according to maternal age, parity, BMI, number of previous CS or the birth weight of the neonate, among the three groups (Table 4).

*** *Cut off levels obtained by plotting a Receiver Operating Characteristics curve with a post-operative hemorrhage of ≥ 500 ml; BMI = Body Mass Index.*

The optimum cut off levels for maternal age (31 years), BMI (24.75 Kg / M^2) and birth weight of the neonate (3 Kg) were obtained by plotting ROC curves against a post-operative haemorrhage of ≥500 ml. In the combined DCC groups (60-135 seconds) maternal BMI ≥24.75 Kg and birth weight of neonate ≥3 Kg were associated with a higher odds of a post-operative haemorrhage of ≥500ml (OR 2.4; 95% CI 1.01-5.72; *p*=0.029, and OR 3 .47; 95%CI 1.42-8.58; *p*=0.002 respectively) (Table5).

Discussion

DCC during antepartum LSCS was not associated with any significant increase of postoperative haemorrhage when compared with early cord clamping. Although the mean duration for placental delivery was increased in the DCC groups, there was no increase in retained placentae, clinically significant excessive maternal bleeding or neonatal morbidity. As all the participants with a postoperative blood loss of ≥500 ml were asymptomatic and haemodynamically stable, and there were no participants with a postoperative blood loss of≥1000 ml, none of the participants needed a blood transfusion. A few decades ago drainage of the cord was recommended to facilitate placental separation and expulsion. In the current study there were non-significant trends towards reductions in the need for a manual removal of placenta and additional uterotonics in the DCC groups. Further multi-center studies with appropriate sample size may confirm these additional benefits and further strengthen the arguments for DCC during CS. Until the cord is clamped, the baby should be placed on the mother's thighs, wrapped well with sterile, dry cloths to prevent neonatal hypothermia especially in air-conditioned operating theaters.

A strength of the study is that the postoperative blood loss after CS was calculated by the combined method involving direct measurements and weighing, which is considered to be the most accurate practical method [23]. Even with maximum efforts to drain the amniotic fluid into the sucker bottle, there would have been some conta-mination of towels and drapes, and some evaporation could also have occurred from the soaked towels and drapes, and using a sample of 10 ml to estimate the volume of blood in the sucker bottle solution would have had a margin of error. However, the combined method should be more accurate than visual estimations by the surgeon and anesthesiologists, which are the commoner methods used for estimating postoperative blood loss.

The hematological benefits of DCC to the baby during its infancy, are well documented in studies carried out during vaginal delivery, and there is no reason to doubt that the same benefits would be seen after CS. Therefore haematological studies were not carried out either in the neonate or later during its infancy. As the primary objective of the study was to study whether DCC resulted

in a clinically significant difference in postoperative blood loss after CS, in comparison to early cord clamping, the sample size was calculated to detect such a difference and not to study the occurrence of neonatal jaundice requiring phototherapy. Therefore the higher occurrence of neonatal jaundice requiring phototherapy in the DCC groups did not reach statistical significance.

The moderate increase in the risk of a post-operative haemorrhage of ≥500 ml in the combined DCC groups with maternal BMI ≥24.75 Kg and birth weight of neonate≥3 Kg probably reflects the higher risk of PPH asso-ciated with increasing maternal BMI and fetal macro-somia, which has been observed in audits carried out in the unit previously.

In conclusion, DCC during antepartum LSCS is feasible and safe, and there should be no hesitation in implementing this procedure routinely. DCC is not associated with any clinically significant difference in the risk of postoperative haemorrhage, manual removal of placenta, or maternal or neonatal morbidity, compared to early cord clamping. During DCC, the baby should be well wrapped to prevent hypothermia, and placed on the mothers thighs.
