COLLECTION, ISOLATION AND IDENTIFICATION OF PATHOGENIC BACTERIA 
FROM BLOOD CLINICAL SPECIMENS IN BAGHDAD

ABSTRACT

One hundred and five of clinical sample were collected from Central Teaching Hospital of paediatric and Medical city / Educational laboratory, from patients (Male, Female and infant) of age range between (≤ 1 day - 70 year) during the period from 17/10/2016 to 23/1/2017. Out of one hundred and five clinical samples were screened, only seventy isolates were collected in 17 identified as Staphylococcus aureus, 12 identified as Klebsiella pneumonia depending on cultural, microscopic and biochemical characteristics. The remaining isolates were identified as Staphylococcus spp., E.coli and Acinetobacter baumannii, pseudomonas aeruginosa, Enterobacter spp and Proteus spp. Regarding to the patient gender, it was found that infants had a tendency to get infected more than males and female when 30 (28.57 %) of patients were males, 33 (31.42 %) females and 42 (40%) infant. Moreover, the age group ≤ 1year were most subjected to the infection of bloodstream infection.

KEYWORDS: Bacteriological, pathogenic, blood.

INTRODUCTION

Bloodstream infection is the most common cause of sepsis, so there are more than 45% of BSI are caused by single bacterial species, which can introduce in the blood, such opportunistic pathogens (e.g., Staphylococcus aureus, Escherichia coli, Acinetobacter spp, klebsiella pneumonia), and fungi species (Wisplinghoff et al., 2004; Risan, 2016). Staphylococcus aureus have different virulence factors which give the bacteria the ability to invade the host, such as surface proteins that promote colonization and invasiveness (leukocidin, kinases, hyaluronidase) and surface factors that inhibit phagocytic engulfment (capsule, ProteinA). Klebsiella pneumonia have different virulence factors which gave the bacteria the ability to invade the host, such as capsular polysaccharide, lipopolysaccharide, serum resistance, siderophore production, fimbriae and other factors such as the production of urea and enterotoxin (Aher et al., 2012). The pathogenicity of Staphylococcus aureus, is related to production of wide variety of exoproteins, including alpha and beta haemolysins which contributes to its ability to cause diseases in humans (Dinges et al., 2000). Alpha-haemolysin or alpha toxin considered to be a main pathogenicity factor because of its haemolytic, dermonecrotic and neurotoxic effects. Additionally, beta-haemolysin contains sphingomyelinase that more active against sheep and bovine erythrocytes (De-Silva et al., 2005). Staphylococcal enterotoxin B (SEB) is one of the 20 exotoxin excreted by the Staphylococcus aureus bacterium, Staphylococcal enterotoxin B (SEB) is the toxin most commonly associated with classic food poisoning. It has also been demonstrated to cause a nonmenstrual toxic shock syndrome (TSS) (Hennekinne et al., 2012). Therefore this study was aimed to isolation and identification of pathogenic bacteria in blood.

MATERIALS AND METHODS

Collection of samples

One Hundred and five samples of blood were collected from patients suspected of having blood stream infection and certain clinical symptoms. These samples were collected from Medical city Hospital / educational laboratories and Central Teaching Hospital of pediatric in Baghdad. Samples were collected from different age groups and genders from 17/10/2016 to 23/1/2017.

Blood samples

Blood is drawn from patients by using a syringe (5 ml). It is immediately transferred to a clean sterilized brain heart infusion broth tube, the blood is then allowed to clot for at least 10 to 15 minutes at room temperature, then kept in an incubator for 18 hours for further laboratory investigations (Tille et al., 2013).

Blood Culture

The blood specimens were inoculated on blood agar, McConkey agar and chocolate agar plates by direct
streaking method using a loop to deliver a loopful of the blood specimens. After incubation overnight at 37°C the bacterial growth is examined, if there were no growth, the plates were re-incubated for another 24 hours before they were considered as a negative culture (Novak-Weekley and Dunne, 2016).

Isolation and identification of bacteria
Bacteria have been isolated from pure colonies and cultured on blood, McConkey, and chocolate agar then isolated bacteria were examined microscopically by using Grams stain technique for referred to as Gram-positive or Gram-negative bacteria. The identification tests include cultural, morphology, and physiological characteristics of each bacterial isolates were done (Brown, 2005).

Identification of Morphological characteristics
Colonies of the bacterial isolates that cultured on blood agar and MacConkey media were described according to their shapes, color, diameter, odor, and other characteristics (Macfaddin, 2000).

Microscopic Examination
The microscopic examination includes two procedures, gram stain, and capsule stain, according to (Atlas et al., 1995).

Biochemical tests
The following biochemical tests were performed for the identification of bacteria. These tests were carried out according to (Forbes et al., 2002) includes (Catalase test, Blood hemolysis test, Oxidase test and Indole test) and according to (Atlas, 2010) of Citrate utilization test and Urease production test.

Culturing on Eosin methylene blue (EMB) agar:
EMB, a differential medium used to distinguish E. coli isolates from others; bacterial isolates were cultured on this medium and incubated at 37°C for 24 hours. E. coli bacteria that grow on this medium gave a distinctive green metallic sheen indicate that the inoculated isolate belonged to E. coli (Atlas, 2010).

Mannitol fermentation: (Collee et al., 1996)
Mannitol semisolid agar medium was inoculated and incubated at 37 C° for 24 hrs. The changing of medium color to yellow indicates positive results for mannitol fermentation. This test is specific for Staphylococcus aureus.

RESULTS AND DISCUSSION
Isolation of bacteria
Blood samples from a total of 105 clinical different blood samples were collected from Central Teaching Hospital of paediatric and Medical city / Educational laboratory, In Baghdad /Iraq. Table (1) samples were collected from different age groups and gender during the period from 17/10/2016 to 23/1/2017. Seventy (66.6 %) were clinical blood positive samples, while the rest (35) were negative blood samples (33.3 %). The relationship of BSI with the age of patients was investigated in this study and the patients were grouped into three categories according to their age as shown in table (1).

Incidence of blood stream infection (BSI)
Blood samples from a total of 105 clinical different blood samples were collected, their ages ranging from (infant: 1 day - 12 month), (adult: 19 - 75 years). The results have showed that 70 (66.6%) of blood samples contained heavy bacterial growth while 35 (33.3%) of samples had no bacterial growth as demonstrated in table (2). This study agrees with cases in Pakistan (Latif and Ahmed, 2017) when they reported that incidence of BSI in patient were 97.6% while disagreement in India Waghmare et al., (2015) when they reported that incidence of BSI in patients were 18.6%.

Identification of bacterial isolates
Several morphological, physiological and biochemical tests were made to identify bacterial isolates. Seventeen isolates were obtained from one hundred and five samples. Results showed that Klebsiella spp. constitute 17.1% (12 isolates), and identified as K. pneumoniae, Staphylococcus spp. Constitute 15.7% (11 isolates), Staphylococcus aureus constitute 24.2% (17 isolates). The other bacterial isolates were constituted Escherichia coli 14.2% (10 isolates), Acinetobacter baumannii 14.28% (10 isolates), Proteus spp. 2.82% (2 isolates), pseudomonas aeruginosa 7.14% (5 isolates), and Enterobacterspp. 4.28% (3 isolates). Figure (1) illustrates the percentages of each bacterial species found in the collected samples.
Bacterial isolates were identified according to their cultural, microscopical and biochemical characteristics that were in agreement with (Holt et al., 1994; Atlas et al., 1995; Collee et al., 1996).

** Colony morphology**

First identification of bacterial isolates were done after incubated aerobically on MacConkey agar, blood agar and EMB agar plates and anaerobically on chocolate agar plates at 37 Cº for 24-48 hrs (figure 2 - A-H). On MacConkey agar, *Klebsiella pneumoniae* are gram negative colonies which are lactose fermenting colonies and gave pink color, regular edge, round; mucoid texture with large size. The first is characterized by producing pink colonies due to the conversion of neutral red indicator dye when it is below pH 6.8. Adversely, the Non-lactose bacterial growth appears colorless or transparent (Holt et al., 1994). *Staphylococcus aureus* are gram positive colonies which are mannitol fermenting, about 1–2 mm in diameter and appears as grape-like clusters when viewed through a microscope, and has large, round, golden-yellow colonies. *Staphylococcus aureus* produces yellow colonies with yellow zones, whereas other coagulase-negative staphylococci produce small pink or red colonies with no colour change to the medium. *Escherichia coli* are gram negative, rod shape, coliform bacterium. On MacConkey Agar grown for 24 hrs at 37 degrees, *E. coli* demonstrates strong lactose fermentation and gave bright pink halo, bile precipitant around the colonies, and pink colony growth, while on EMB agar which is selective media for *E. coli* which gave a distinctive metallic green sheen (due to the metachromatic properties of the dyes *E. coli* movement using flagella, and strong acid end-products of fermentation) (Kim et al., 2002). *Pseudomonas aeruginosa* are gram negative, road shaped bacterium, with large colonies, irregular surface, yellow green colour, non-lactose fermenter which produces colonies with a characteristic "grape-like" or "fresh-tortilla" odour on bacteriological media (Hoiby et al., 2010). *Proteus* spp are gram negative bacilli, road shaped, large, circular grey, and smooth colonies. On blood agar shows swarming effect on the plate as a consequence of the organism motility activity, *Proteus* species do not usually ferment lactose, but have shown to be capable lactose fermenters depending on the species, give out an odour described as fishy (Drzewiecka, 2016). *Acinetobacter baumannii* is a typically short, almost round, rod-shaped (coccobacilli) gram-negative bacterium which grows well on MacConkey agar (without salt). *Enterobacter* spp. grows rapidly on blood agar medium and MacConkey agar which large lactose-fermenting. In general, the strains from environmental sources grow better at 20-30 degrees, whereas strains from clinical sources grow better at 37°C. "cauliflower" type colonies. Anaerogenic strains often exhibit yellow pigmented colonies (Holt et al., 1994).

Figure (2): E. coli on EMB agar (A), Mucoid colonies of *Klebsiella pneumoniae* on MacConkey agar (B), Mannitol fermenting *Staphylococcus aureus* on Mannitol salt agar (C), Non-mannitol fermenting *Staphylococcus epidermis* (D), Yellow green colour of *Pseudomonas aeruginosa* (E), *Acinetobacter baumannii* on MacConkey agar (F), *Enterobacter spp.* on blood agar (G), Swarming *Proteus spp.* on blood agar (H).

Biochemical Tests

The biochemical tests were used for further identification of bacterial isolates. Table (3) showed that all isolates of *Klebsiella*, *Staphylococcus*, *Proteus*, *Pseudomonas*, and *Enterobacter* were negative result for indole while positive result for *E. coli*. In the indole test (Figure 3), ability to hydrolyze tryptophan to indole is a characteristic of certain enteric bacteria possessing the enzyme tryptophanase, an enzyme that decomposes amino acid tryptophan to indole, pyruvic acid and water. Indole negative bacteria was not produced tryptophanase, so that when Kovac's reagent was added to a broth free of indole, a red ring will not be formed at the top of the broth (Collee *et al.*, 1996).

In Kligler Iron Agar (KIA) test, it differentiates the genera of *Enterobacteriaceae* from each other based on their carbohydrate fermentation patterns and H2S production. KIA slants contain 1% lactose and 1% glucose. The pH indicator (phenol red) changed the medium colour from orange-red to yellow in the presence of acids. KIA also contains sodium thiosulfate, a substrate for H2S production, and ferrous sulfate that produces black precipitate to differentiate H2S producing bacteria from others.

Results Table (3) showed that *Klebsiella* isolates turned the color of both the slant and butt, which produced acidic slant (yellow) and acid butt (yellow) accompanied by gas production (bubbles formation), but without black precipitate formation, which indicates that lactose and glucose fermentation had occurred and no H2S was produced. These results agreed with those declared by Garrity (2005). *E.coli* isolates turned the color of both the slant and butt, which produced acidic slant (yellow) and acid butt (yellow) accompanied by CO2 production but without black precipitate formation, which indicates that lactose and glucose fermentation had occurred and no H2S was produced. These results agreed with those declared by (Penalver *et al.*, 2005).

*Proteus spp* isolates turned the color of both the slant and butt, which produce acidic butt (yellow) and alkaline slant (red) accompanied by H2S production (black precipitant) that indicates of glucose fermenting and non-
lactose fermenting. These results agreed with those declared by (Saadabi et al., 2010). Acinetobacter baumannii isolates turned the colour of slant to alkaline but no change bottom, no gas, no H₂S production that indicate non-lactose fermenting. These results agreed with those declared by (Hussein et al., 2013). Pseudomonas aeruginosa isolates turned the colour of slant and butt to alkaline without production of H₂S and gas that indicate non-lactose fermenting, these results agreed with those declared by (Tunç and Olgun, 2006).

Whereas urease test, figure (4), were positive for Klebsiella, Staphylococcus and negative for Enterobacter, proteus, E.coli, pseudomonas and Acinetobacter (Forbes et al., 2002). Urease enzyme catalyzes the breakdown of urea, and the bacteria that can produce this enzyme is able to detoxify the waste products and to drive metabolic energy from its utilization which change the medium color from yellow to purple-pink, indicating urease positive test. Klebsiella can produce urease enzyme and gives urease positive test (Atlas et al., 1995).

In the motility test, Klebsiella isolates were non-motile. The movement of the growth away from the stab line or a hazy appearance through the semisolid medium indicates that the bacteria are motile. But the linear growth means negative result a property which Klebsiella is characterized by Gwendolyn (1988). While Acinetobacter baumannii isolates were non-motile, these results agreed with those declared by (Hussein et al., 2013).

Moreover E.coli, Pseudomonas aeruginosa, Enterobacter spp, and Proteus spp isolates virable motile as expiated in figure (5) (O’toole and Kolter, 1998; RÖmling, 2005; Pomorski et al., 2007; Berg, 2008).

Figure (4): urease test, positive result (2), and negative result (1).
Another hand in oxidase test, figure (6), *Klebsiella*, *E. coli*, *proteus*, *Enterobacter* isolates were oxidase negative and catalase positive or negative result (Bernere and Farmer, 2005), where else *Pseudomonas aeruginosa* isolates were oxidase positive and catalase positive (PHE, 2015), while *Staphylococcus aureus* isolates were oxidase negative and catalase positive (Orwin et al., 2003), and finally *Acinetobacter baumannii* isolates were oxidase negative and catalase positive (Doughari et al., 2011). The coagulase test is specific to differentiate *Staphylococcus aureus* from other species and genera which is positive (Kateete et al., 2010).

Results presented in table (4) show that out of 105 clinical samples, 17 (15.7%) *Staphylococcus aureus*, 12 (17.1%) *Klebsiella pneumoniae*, 11 (15.71%) *Staphylococcus spp.*, 10 (14.2%) *E. coli*, 10 (14.2%) *Acinetobacter baumannii*, 5 (7.14%) *Pseudomonas aeruginosa*, 3 (4.28%) *Enterobacter spp.* and 2 (2.82%) *Proteus spp.* isolates were recovered.

Results revealed that *S. aureus* and *K. pneumoniae* (17, 12 isolates respectively) was the dominant among all other species of bacteria. This result was in agreement with the report documented by Waghmare et al., (2015).
and Karki (2010) whom found that those two species was the most frequently occurring among other species, when its account for 29% of *Klebsiella pneumoniae* and 65% of *Staphylococcus aureus* isolated clinically.
