

INFORMATION TO USERS

This reproduction was made from a copy of a document sent to us for microfilming. While the most advanced technology has been used to photograph and reproduce this document, the quality of the reproduction is heavily dependent upon the quality of the material submitted.

The following explanation of techniques is provided to help clarify markings or notations which may appear on this reproduction.

1. The sign or "target" for pages apparently lacking from the document photographed is "Missing Page(s)". If it was possible to obtain the missing page(s) or section, they are spliced into the film along with adjacent pages. This may have necessitated cutting through an image and duplicating adjacent pages to assure complete continuity.
2. When an image on the film is obliterated with a round black mark, it is an indication of either blurred copy because of movement during exposure, duplicate copy, or copyrighted materials that should not have been filmed. For blurred pages, a good image of the page can be found in the adjacent frame. If copyrighted materials were deleted, a target note will appear listing the pages in the adjacent frame.
3. When a map, drawing or chart, etc., is part of the material being photographed, a definite method of "sectioning" the material has been followed. It is customary to begin filming at the upper left hand corner of a large sheet and to continue from left to right in equal sections with small overlaps. If necessary, sectioning is continued again—beginning below the first row and continuing on until complete.
4. For illustrations that cannot be satisfactorily reproduced by xerographic means, photographic prints can be purchased at additional cost and inserted into your xerographic copy. These prints are available upon request from the Dissertations Customer Services Department.
5. Some pages in any document may have indistinct print. In all cases the best available copy has been filmed.

ABSTRACT

OCCUPATIONAL AND INDUSTRIAL
MORTALITY IN RHODE ISLAND (1968-1972)

David Mueller Gute

Yale University, 1981

The association between occupation and the development of specific disease entities has long been recognized. Given that the majority of these conditions are theoretically preventable there has been an increasing need to develop methods to identify groups of workers at increased risk. This study has sought to develop such a capacity by utilizing cross-sectional death certificate data.

Data for this study were obtained from 43,311 white Rhode Island resident death certificates for the years 1968-1972. The decedent's occupation and industry were coded directly from death certificates employing the occupational coding system used in the 1970 United States Census.

The completeness of the occupation and industry entry on the death certificates was found to be quite good. For males only 6.2 percent of all occupational statements were to some extent incomplete as compared to 9.2 percent for the industrial statements. The respective incompleteness figures for females was 8.9 and 11.0 percent.

These data were analyzed by the calculation of standardized mortality ratios (SMRs) by occupation, industry, sex, and cause

of death for the age intervals: 16-34, 35-44, 45-54, and 55-64. Proportionate mortality ratios (PMRs) were calculated for identical age intervals and also for ages 65-74, 75-84, and ≥ 85 .

These analyses yielded a set of ratios which were significantly elevated ($p < .05$). Examples of significant findings for males included an increased risk of lung cancer for construction craftsmen, metal craftsmen, and transport operatives, an excess experience of accidental deaths among construction workers and an elevated finding for acute myocardial infarction mortality among managers.

Significantly elevated results for females included an increased breast cancer experience for clerical workers, raised mortality due to acute myocardial infarction and chronic ischemic heart disease among textile product workers, and an increased risk of stomach cancer among female decedents ≥ 65 years of age employed as jewelry workers.

An attempt was made to ascertain the relationship of the joint effects of industry and occupation and mortality by cause. The technique of log-linear modeling was employed with limited success. As a final approach at documenting the joint effect of industry and occupation PMRs were calculated for selected occupational groups within industry categories. In analyzing male accidental deaths by occupation within the mining and construction industry it was demonstrated that those occupations most directly

engaged in actual construction, craftsmen, laborers, and transport operatives, suffered the highest mortality experience due to accidental deaths. In a similar fashion male bladder cancer mortality was seen to be significantly elevated for the occupational group "operatives, not transport" within the textile industry.

ACKNOWLEDGMENTS

I wish to express my gratitude to those people who have made the completion of this dissertation research possible.

Since the beginning of my dissertation research Dr. Jan A. J. Stolwijk has served as my primary advisor and mentor. His wise counsel and quiet strength, tempered with a ready wit, have made this project enjoyable and fulfilling. Dr. Stolwijk's contributions are not bounded by academic insight, however, for he has also deeply influenced me in his capacity as a researcher, administrator, and most importantly, as a friend.

To Dr. Jennifer L. Kelsey go my thanks for being my first teacher in epidemiology and for providing an example of dedication and thoroughness which shall serve me well throughout my professional career.

I also owe my gratitude to Dr. Daniel H. Freeman for his valuable assistance concerning the biostatistical aspects of this dissertation. Dr. Freeman's ability to enliven these discussions with a sense of humor will always be appreciated.

My thanks go to many individuals at the Rhode Island Department of Health. Dr. William J. Waters, Mrs. Lera O'Hara, and Edward J. Martin were all instrumental in bringing my research to successful completion. My immediate supervisor at the Department, Dr. Bruce C. Kelley, deserves special mention for his consideration and support. Without the

active support of the Department of Health and the many contributions of expertise by Department staff, particularly within the Division of Vital Statistics, this research simply would not have been possible.

This research benefitted from the active support of the National Institute for Occupational Safety and Health (NIOSH). My personal thanks go particularly to Stanley Kusnetz who served as NIOSH Project officer.

To those friends who provided me a source of strength to draw upon during this work I also owe my gratitude. They include: Harish Khare, Jill Bowers, Nancy Stroup, and Michael and Rebecca Zagraniski, each of whom was a source of hospitality, fine meals, and needed camaraderie.

Finally I owe my greatest debt of gratitude to Ann K. Tousignant for providing a sense of purpose and perspective throughout this endeavor.

CHAPTER I
INTRODUCTION

The observation that certain disease entities are associated with specific occupations is as old as recorded history. Hunter (1975), in his classic work, The Diseases of Occupations, relates that such records can be traced back to as far as Pharoah's Egypt with the description of the diseases suffered by miners. It is plausible to assume that the nature of tasks performed for seven to eight hours each working day might be expected to exert some influence on a given worker's health.

A continuing problem surrounding inquiry into the relationship between occupation and health is the characterization of the discrete impact of employment on health above and beyond the cumulative effects on the host of extrinsic factors which have a known influence on the expression of disease such as, age, race, sex, personal characteristics, social class, etc. Accompanying this problem of measuring the discrete impact of occupation is the concomitant problem of obtaining accurate and reliable information regarding occupational status and the health outcomes of a working population; namely, morbidity and mortality.

The linkage of occupational information with health outcome data for specific and broad population groups continues to be a goal in occupational health research. Analyses based

on such linkages have been conducted with varying levels of vigor by numerous investigators. The earliest link uncovered between an occupation and a specific association with cancer was first reported by Pott (1775) when he identified soot as the cause of scrotal cancer among chimney sweeps. Such associations have proliferated in the 20th century with the growing interest in the causes of chronic diseases.

The majority of studies evaluating the relationship between work and health usually involve the analysis of specific occupational groups which already manifest adverse morbidity or mortality. Such research contributes greatly to our knowledge of known hazards in selected populations. This work is also of critical importance in the development of control technologies to hopefully lessen the observed risks.

The object of this present research will be to devise a method by which occupational data and health status outcome can be analyzed for large populations of workers across occupational and industrial categories. Because of the difficulty in obtaining reliable morbidity information on free living populations, such research is usually restricted to mortality data as represented by the death certificate.

As will be discussed in the body of this report, there are many inherent problems involved with analyses of death certificates. These difficulties are largely offset by the accessibility and availability of the death certificate and

the many possibilities the death certificate affords in terms of research regarding work and health.

The British have most fully realized the potential of deriving estimates of death rates from routine mortality data for different subpopulations. For each ten year period since 1861, an examination of mortality rates by occupation has been conducted by the Registrar General.

The importance of such routine analysis is basic and compelling. Results from such analysis may reinforce findings of other studies. Periodic analysis allows for a consideration of the effect of technologic changes in the workplace and the subsequent influence on health. Such analyses are also useful in drawing attention to specific groups at higher than normal risk for specific disease entities.

These groups may be studied more intensely to gain a better understanding of the potential effect of occupation on the natural history of the disease under observation. The development of hypotheses speaks to one of the basic reasons for the comparison of mortality rates. Such a mechanism has been fruitfully employed by the British investigators for many years and also forms a data base through which research workers may test potential models expressing work and the possible development of disease.

The principal thesis behind the design of the Occupational Mortality Study (OMS) conducted in Rhode Island is parallel

to that of the British investigators. There did not exist in Rhode Island, prior to the conducting of the OMS, any meaningful estimates of risk borne specifically by Rhode Island's workforce. What is sought by this exercise is the elucidation of specific associations involving work and health which are measurable through an analysis of death certificates. Such analysis, based on state specific data, is a vast improvement over the calculation of synthetic estimates of disease incidence rates within the Rhode Island workforce as obtained from national data. This is because of the characteristic differences which exist when comparing the mixture of industries in Rhode Island to that found in the United States as a whole.

The description of the mortality experience of Rhode Island's workforce will prove most valuable in the targeting of preventive programs aimed at specific subpopulations for which excess risk has been observed. This is especially useful in that a large proportion of work related illness and injury is potentially preventable. The present study was not only designed to investigate the relationship between work and health but also to serve as a data base which can provide guidance for the prevention of further morbidity and mortality arising from occupational exposures.
