37.8. An alien spacecraft is flying overhead at a great distance as you stand in your backyard. You see its searchlight blink on for 0.190 s. The first officer on the spacecraft measures that the searchlight is on for 12.0 ms. (a) Which of these two measured times is the proper time? (b) What is the speed of the spacecraft relative to the earth expressed as a fraction of the speed of light c?

Section 37.4 Relativity of Length

37.9. A spacecraft of the Trade Federation flies past the planet Coruscant at a speed of $0.600c$. A scientist on Coruscant measures the length of the moving spacecraft to be 74.0 m. The spacecraft later lands on Coruscant, and the same scientist measures the length of the now stationary spacecraft. What value does she get?

37.10. A metre stick moves past you at great speed. Its motion relative to you is parallel to its long axis. If you measure the length of the moving metre stick to be 0.3048 m at what speed is the metre stick moving relative to you?

37.11. Muons are unstable subatomic particles that decay to electrons with a mean lifetime of 2.2 μs. They are produced when cosmic rays bombard the upper atmosphere about 10 km above the earth's surface, and they travel very close to the speed of light. The problem we want to address is why we see any of them at the earth's surface. (a) What is the greatest distance a muon could travel during its 2.2-μs lifetime? (b) According to your answer in part (a), it would seem that muons could never make it to the ground. But the 2.2-μs lifetime is measured in the frame of the muon, and muons are moving very fast. At a speed of $0.999c$. what is the mean lifetime of a muon as measured by an observer at rest on the earth? How far would the muon travel in this time? Does this result explain why we find muons in cosmic rays? (c) From the point of view of the muon, it still lives for only 2.2 μs, so how does it make it to the ground? What is the thickness of the 10 km of atmosphere through which the muon must travel, as measured by the muon? It is now clear how the muon is able to reach the ground?

37.12. An unstable particle is created in the upper atmosphere from a cosmic ray and travels straight down towards the surface of the earth with a speed of $0.99540c$ relative to the earth. A scientist at rest on the earth's surface measures that the particle is created at an altitude of 45.0 km. (a) As measured by the scientist, how much time does it take the particle to travel the 45.0 km to the surface of the earth? (b) Use the length-contraction formula to calculate the distance from where the particle is created to the surface of the earth as measured in the particle's frame. (c) In the particle's frame, how much time does it take the particle to travel from where it is created to the surface of the earth? Calculate this time both by the time dilation formula and from the distance calculated in part (b). Do the two results agree?

37.13. As measured by an observer on the earth, a spacecraft runway on earth has a length of 3600 m. (a) What is the length of the runway as measured by a pilot of a spacecraft flying past at a speed of 4.00×10^7 m/s relative to the earth? (b) An observer on earth measures the time interval from when the spacecraft is directly over one end of the runway until it is directly over the other end. What result does she get? (c) The pilot of the spacecraft measures the time it takes him to travel from one end of the runway to the other end. What value does he get?

Section 37.5 The Lorentz Transformations

37.14. Solve Eqs (37.21) to obtain x and t in terms of x' and t', and show that the resulting transformation has the same form as the original one except for a change of sign for u.

37.15. An observer in frame S' is moving to the right $(+x\text{-direction})$ at speed $u = 0.600c$ away from a stationary observer in frame S.

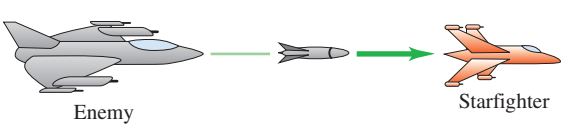
Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

The observer in S' measures the speed v' of a particle moving to the right away from her. What speed v does the observer in S measure for the particle if (a) $v' = 0.400c$; (b) $v' = 0.900c$; (c) $v' = 0.990c$?

37.16. Space pilot Mavis zips past Stanley at a constant speed relative to him of $0.800c$. Mavis and Stanley start timers at zero when the front of Mavis's ship is directly above Stanley. When Mavis reads 5.00 s on her timer, she turns on a bright light under the front of her spaceship. (a) Use the Lorentz coordinate transformation derived in Exercise 37.14 and Example 37.7 to calculate x and t as measured by Stanley for the event of turning on the light. (b) Use the time dilation formula, Eq. (37.6), to calculate the time interval between the two events (the front of the spaceship passing overhead and turning on the light) as measured by Stanley. Compare to the value of t you calculated in part (a). (c) Multiply the time interval by Mavis's speed, both as measured by Stanley, to calculate the distance she has travelled as measured by him when the light turns on. Compare to the value of x you calculated in part (a).

37.17. A pursuit spacecraft from the planet Tatooine is attempting to catch up with a Trade Federation cruiser. As measured by an observer on Tatooine, the cruiser is travelling away from the planet with a speed of $0.600c$. The pursuit ship is travelling at a speed of $0.800c$ relative to Tatooine, in the same direction as the cruiser. (a) For the pursuit ship to catch the cruiser, should the velocity of the cruiser relative to the pursuit ship be directed towards or away from the pursuit ship? (b) What is the speed of the cruiser relative to the pursuit ship?

37.18. Equation 37.23 gives the transformation for only the x-component of an object's velocity. Suppose the object considered in the derivation also moved in the y/y'-direction. Find an expression for v in terms of the components of u and v', which represents the transformation for the y-component of the velocity. (*Hint:* Apply the Lorentz transformations and relationships like $x_x = dx/dt$, $x'_x = dx'/dt'$, and so on, to the y-components.)



37.19. Two particles are created in a high-energy accelerator and move off in opposite directions. The speed of one particle, as measured in the laboratory, is $0.650c$, and the speed of each particle relative to the other is $0.950c$. What is the speed of the second particle, as measured in the laboratory?

37.20. Two particles in a high-energy accelerator experiment are approaching each other head-on, each with a speed of $0.9520c$ as measured in the laboratory. What is the magnitude of the velocity of one particle relative to the other?

37.21. Two particles in a high-energy accelerator experiment approach each other head-on with a relative speed of $0.890c$. Both particles travel at the same speed as measured in the laboratory. What is the speed of each particle, as measured in the laboratory?

37.22. An enemy spaceship is moving towards your starfighter with a speed, as measured in your frame, of $0.400c$. The enemy ship fires a missile towards you at a speed of $0.700c$ relative to the enemy ship (Fig. 37.27). (a) What is the speed of the missile relative to you? Express your answer in terms of the speed of light. (b) If you measure that the enemy ship is 8.00×10^6 km away from you when the missile is fired, how much time, measured in your frame, will it take the missile to reach you?

Figure **37.27** Exercise 37.22.

37.23. An imperial spaceship, moving at high speed relative to the planet Arrakis, fires a rocket towards the planet with a speed of $0.920c$ relative to the spaceship. An observer on Arrakis measures that the rocket is approaching with a speed of $0.360c$. What is the speed of the spaceship relative to Arrakis? Is the spaceship moving towards or away from Arrakis?

*Section 37.6 The Doppler Effect for Electromagnetic Waves

***37.24.** Rewrite Eq. 37.25 to find the relative velocity u between the electromagnetic source and an observer in terms of the ratio of the observed frequency and the source frequency of light. What relative velocity u will produce (a) a 5.0% decrease in frequency and (b) an increase by a factor of 5 of the frequency of the observed light?

***37.25.** (a) How fast must you be approaching a red traffic light $(\lambda = 675\text{ nm})$ for it to appear yellow $(\lambda = 575\text{ nm})$? Express your answer in terms of the speed of light. (b) If you used this as a reason not to get a ticket for running a red light, how much of a fine would you get for speeding? Assume that the fine is \$1.00 for each kilometre per hour that your speed exceeds the posted limit of 90 km/h.

***37.26.** Show that when the source of electromagnetic waves moves away from us at $0.600c$, the frequency we measure is half the value measured in the rest frame of the source.

Section 37.7 Relativistic Momentum

37.27. (a) A particle with mass m moves along a straight line under the action of a force F directed along the same line. Evaluate the derivative in Eq. (37.29) to show that the acceleration $a = dv/dt$ of the particle is given by $a = (F/m)(1 - v^2/c^2)^{3/2}$. (b) Evaluate the derivative in Eq. (37.29) to find the expression for the magnitude of the acceleration in terms of F, m, and v/c if the force is perpendicular to the velocity.

37.28. As you have seen, relativistic calculations usually involve the quantity γ. When γ is appreciably greater than 1, we must use relativistic formulas instead of Newtonian ones. For what speed v (in terms of c) is the value of γ (a) 1.0% greater than 1; (b) 10% greater than 1; (c) 100% greater than 1?

37.29. (a) At what speed is the momentum of a particle twice as great as the result obtained from the nonrelativistic expression mv? Express your answer in terms of the speed of light. (b) A force is applied to a particle along its direction of motion. At what speed is the magnitude of force required to produce a given acceleration twice as great as the force required to produce the same acceleration when the particle is at rest? Express your answer in terms of the speed of light.

37.30. Calculate the magnitude of the force required to give a 0.145-kg ball an acceleration $a = 1.00\text{ m/s}^2$ in the direction of the ball's initial velocity when this velocity has a magnitude of (a) 10.0 m/s; (b) $0.900c$; (c) $0.990c$. (d) Repeat parts (a), (b) and (c) if the force and acceleration are perpendicular to the velocity.

Section 37.8 Relativistic Work and Energy

37.31. What is the speed of a particle whose kinetic energy is equal to (a) its rest energy and (b) five times its rest energy?

37.32. In proton–antiproton annihilation a proton and an antiproton (a negatively charged proton) collide and disappear, producing electromagnetic radiation. If each particle has a mass of 1.67×10^{-27} kg and they are at rest just before the annihilation, find the total energy of the radiation. Give your answers in joules and in electron volts.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

37.33. A proton (rest mass $1.67 \times 10^{\times 27}$ kg) has total energy that is 4.00 times its rest energy. What are (a) the kinetic energy of the proton; (b) the magnitude of the momentum of the proton; (c) the speed of the proton?

37.34. (a) How much work must be done on a particle with mass m to accelerate it (a) from rest to a speed of $0.090c$ and (b) from a speed of $0.900c$ to a speed of $0.990c$? (Express the answers in terms of mc^2.) (c) How do your answers in parts (a) and (b) compare?

37.35. (a) By what percentage does your rest mass increase when you climb 30 m to the top of a ten-story building? Are you aware of this increase? Explain. (b) By how many grams does the mass of a 12.0 g spring with force constant 200 N/cm change when you compress it by 6.0 cm? Does the mass increase or decrease? Would you notice the change in mass if you were holding the spring? Explain.

37.36. A 60.0 kg person is standing at rest on level ground. How fast would she have to run to (a) double her total energy and (b) increase her total energy by a factor of 10?

37.37. When a particle meets its antiparticle, they annihilate each other and their mass is converted to light energy. A country uses approximately 1.0×10^{19} J of energy per year. (a) If all this energy came from a futuristic antimatter reactor, how much mass of matter and antimatter fuel would be consumed yearly? (b) If this fuel had the density of iron (7.86 g/cm^3) and were stacked in bricks to form a cubical pile, how high would it be? (Before you get your hopes up, antimatter reactors are a *long* way in the future—if they ever will be feasible.)

37.38. A ψ ('psi') particle has mass 5.52×10^{-27} kg. Compute the rest energy of the ψ particle in MeV.

37.39. A particle has rest mass 6.64×10^{-27} kg and momentum 2.10×10^{-18} kg · m/s. (a) What is the total energy (kinetic plus rest energy) of the particle? (b) What is the kinetic energy of the particle? (c) What is the ratio of the kinetic energy to the rest energy of the particle?

37.40. Starting from Eq. (37.39), show that in the classical limit ($pc \ll mc^2$) the energy approaches the classical kinetic energy $\frac{1}{2}mv^2$ plus the rest mass energy mc^2.

37.41. Compute the kinetic energy of a proton (mass 1.67×10^{-27} kg using both the nonrelativistic and relativistic expressions, and compute the ratio of the two results (relativistic divided by nonrelativistic) for speeds of (a) 8.00×10^7 m/s and (b) 2.85×10^8 m/s.

37.42. What is the kinetic energy of a proton moving at (a) $0.100c$; (b) $0.500c$; (c) $0.900c$? How much work must be done to (d) increase the proton's speed from $0.100c$ to $0.500c$ and (e) increase the proton's speed from $0.500c$ to $0.900c$? (f) How do the last two results compare to results obtained in the nonrelativistic limit?

37.43. (a) Through what potential difference does an electron have to be accelerated, starting from rest, to achieve a speed of $0.980c$? (b) What is the kinetic energy of the electron at this speed? Express your answer in joules and in electron volts.

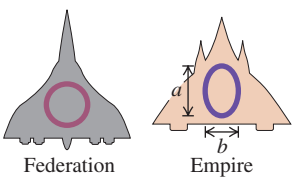
37.44. Two protons (each with rest mass $M = 1.67 \times 10^{-27}$ kg) are initially moving with equal speeds in opposite directions. The protons continue to exist after a collision that also produces an η^0 particle (see Chapter 44). The rest mass of the η^0 is $m = 9.75 \times 10^{-28}$ kg. (a) If the two protons and the η^0 are all at rest after the collision, find the initial speed of the protons, expressed as a fraction of the speed of light. (b) What is the kinetic energy of each proton? Express your answer in MeV. (c) What is the rest energy of the η^0, expressed in MeV? (d) Discuss the relationship between the answers to parts (b) and (c).

37.45. Find the speed of a particle whose relativistic kinetic energy is 50% greater than the Newtonian value for the same speed.

37.46. In a hypothetical nuclear fusion reactor, two deuterium nuclei combine or 'fuse' to form one helium nucleus. The mass of a deuterium nucleus, expressed in atomic mass units (u), is 2.0136 u; the mass of a helium nucleus is 4.0015 u (1 u $= 1.6605402 \times 10^{-27}$ kg). How much energy is released when 1.0 kg of deuterium undergoes fusion?

37.47. The sun produces energy by nuclear fusion reactions, in which matter is converted into energy. By measuring the amount of energy we receive from the sun, we know that it is producing energy at a rate of 3.8×10^{26} W. (a) How many kilograms of matter does the sun lose each second? (b) At this rate, how long would it take the sun to use up all its mass?

37.48. A 0.100 μg speck of dust is accelerated from rest to a speed of $0.900c$ by a constant 1.00×10^6 N force. (a) If the nonrelativistic form of Newton's second law ($\sum F = ma$) is used, how far does the object travel to reach its final speed? (b) Using the correct relativistic treatment of Section 37.8, how far does the object travel to reach its final speed? (c) Which distance is greater? Why?



Problems

37.49. After being produced in a collision between elementary particles, a positive pion (π^+) must travel down a 1.20-km-long tube to reach an experimental area. A π^+ particle has an average lifetime (measured in its rest frame) of 2.60×10^{-8} s; the π^+ we are considering has this lifetime. (a) How fast must the π^+ travel if it is not to decay before it reaches the end of the tube? (Since u will be very close to c, write $u = (1 - \Delta)c$ and give your answer in terms of Δ rather than u.) (b) The π^+ has a rest energy of 139.6 MeV. What is the total energy of the π^+ at the speed calculated in part (a)?

37.50. A cube of metal with sides of length a sits at rest in a frame S with one edge parallel to the x-axis. Therefore, in S the cube has volume a^3. Frame S' moves along the x-axis with a speed u. As measured by an observer in frame S', what is the volume of the metal cube?

37.51. The starships of the Solar Federation are marked with the symbol of the federation, a circle, while starships of the Denebian Empire are marked with the empire's symbol, an ellipse whose major axis is 1.40 times longer than its minor axis ($a = 1.40b$ in Fig. 37.28). How fast, relative to an observer, does an empire ship have to travel for its marking to be confused with the marking of a federation ship?

Figure **37.28** Problem 37.51.

37.52. A space probe is sent to the vicinity of the star Capella, which is 42.2 light-years from the earth. (A light-year is the distance light travels in a year.) The probe travels with a speed of $0.9910c$. An astronaut recruit on board is 19 years old when the probe leaves the earth. What is her biological age when the probe reaches Capella?

37.53. A particle is said to be *extremely relativistic* when its kinetic energy is much greater than its rest energy. (a) What is the speed of a particle (expressed as a fraction of c) such that the total energy is

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

ten times the rest energy? (b) What is the percentage difference between the left and right sides of Eq. (37.39) if $(mc^2)^2$ is neglected for a particle with the speed calculated in part (a)?

37.54. Two atomic clocks are carefully synchronised. One remains in New York, and the other is loaded on an airliner that travels at an average speed of 250 m/s and then returns to New York. When the plane returns, the elapsed time on the clock that stayed behind is 4.00 h. By how much will the readings of the two clocks differ, and which clock will show the shorter elapsed time? (*Hint:* Since $u \ll c$, you can simplify $\sqrt{1 - u^2/c^2}$ by a binomial expansion.)

37.55. Engineering. Physicists and engineers from around the world have come together to build the largest accelerator in the world, the Large Hadron Collider (LHC) at the CERN Laboratory in Geneva, Switzerland. The machine will accelerate protons to kinetic energies of 7 TeV in an underground ring 27 km in circumference. (For the latest news and more information on the LHC, visit www.cern.ch.) (a) What speed v will protons reach in the LHC? (Since v is very close to c, write $v = (1 - \Delta)c$ and give your answer in terms of Δ.) (b) Find the relativistic mass, m_{rel}, of the accelerated protons in terms of their rest mass.

37.56. Engineering. A nuclear bomb containing 8.00 kg of plutonium explodes. The sum of the rest masses of the products of the explosion is less than the original rest mass by one part in 10^4. (a) How much energy is released in the explosion? (b) If the explosion takes place in 4.00 μs, what is the average power developed by the bomb? (c) What mass of water could the released energy lift to a height of 1.00 km?

37.57. The Russian physicist P. A. Čerenkov discovered that a charged particle travelling in a solid with a speed exceeding the speed of light in that material radiates electromagnetic radiation. (This is analogous to the sonic boom produced by an aircraft moving faster than the speed of sound in air; see Section 16.9. Čerenkov shared the 1958 Nobel Prize for this discovery.) What is the minimum kinetic energy (in electron volts) that an electron must have while travelling inside a slab of crown glass $(n = 1.52)$ in order to create this Čerenkov radiation?

37.58. A photon with energy E is emitted by an atom with mass m, which recoils in the opposite direction. (a) Assuming that the motion of the atom can be treated nonrelativistically, compute the recoil speed of the atom. (b) From the result of part (a), show that the recoil speed is much less than c whenever E is much less than the rest energy mc^2 of the atom.

37.59. In an experiment, two protons are shot directly towards each other, each moving at half the speed of light relative to the laboratory. (a) What speed does one proton measure for the other proton? (b) What would be the answer to part (a) if we used only nonrelativistic Newtonian mechanics? (c) What is the kinetic energy of each proton as measured by (i) an observer at rest in the laboratory and (ii) an observer riding along with one of the protons? (d) What would be the answers to part (c) if we used only nonrelativistic Newtonian mechanics?

37.60. For the protons in Problem 37.59, suppose that their speed is such that each proton measures a speed of half the speed of light for the other proton. (a) What does an observer in the laboratory measure for the speeds of these protons? (b) What is the kinetic energy of each proton as measured by (i) an observer in the lab and (ii) the other proton?

37.61. Frame S' has an x-component of velocity u relative to frame S, and at $t = t' = 0$ the two frames coincide (see Fig. 37.3). A light pulse with a spherical wave front is emitted at the origin of S' at time $t' = 0$. Its distance x' from the origin after a time t' is given by $x'^2 = c^2t'^2$. Use the Lorentz coordinate transformation to transform this equation to an equation in x and t, and show that the result is $x^2 = c^2t^2$; that is, the motion appears exactly the same in frame of reference S as it does in S'; the wave front is observed to be spherical in both frames.

37.62. In certain radioactive beta decay processes, the beta particle (an electron) leaves the atomic nucleus with a speed of 99.95% the speed of light relative to the decaying nucleus. If this nucleus is moving at 75.00% the speed of light in the labratory reference frame, find the speed of the emitted electron relative to the laboratory reference frame if the electron is emitted (a) in the same direction that the nucleus is moving and (b) in the opposite direction from the nucleus's velocity. (c) In each case in parts (a) and (b), find the kinetic energy of the electron as measured in (i) the laboratory frame and (ii) the reference frame of the decaying nucleus.

37.63. A particle with mass m accelerated from rest by a constant force F will, according to Newtonian mechanics, continue to accelerate without bound; that is, as $t \to \infty$, $v \to \infty$. Show that according to relativistic mechanics, the particle's speed approaches c as $t \to \infty$. [*Note:* A useful integral is $\int (1 - x^2)^{-3/2}\, dx = x/\sqrt{1 - x^2}$.]

37.64. Two events are observed in a frame of reference S to occur at the same space point, the second occurring 1.80 s after the first. In a second frame S' moving relative to S, the second event is observed to occur 2.35 s after the first. What is the difference between the positions of the two events as measured in S'?

37.65. Two events observed in a frame of reference S have positions and times given by (x_1, t_1) and (x_2, t_2), respectively. (a) Frame S' moves along the x-axis just fast enough that the two events occur at the same position in S'. Show that in S', the time interval $\Delta t'$ between the two events is given by

$$\Delta t' = \sqrt{(\Delta t)^2 - \left(\frac{\Delta x}{c}\right)^2}$$

where $\Delta x = x_2 - x_1$ and $\Delta t = t_2 - t_1$. Hence show that if $\Delta x > c\,\Delta t$, there is *no* frame S' in which the two events occur at the same point. The interval $\Delta t'$ is sometimes called the *proper time interval* for the events. Is this term appropriate? (b) Show that if $\Delta x > c\,\Delta t$, there is a different frame of reference S' in which the two events occur *simultaneously*. Find the distance between the two events in S'; express your answer in terms of Δx, Δt, and c. This distance is sometimes called a *proper length*. Is this term appropriate? (c) Two events are observed in a frame of reference S' to occur simultaneously at points separated by a distance of 2.50 m. In a second frame S moving relative to S' along the line joining the two points in S', the two events appear to be separated by 5.00 m. What is the time interval between the events as measured in S? [*Hint:* Apply the result obtained in part (b).]

37.66. Einstein and Lorentz, being avid tennis players, play a fast-paced game on a court where they stand 20.0 m from each other. Being very skilled players, they play without a net. The tennis ball has mass 0.0580 kg. You can ignore gravity and assume that the ball travels parallel to the ground as it travels between the two players. Unless otherwise specified, all measurements are made by the two men. (a) Lorentz serves the ball at 80.0 m/s. What is the ball's kinetic energy? (b) Einstein slams a return at 1.80×10^8 m/s. What is the ball's kinetic energy? (c) During Einstein's return of the ball in part (a), a white rabbit runs beside the court in the direction from Einstein to Lorentz. The rabbit has a speed of 2.20×10^8 m/s relative to the two men. What is the speed of the rabbit relative to the ball? (d) What does the rabbit measure as the distance from Einstein to Lorentz? (e) How much time does it take for the rabbit to run 20.0 m, according to the players?

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

(f) The white rabbit carries a pocket watch. He uses this watch to measure the time (as he sees it) for the distance from Einstein to Lorentz to pass by under him. What time does he measure?

***37.67.** One of the wavelengths of light emitted by hydrogen atoms under normal laboratory conditions is $\lambda = 656.3$ nm, in the red portion of the electromagnetic spectrum. In the light emitted from a distant galaxy this same spectral line is observed to be Doppler-shifted to $\lambda = 953.4$ nm, in the infrared portion of the spectrum. How fast are the emitting atoms moving relative to the earth? Are they approaching the earth or receding from it?

***37.68.** A coach uses a radar device to measure the speed of an approaching bowled cricket ball. This device sends out electromagnetic waves with frequency f_0 and then measures the shift in frequency Δf of the waves reflected from the moving ball. If the fractional frequency shift produced by a ball is $\Delta f/f_0 = 2.86 \times 10^{-7}$, what is the ball's speed in km/h? (*Hint:* Are the waves Doppler-shifted a second time when reflected off the ball?)

37.69. Travel to the stars requires hundreds or thousands of years, even at the speed of light. Some people have suggested that we can get around this difficulty by accelerating the rocket (and its astronauts) to very high speeds so that they will age less due to time dilation. The fly in this ointment is that it takes a great deal of energy to do this. Suppose you want to go to the immense red giant Betelgeuse, which is about 500 light-years away. (A light-year is the distance that light travels in a year.) You plan to travel at constant speed in a 1000 kg rocket ship, which, in reality, is far too small for this purpose. In each case that follows, calculate the time for the trip, as measured by people on earth and by astronauts in the rocket ship, the energy needed in joules, and the energy needed as a percentage of U.S. yearly use (which is 1.0×10^{19} J). For comparison, arrange your results in a table showing v_{rocket}, t_{earth}, t_{rocket}, E (in J) and E (as % of U.S. use). The rocket ship's speed is (a) 0.50c; (b) 0.99c; (c) 0.9999c. On the basis of your results, does it seem likely that any government will invest in such high-speed space travel any time soon?

***37.70.** A spaceship moving at constant speed u relative to us broadcasts a radio signal at constant frequency f_0. As the spaceship approaches us, we receive a higher frequency f; after it has passed, we receive a lower frequency. (a) As the spaceship passes by, so it is instantaneously moving neither towards nor away from us, show that the frequency we receive is not f_0, and derive an expression for the frequency we do receive. Is the frequency we receive higher or lower than f_0? (*Hint:* In this case, successive wave crests move the same distance to the observer and so they have the same transit time. Thus f equals $1/T$. Use the time dilation formula to relate the periods in the stationary and moving frames.) (b) A spaceship emits electromagnetic waves of frequency $f_0 = 345$ MHz as measured in a frame moving with the ship. The spaceship is moving at a constant speed $0.758c$ relative to us. What frequency f do we receive when the spaceship is approaching us? When it is moving away? In each case what is the shift in frequency, $f - f_0$? (c) Use the result of part (a) to calculate the frequency f and the frequency shift $(f - f_0)$ we receive at the instant that the ship passes by us. How does the shift in frequency calculated here compare to the shifts calculated in part (b)?

***37.71.** Suppose a *very* fast runner $(v = 0.600c)$ holding a long, horizontal pole runs through a barn open at both ends. The length of the pole (in its rest frame) is 6.00 m, and the length of the barn (in *its* rest frame) is 5.00 m. In the barn's reference frame, the pole will undergo length contraction and can all fit inside the barn at the same time. But in the runner's reference frame, the *barn* will undergo length contraction and the entire pole can *never* be entirely within the barn at any time! Explain the resolution of this paradox.

37.72. The French physicist Armand Fizeau was the first to measure the speed of light accurately. He also found experimentally that the speed, relative to the lab frame, of light travelling in a tank of water that is itself moving at a speed V relative to the lab frame is

$$v = \frac{c}{n} + kV$$

where $n = 1.333$ is the index of refraction of water. Fizeau called k the dragging coefficient and obtained an experimental value of $k = 0.44$. What value of k do you calculate from relativistic transformations?

Challenge Problems

37.73. Using a method analogous to the one in the text to find the Lorentz transformation formula for velocity, we can find the Lorentz transformation for *acceleration*. Let frame S' have a constant x-component of velocity u relative to frame S. An object moves relative to frame S along the x-axis with instantaneous velocity v_x and instantaneous acceleration a_x. (a) Show that its instantaneous acceleration in frame S' is

$$a'_x = a_x\left(1 - \frac{u^2}{c^2}\right)^{3/2}\left(1 - \frac{uv_x}{c^2}\right)^{-3}$$

[*Hint:* Express the acceleration in S' as $a'_x = dv'_x/dt'$. Then use Eq. (37.21) to express dt' in terms of dt and dx, and use Eq. (37.22) to express dv'_x in terms of u and dv_x. The velocity of the object in S is $v_x = dx/dt$.] (b) Show that the acceleration in frame S can be expressed as

$$a_x = a'_x\left(1 - \frac{u^2}{c^2}\right)^{3/2}\left(1 + \frac{uv'_x}{c^2}\right)^{-3}$$

where $v'_x = dx'/dt'$ is the velocity of the object in frame S'.

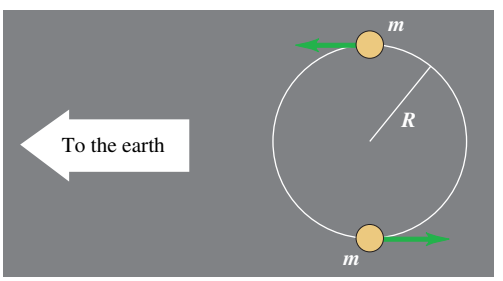
37.74. A rocket ship leaves the earth on 1 January 2100. Stella, one of a pair of twins born in the year 2075, pilots the rocket (reference frame S'); the other twin, Terra, stays on the earth (reference frame S). The rocket ship has an acceleration of constant magnitude g in its own reference frame (this makes the pilot feel at home, since it simulates the earth's gravity). The path of the rocket ship is a straight line in the $+x$-direction in frame S. (a) Using the results of Challenge Problem 37.73, show that in Terra's earth frame S, the rocket's acceleration is

$$\frac{du}{dt} = g\left(1 - \frac{u^2}{c^2}\right)^{3/2}$$

where u is the rocket's instantaneous velocity in frame S. (b) Write the result of part (a) in the form $dt = f(u)\,du$, where $f(u)$ is a function of u, and integrate both sides. (*Hint:* Use the integral given in Problem 37.63.) Show that in Terra's frame, the time when Stella attains a velocity v_{1x} is

$$t_1 = \frac{v_{1x}}{g\sqrt{1 - v_{1x}^2/c^2}}$$

(c) Use the time dilation formula to relate dt and dt' (infinitesimal time intervals measured in frames S and S', respectively). Combine this result with the result of part (a) and integrate as in part (b) to show the following: When Stella attains a velocity v_{1x} relative to Terra, the time t'_1 that has elapsed in frame S' is



Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

$$t_1' = \frac{c}{g}\,\text{arctanh}\left(\frac{v_{1x}}{c}\right)$$

Here arctanh is the inverse hyperbolic tangent. (*Hint:* Use the integral given in Challenge Problem 5.124.) (d) Combine the results of parts (b) and (c) to find t_1 in terms of t_1', g, and c alone. (e) Stella accelerates in a straight-line path for five years (by her clock), slows down at the same rate for five years, turns around, accelerates for five years, slows down for five years and lands back on the earth. According to Stella's clock, the date is 1 January 2120. What is the date according to Terra's clock?

***37.75.** Many of the stars in the sky are actually *binary stars*, in which two stars orbit about their common centre of mass. If the orbital speeds of the stars are high enough, the motion of the stars can be detected by the Doppler shifts of the light they emit. Stars for which this is the case are called *spectroscopic binary stars*. Figure 37.29 shows the simplest case of a spectroscopic binary star: two identical stars, each with mass m, orbiting their centre of mass in a circle of radius R. The plane of the stars' orbits is edge-on to the line of sight of an observer on the earth. (a) The light produced by heated hydrogen gas in a laboratory on the earth has a frequency of 4.568110×10^{14} Hz. In the light received from the stars by a telescope on the earth, hydrogen light is observed to vary in frequency between 4.567710×10^{14} Hz and 4.568910×10^{14} Hz. Determine whether the binary star system as a whole is moving towards or away from the earth, the speed of this motion, and the orbital speeds of the stars. (*Hint:* The speeds involved are much less than c, so you may use the approximate result $\Delta f/f = u/c$ given in Section 37.6.) (b) The light from each star in the binary system varies from its maximum frequency to its minimum frequency and back again in 11.0 days. Determine the orbital radius R and the mass m of each star. Give your answer for m in kilograms and as a multiple of the mass of the sun, 1.99×10^{30} kg. Compare the value of R to the distance from the earth to the sun, 1.50×10^{11} m. (This technique is actually used in astronomy to determine the masses of stars. In practice, the problem is more complicated because the two stars in a binary system are usually not identical, the orbits are usually not circular, and the plane of the orbits is usually tilted with respect to the line of sight from the earth.)

Figure **37.29** Challenge Problem 37.75.

37.76. (a) Consider the Galilean transformation along the x-direction: $x' = x - vt$ and $t' = t$. In frame S the wave equation for electromagnetic waves in a vacuum is

$$\frac{\partial^2 E(x,t)}{\partial x^2} - \frac{1}{c^2}\frac{\partial^2 E(x,t)}{\partial t^2} = 0$$

where E represents the electric field in the wave. Show that by using the Galilean transformation the wave equation in frame S' is found to be

$$\left(1 - \frac{v^2}{c^2}\right)\frac{\partial^2 E(x',t')}{\partial x'^2} + \frac{2v}{c^2}\frac{\partial^2 E(x',t')}{\partial x'\partial t'} - \frac{1}{c^2}\frac{\partial^2 E(x',t')}{\partial t'^2} = 0$$

This has a different form than the wave equation in S. Hence the Galilean transformation *violates* the first relativity postulate that all physical laws have the same form in all inertial reference frames. (*Hint:* Express the derivatives $\partial/\partial x$ and $\partial/\partial t$ in terms of $\partial/\partial x'$ and $\partial/\partial t'$ by use of the chain rule.) (b) Repeat the analysis of part (a), but use the Lorentz coordinate transformations, Eqs (37.21), and show that in frame S' the wave equation has the same form as in frame S:

$$\frac{\partial^2 E(x',t')}{\partial x^2} - \frac{1}{c^2}\frac{\partial^2 E(x',t')}{\partial t'^2} = 0$$

Explain why this shows that the speed of light in vacuum is c in both frames S and S'.

37.77. In high-energy physics, new particles can be created by collisions of fast-moving projectile particles with stationary particles. Some of the kinetic energy of the incident particle is used to create the mass of the new particle. A proton–proton collision can result in the creation of a negative kaon (K^-) and a positive kaon (K^+):

$$p + p \rightarrow p + p + K^- + K^+$$

(a) Calculate the minimum kinetic energy of the incident proton that will allow this reaction to occur if the second (target) proton is initially at rest. The rest energy of each kaon is 493.7 MeV, and the rest energy of each proton is 938.3 MeV. (*Hint:* It is useful here to work in the frame in which the total momentum is zero. See Problem 8.106, but note that here the Lorentz transformation must be used to relate the velocities in the laboratory frame to those in the zero-total-momentum frame.) (b) How does this calculated minimum kinetic energy compare with the total rest mass energy of the created kaons? (c) Suppose that instead the two protons are both in motion with velocities of equal magnitude and opposite direction. Find the minimum combined kinetic energy of the two protons that will allow the reaction to occur. How does this calculated minimum kinetic energy compare with the total rest mass energy of the created kaons? (This example shows that when colliding beams of particles are used instead of a stationary target, the energy requirements for producing new particles are reduced substantially.)

38 PHOTONS, ELECTRONS AND ATOMS

LEARNING GOALS

By studying this chapter, you will be able to explain:

- How experiments involving line spectra, the photoelectric effect, and x-rays pointed the way to a radical reinterpretation of the nature of light.
- How Einstein's photon picture of light explains the photoelectric effect.
- How the spectrum of light emitted by atomic hydrogen reveals the existence of atomic energy levels.
- How physicists discovered the atomic nucleus.
- How Bohr's model of electron orbits explained the spectra of hydrogen and hydrogenlike atoms.
- The operating principles of a laser.
- How experiments with x-rays helped confirm the photon picture of light.
- How the photon picture explains the spectrum of light emitted by a hot, opaque object.
- How we can reconcile the wave and particle aspects of light.

? Although the glowing gas cloud called the Lagoon Nebula is more than 5000 light-years away, we can tell that it contains mostly hydrogen because of its red colour. This red light has a wavelength of 656.3 nm, which is emitted by hydrogen and no other substance. What happens within a hydrogen atom to emit light of this wavelength?

In Chapter 32 we saw how Maxwell, Hertz and others established firmly that light is an electromagnetic wave. Interference, diffraction and polarisation, discussed in Chapters 35 and 36, further demonstrate this *wave nature* of light.

When we look more closely at the emission, absorption and scattering of electromagnetic radiation, however, we discover a completely different aspect of light. We find that the energy of an electromagnetic wave is *quantised*; it is emitted and absorbed in particle-like packages of definite energy, called *photons* or *quanta*. The energy of a single photon is proportional to the frequency of the radiation.

The internal energy of atoms is also quantised. For a given kind of individual atom the energy can't have just any value; only discrete values called *energy levels* are possible.

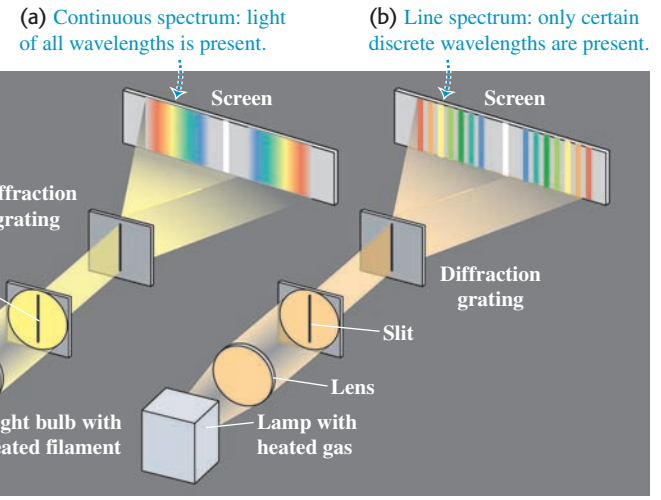
The basic ideas of photons and energy levels take us a long way towards understanding a wide variety of otherwise puzzling observations. Among these are the unique sets of wavelengths emitted and absorbed by gaseous elements, the emission of electrons from an illuminated surface, the operation of lasers, and the production and scattering of x-rays. Our studies of photons and energy levels will take us to the threshold of *quantum mechanics*, which involves some radical changes in our views of the nature of electromagnetic radiation and of matter itself.

38.1 Emission and Absorption of Light

How is light produced? In Chapter 32 we discussed how Heinrich Hertz produced electromagnetic waves using oscillations in a resonant L-C circuit similar to those we studied in Chapter 30. He used frequencies of the order of 10^8 Hz, but visible light has frequencies of the order of 10^{15} Hz, far higher than any frequency that

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

can be attained with conventional electronic circuits. At the end of the 19th century, some physicists speculated that waves in this frequency range might be produced by oscillating electric charges within individual atoms. However, their speculations were unable to give explanations for some key experimental data. Among the great challenges facing physicists in 1900 were how to explain *line spectra*, the *photoelectric effect* and the nature of x-rays. We'll describe each of these in turn.



Line Spectra

We can use a prism or a diffraction grating to separate the various wavelengths in a beam of light into a spectrum. If the light source is a hot solid (such as a light-bulb filament) or liquid, the spectrum is *continuous*; light of all wavelengths is present (Fig. 38.1a). But if the source is a gas carrying an electric discharge (as in a neon sign) or a volatile salt heated in a flame (as when table salt is thrown into a campfire), only a few colours appear, in the form of isolated sharp parallel lines (Fig. 38.1b). (Each 'line' is an image of the spectrograph slit, deviated through an angle that depends on the wavelength of the light forming that image; see Section 36.5.) A spectrum of this sort is called a **line spectrum**. Each line corresponds to a definite wavelength and frequency.

It was discovered early in the 19th century that each element in its gaseous state has a unique set of wavelengths in its line spectrum. The spectrum of hydrogen always contains a certain set of wavelengths; sodium produces a different set, iron still another, and so on. Scientists find the use of spectra to identify elements and compounds to be an invaluable tool (see the photograph that opens this chapter). For instance, astronomers have detected the spectra from more than 100 different molecules in interstellar space, including some that are not found naturally on earth. The characteristic spectrum of an atom was presumably related to its internal structure, but attempts to understand this relationship solely on the basis of *classical* mechanics and electrodynamics—the physics summarised in Newton's three laws and Maxwell's four equations—were not successful.

Photoelectric Effect

There were also mysteries associated with *absorption* of light. In 1887, during his electromagnetic-wave experiments, Hertz discovered the *photoelectric effect*. When light struck a metal surface, some electrons near the surface absorbed enough energy to overcome the attraction of the positive ions in the metal and

38.1 (a) Continuous spectrum produced by a glowing light bulb filament. (b) Line spectrum emitted by a lamp containing a heated gas.

Activ Online Physics 17.3 Photoelectric Effect

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

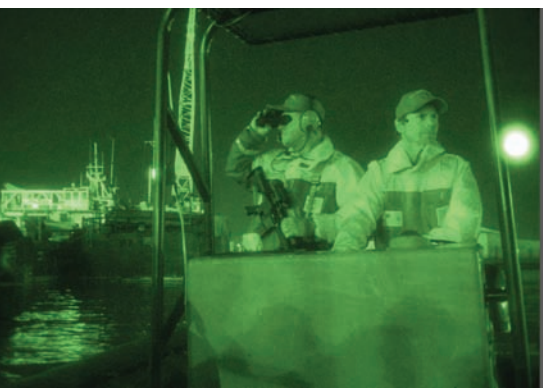
escape into the surrounding space. Detailed investigation of this effect revealed some puzzling features that couldn't be understood on the basis of classical optics. We will discuss these in the next section.

X-rays

Other unsolved problems in the emission and absorption of radiation centred on the production and scattering of *x-rays*, discovered in 1895. These rays were produced in high-voltage electric discharge tubes, but no one understood how or why they were produced or what determined their wavelengths (which are much shorter those of visible light). Even worse, when x-rays collided with matter, the scattered rays sometimes had longer wavelengths than the original ray. This is analogous to a beam of blue light striking a mirror and reflecting back as red!

Photons and Energy Levels

All these phenomena (and several others) pointed forcefully to the conclusion that classical optics, successful though it was in explaining lenses, mirrors, interference and polarisation, had its limitations. We now understand that all these phenomena result from the *quantum* nature of radiation. Electromagnetic radiation, along with its *wave* nature, has properties resembling those of *particles*. In particular, the energy in an electromagnetic wave is always emitted and absorbed in packages called *photons* or *quanta*, with energy proportional to the frequency of the radiation.



The two common threads that are woven through this chapter are the quantisation of electromagnetic radiation and the existence of discrete energy levels in atoms. In the remainder of this chapter we will show how these two concepts contribute to understanding the phenomena mentioned above. We are not yet ready for a comprehensive theory of atomic structure; that will come in Chapters 40 and 41. But we'll look at the Bohr model of the hydrogen atom, one attempt to predict atomic energy levels on the basis of atomic structure.

38.2 (a) A night vision scope makes use of the photoelectric effect. Photons entering the scope strike a plate, ejecting electrons that pass through a thin disk in which there are millions of tiny channels. The current through each channel is amplified electronically and then directed towards a screen that glows when hit by electrons. (b) The image formed on the screen, which is a combination of these millions of glowing spots, is thousands of times brighter than the naked-eye view.

(a)

(b)

38.2 The Photoelectric Effect

The **photoelectric effect** is the emission of electrons when light strikes a surface. This effect has numerous practical applications (Fig. 38.2). To escape from the surface, the electron must absorb enough energy from the incident radiation to overcome the attraction of positive ions in the material of the surface. This attraction causes a potential-energy barrier that normally confines the electrons inside the material. Think of this barrier as being like a rounded curb separating a flat street from a raised footpath. The curb will keep a slowly moving soccer ball in the street. But if the ball is kicked hard enough, it can roll up onto the footpath, with the work done against the gravitational attraction (the gain in gravitational potential energy) equal to its loss in kinetic energy.

Threshold Frequency and Stopping Potential

The photoelectric effect was first observed in 1887 by Heinrich Hertz, who noticed that a spark would jump more readily between two electrically charged spheres when their surfaces were illuminated by the light from another spark. Light shining on the surfaces somehow facilitated the escape of what we now know to be electrons. This idea in itself was not revolutionary. The existence of the surface potential-energy barrier was already known. In 1883 Thomas Edison had discovered *thermionic emission*, in which the escape energy is supplied by

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

heating the material to a very high temperature, liberating electrons by a process analogous to boiling a liquid. The *minimum* amount of energy an individual electron has to gain to escape from a particular surface is called the **work function** for that surface, denoted by ϕ. However, the surfaces that Hertz used were not at the high temperatures needed for thermionic emission.

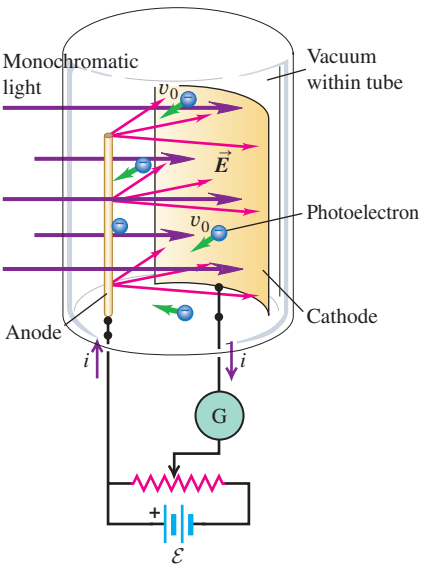
The photoelectric effect was investigated in detail by the German physicists Wilhelm Hallwachs and Philipp Lenard during the years 1886–1900; their results were quite unexpected. We will describe their work in terms of a more modern phototube (Fig. 38.3). Two conducting electrodes, the anode and the cathode, are enclosed in an evacuated glass tube. The battery or other source of potential difference creates an electric field in the direction from anode to cathode in Fig. 38.3a. Light (indicated by the magenta arrows) falling on the surface of the cathode causes a current in the external circuit; the current is measured by the galvanometer (G). Hallwachs and Lenard studied how this *photocurrent* varies with voltage and with the frequency and intensity of the light.

After the discovery of the electron in 1897, it became clear that the light causes electrons to be emitted from the cathode. Because of their negative charge $-e$, the emitted *photoelectrons* are then pushed towards the anode by the electric field. A high vacuum with residual pressure of 0.01 Pa $(10^{-7}\,\text{atm})$ or less is needed to minimise collisions of the electrons with gas molecules.

Hallwachs and Lenard found that when monochromatic light fell on the cathode, *no* photoelectrons at all were emitted unless the frequency of the light was greater than some minimum value called the **threshold frequency**. This minimum frequency depends on the material of the cathode. For most metals the threshold frequency is in the ultraviolet (corresponding to wavelengths λ between 200 and 300 nm), but for potassium and cesium oxides it is in the visible spectrum (λ between 400 and 700 nm).

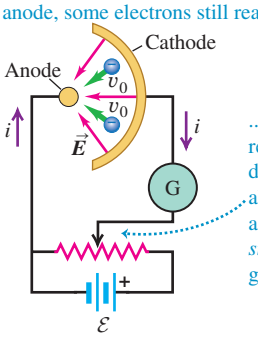
When the frequency f is *greater* than the threshold frequency, some electrons are emitted from the cathode with substantial initial speeds. This can be shown by reversing the polarity of the battery (Fig. 38.3b) so that the electric-field force on the electrons is back towards the cathode. If the magnitude of the field is not too great, the highest-energy emitted electrons still reach the anode and there is still a current. We can determine the *maximum* kinetic energy of the emitted electrons by making the potential of the anode relative to the cathode, V_{AC}, just negative enough so that the current stops. This occurs for $V_{AC} = -V_0$, where V_0 is called the **stopping potential**. As an electron moves from the cathode to the anode, the potential decreases by V_0 and negative work $-eV_0$ is done on the (negatively charged) electron; the most energetic electron leaves the cathode with kinetic energy $K_{max} = \frac{1}{2}mv_{max}^2$ and has zero kinetic energy at the anode. Using the work–energy theorem, we have

$$W_{tot} = -eV_0 = \Delta K = 0 - K_{max}$$
$$K_{max} = \frac{1}{2}mv_{max}^2 = eV_0 \qquad \text{(maximum kinetic energy of photoelectrons)} \qquad (38.1)$$



Hence by measuring the stopping potential V_0, we can determine the maximum kinetic energy with which electrons leave the cathode. (We are ignoring any effects due to differences in the materials of the cathode and anode.)

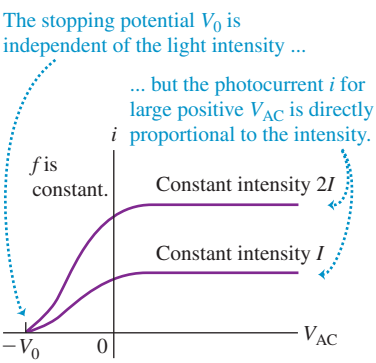
Figure 38.4 shows graphs of photocurrent as a function of potential difference V_{AC} for light of constant frequency and two different intensities. When V_{AC} is sufficiently large and positive, the curves level off, showing that *all* the emitted electrons are being collected by the anode. The reverse potential difference $-V_0$ needed to reduce the current to zero is shown.



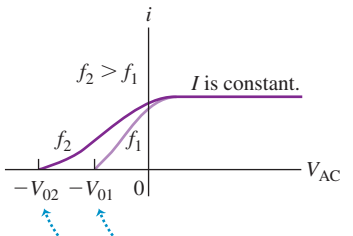
If the intensity of light is increased while its frequency is kept the same, the current levels off at a higher value, showing that more electrons are being emitted per time. But the stopping potential V_0 is found to be the same.

38.3 Demonstrating the photoelectric effect.

(a) Light causes the cathode to emit electrons, which are pushed towards the anode by the electric-field force.



(b) Overhead view with $\vec{E}$ field reversed. Even when the direction of $\vec{E}$ field is reversed so that the electric-field force points away from the anode, some electrons still reach the anode ...



... unless the reversed potential difference has an absolute value of at least V_0. This *stopping potential* gives zero current.

38.4 Photocurrent i for a constant light frequency f as a function of the potential V_{AC} of the anode with respect to the cathode.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

38.5 Photocurrent i for two different light frequencies f_1 and f_2 as functions of the potential V_{AC} of the anode with respect to the cathode.

The stopping potential V_0 (and therefore the maximum kinetic energy of the photoelectrons) increases linearly with frequency: since $f_2 > f_1$, $V_{02} > V_{01}$.

Figure 38.5 shows current as a function of potential difference for two different frequencies. We see that when the frequency of the incident monochromatic light is increased, the stopping potential V_0 increases. In fact, V_0 turns out to be a linear function of the frequency f.

Einstein's Photon Explanation

These results are hard to understand on the basis of classical physics. When the intensity (average energy per unit area per unit time) increases, electrons should be able to gain more energy, increasing the stopping potential V_0. But V_0 was found *not* to depend on intensity. Also, classical physics offers no explanation for the threshold frequency. In Section 32.4 we found that the intensity of an electromagnetic wave such as light does not depend on frequency, so an electron should be able to acquire its needed escape energy from light of any frequency. Thus there should not be a threshold frequency f_0. Finally, we would expect it to take a while for an electron to collect enough energy from extremely faint light. But experiment also shows that electrons are emitted as soon as *any* light with $f \geq f_0$ hits the surface.

The correct analysis of the photoelectric effect was developed by Albert Einstein in 1905. Building on an assumption made five years earlier by Max Planck (to be discussed in Section 38.8), Einstein postulated that a beam of light consists of small packages of energy called **photons** or *quanta*. The energy E of a photon is equal to a constant h times its frequency f. From $f = c/\lambda$ for electromagnetic waves in vacuum we have

$$E = hf = \frac{hc}{\lambda} \qquad \text{(energy of a photon)} \tag{38.2}$$

where h is a universal constant called **Planck's constant**. The numerical value of this constant, to the accuracy known at present, is

$$h = 6.6260693(11) \times 10^{-34}\ \text{J} \cdot \text{s}$$

A photon arriving at the surface is absorbed by an electron. This energy transfer is an all-or-nothing process, in contrast to the continuous transfer of energy in the classical theory; the electron gets all the photon's energy or none at all. If this energy is greater than the work function ϕ, the electron may escape from the surface. Greater intensity at a particular frequency means a proportionally greater number of photons per second absorbed, and thus a proportionally greater number of electrons emitted per second and the proportionally greater current seen in Fig. 38.4.

Recall that ϕ is the *minimum* energy needed to remove an electron from the surface. Einstein applied conservation of energy to find that the *maximum* kinetic energy $K_{max} = \frac{1}{2}mv_{max}^2$ for an emitted electron is the energy hf gained from a photon minus the work function ϕ:

$$K_{max} = \frac{1}{2}mv_{max}^2 = hf - \phi \tag{38.3}$$

Substituting $K_{max} = eV_0$ from Eq. (38.1), we find

$$eV_0 = hf - \phi \qquad \text{(photoelectric effect)} \tag{38.4}$$

We can measure the stopping potential V_0 for each of several values of frequency f for a given cathode material. A graph of V_0 as a function of f turns out to be a straight line, verifying Eq. (38.4), and from such a graph we can determine

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

both the work function ϕ for the material and the value of the quantity h/e. (We do this graphical analysis in Example 38.3.) After the electron charge $-e$ was measured by Robert Millikan in 1909, Planck's constant h could also be determined from these measurements.

Electron energies and work functions are usually expressed in electron volts (eV), defined in Section 23.2. To four significant figures,

$$1\text{ eV} = 1.602 \times 10^{-19}\text{ J}$$

To this accuracy, Planck's constant is

$$h = 6.626 \times 10^{-34}\text{ J} \cdot \text{s} = 4.136 \times 10^{-15}\text{ eV} \cdot \text{s}$$

Table 38.1 lists some typical work functions of elements. These values are approximate because they are very sensitive to surface impurities. The greater the work function, the higher the minimum frequency needed to emit photoelectrons.

Table 38.1 Work Functions of Several Elements

Element	Work Function (eV)
Aluminium	4.3
Carbon	5.0
Copper	4.7
Gold	5.1
Nickel	5.1
Silicon	4.8
Silver	4.3
Sodium	2.7

Photon Momentum

We have discussed photons mostly in the context of light. However, the quantisation concept applies to *all* regions of the electromagnetic spectrum, including radio waves, x-rays, and so on. A photon of any electromagnetic radiation with frequency f and wavelength λ has energy E given by Eq. (38.2). Furthermore, according to the special theory of relativity, every particle that has energy must also have momentum, even if it has no rest mass. Photons have zero rest mass. As we saw in Eq. (37.40), a photon with energy E has momentum with magnitude p given by $E = pc$. Thus the wavelength λ of a photon and the magnitude of its momentum p are related simply by

$$p = \frac{E}{c} = \frac{hf}{c} = \frac{h}{\lambda} \qquad \text{(momentum of a photon)} \qquad (38.5)$$

The direction of the photon's momentum is simply the direction in which the electromagnetic wave is moving.

Problem-Solving Strategy 38.1 Photons

IDENTIFY *the relevant concepts*: The energy and momentum of an individual photon are proportional to the frequency and inversely proportional to the wavelength. These concepts, along with the idea of stopping potential in the photoelectric effect, allow you to solve almost any problem involving photons.

SET UP *the problem*: Decide what your target variable is. It could be the photon's wavelength λ, frequency f, energy E or momentum p. If the problem involves the photoelectric effect, the target variable could be the maximum kinetic energy of photoelectrons K_{max}, the stopping potential V_0, or the work function ϕ.

EXECUTE *the solution* as follows:

1. Use Eqs (38.2) and (38.5) to relate the energy and momentum of a photon to its wavelength and frequency. If the problem involves the photoelectric effect, use Eqs (38.1), (38.3) and (38.4) to relate the photon frequency, stopping potential, work function and maximum photoelectron kinetic energy.
2. The electron volt is an important and convenient unit. We used it in Chapter 37, and we will use it even more in this and the next three chapters. One electron volt (eV) is the amount of kinetic energy gained by an electron when it moves freely through an increase of potential of one volt: $1\text{ eV} = 1.602 \times 10^{-19}\text{ J}$. If the photon energy E is given in electron volts, use $h = 4.136 \times 10^{-15}\text{ eV} \cdot \text{s}$; if E is in joules, use $h = 6.626 \times 10^{-34}\text{ J} \cdot \text{s}$.

EVALUATE *your answer*: In problems involving photons, the numbers are in such unfamiliar ranges that common sense may not help you identify whether your calculation is off by a large factor. It helps to remember that a visible-light photon with $\lambda = 600\text{ nm}$ and $f = 5 \times 10^{14}\text{ Hz}$ has an energy E of about 2 eV, or about $3 \times 10^{-19}\text{ J}$.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

Example 38.1 FM radio photons

A radio station broadcasts at 89.3 MHz with a radiated power of 43.0 kW. (a) What is the magnitude of the momentum of each photon? (b) How many photons does the station emit each second?

SOLUTION

IDENTIFY: This problem involves the ideas of (a) photon momentum and (b) photon energy.

SET UP: We are given the frequency of the radiation, so we can use Eq. (38.5) directly to find the magnitude of each photon's momentum in part (a). In part (b), note that 'radiated power' means the energy emitted per second and that Eq. (38.2) gives the energy per photon. We can combine these to calculate the number of photons emitted per second.

EXECUTE: (a) From Eq. (38.5), the magnitude of momentum of each photon is

$$p = \frac{hf}{c} = \frac{(6.626 \times 10^{-34}\ \text{J} \cdot \text{s})(89.3 \times 10^{6}\ \text{Hz})}{3.00 \times 10^{8}\ \text{m/s}}$$
$$= 1.97 \times 10^{-34}\ \text{kg} \cdot \text{m/s}$$

(Recall that $1\ \text{J} = 1\ \text{kg} \cdot \text{m}^2/\text{s}^2$ and that $1\ \text{Hz} = 1\ \text{s}^{-1}$.)

(b) From Eq. (38.2), the energy of each photon is

$$E = pc = (1.97 \times 10^{-34}\ \text{kg} \cdot \text{m/s})(3.00 \times 10^{8}\ \text{m/s})$$
$$= 5.92 \times 10^{-26}\ \text{J}$$

The station emits 43.0×10^3 joules each second, so the rate at which photons are emitted is

$$\frac{43.0 \times 10^{3}\ \text{J/s}}{5.92 \times 10^{-26}\ \text{J/photon}} = 7.26 \times 10^{29}\ \text{photons/s}$$

EVALUATE: The result in part (a) is very small, about the magnitude of the momentum an electron would have if it crawled along at a speed of one metre per hour. The photon energy E calculated in part (b) is also very small, equal to 3.69×10^{-7} eV. A visible-light photon has about 10^7 times as much energy. This makes sense: The energy of a photon is proportional to its frequency, and the frequencies of visible light are about 10^7 times greater than those used in FM radio. (You can also check the value of the photon energy by using $E = hf$.)

Our result in part (b) shows that a huge number of photons leave the station each second, each of which has an infinitesimal amount of energy. Hence the discreteness of the photons isn't noticed, and the radiated energy appears to be a continuous flow.

Example 38.2 A photoelectric-effect experiment

While conducting a photoelectric-effect experiment with light of a certain frequency, you find that a reverse potential difference of 1.25 V is required to reduce the current to zero. Find (a) the maximum kinetic energy and (b) the maximum speed of the emitted photoelectrons.

SOLUTION

IDENTIFY: This problem uses the relationship between the maximum kinetic energy K_{max} of a electron in the photoelectric effect and the associated stopping potential V_0.

SET UP: The value of 1.25 V is the stopping potential V_0. We can find the maximum photoelectron kinetic energy K_{max} by using Eq. (38.1); given this value, we can find the maximum photoelectron speed.

EXECUTE: (a) From Eq. (38.1),

$$K_{\text{max}} = eV_0 = (1.60 \times 10^{-19}\ \text{C})(1.25\ \text{V}) = 2.00 \times 10^{-19}\ \text{J}$$

Recall that $1\ \text{V} = 1\ \text{J/C}$. In terms of electron volts,

$$K_{\text{max}} = eV_0 = e(1.25\ \text{V}) = 1.25\ \text{eV}$$

since the electron volt (eV) is the magnitude of the electron charge e times one volt (1 V).

(b) From $K_{\text{max}} = \frac{1}{2}mv_{\text{max}}^2$ we get

$$v_{\text{max}} = \sqrt{\frac{2K_{\text{max}}}{m}} = \sqrt{\frac{2(2.00 \times 10^{-19}\ \text{J})}{9.11 \times 10^{-31}\ \text{kg}}}$$
$$= 6.63 \times 10^{5}\ \text{m/s}$$

EVALUATE: The value of V_{max} is about $\frac{1}{500}$ the speed of light c, so we are justified in using the nonrelativistic expression for kinetic energy. An equivalent justification is that the electron's 1.25 eV kinetic energy is much lower than its rest energy $mc^2 = 0.511$ MeV.

Example 38.3 Determining ϕ and h experimentally

For a certain cathode material in a photoelectric-effect experiment, you measure a stopping potential of 1.0 V for light of wavelength 600 nm, 2.0 V for 400 nm and 3.0 V for 300 nm. Determine the work function for this material and the value of Planck's constant.

SOLUTION

IDENTIFY: This example uses the relationship among stopping potential V_0, frequency f, and work function ϕ in the photoelectric effect.

SET UP: According to Eq. (38.4), a graph of stopping potential V_0 versus frequency f should be a straight line. Such a graph is completely determined by its slope and the value at which it intercepts the vertical axis; we will use these to determine the values of the target variables ϕ and h.

EXECUTE: We rewrite Eq. (38.4) as

$$V_0 = \frac{h}{e}f - \frac{\phi}{e}$$

Continued

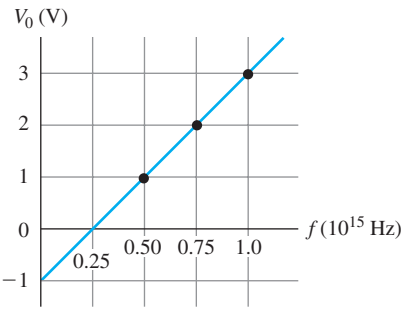
Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

In this form we see that the slope of the line is h/e and the intercept on the vertical axis (corresponding to $f = 0$) is at $-\phi/e$. The frequencies, obtained from $f = c/\lambda$ and $c = 3.00 \times 10^8$ m/s, are 0.50×10^{15} Hz, 0.75×10^{15} Hz, and 1.0×10^{15} Hz, respectively. The graph is shown in Fig. 38.6. From it we find

$$-\frac{\phi}{e} = \text{vertical intercept} = -1.0\ \text{V}$$

$$\phi = 1.0\ \text{eV} = 1.6 \times 10^{-19}\ \text{J}$$

and



$$\text{Slope} = \frac{\Delta V_0}{\Delta f} = \frac{3.0\ \text{V} - (-1.0\ \text{V})}{1.00 \times 10^{15}\ \text{s}^{-1} - 0} = 4.0 \times 10^{-15}\ \text{J} \cdot \text{s/C}$$

$$h = \text{slope} \times e = (4.0 \times 10^{-15}\ \text{J} \cdot \text{s/C})(1.60 \times 10^{-19}\ \text{C})$$

$$= 6.4 \times 10^{-34}\ \text{J} \cdot \text{s}$$

EVALUATE: This experimental value differs by about 3% from the accepted value. The small value of ϕ tells us that the cathode surface is not composed solely of one of the elements in Table 38.1.

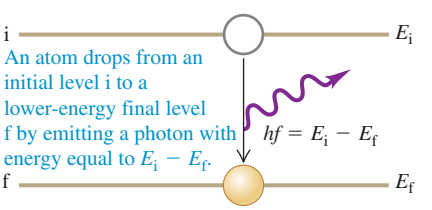
38.6 Stopping potential as a function of frequency. For a different cathode material having a different work function, the line would be displaced up or down but would have the same slope, equal to h/e within experimental error.

Test Your Understanding of Section 38.2 Silicon films become better electrical conductors when illuminated by photons with energies of 1.14 eV or greater, an effect called *photoconductivity*. Which of the following wavelengths of electromagnetic radiation can cause photoconductivity in silicon films? (i) ultraviolet light with $\lambda = 300$ nm; (ii) red light with wavelength $\lambda = 600$ nm; (iii) infrared light with $\lambda = 1200$ nm.

38.3 Atomic Line Spectra and Energy Levels

The origin of *line spectra*, described in Section 38.1, can be understood in general terms on the basis of two central ideas. One is the photon concept; the other is the concept of *energy levels* of atoms. These two ideas were combined by the Danish physicist Niels Bohr in 1913.

Activ ONLINE Physics
18.2 Spectroscopy



Photon Emission by Atoms

Bohr's hypothesis represented a bold breakaway from 19th century ideas. His reasoning went like this. The line spectrum of an element results from the emission of photons with specific energies from the atoms of that element. During the emission of a photon, the internal energy of the atom changes by an amount equal to the energy of the photon. Therefore, said Bohr, each atom must be able to exist with only certain specific values of internal energy. Each atom has a set of possible **energy levels**. An atom can have an amount of internal energy equal to any one of these levels, but it *cannot* have an energy *intermediate* between two levels. All isolated atoms of a given element have the same set of energy levels, but atoms of different elements have different sets. In electric discharge tubes atoms are raised, or *excited*, to higher energy levels mainly through inelastic collisions with electrons.

According to Bohr, an atom can make a *transition* from one energy level to a lower level by emitting a photon with energy equal to the energy *difference* between the initial and final levels (Fig. 38.7). If E_i is the initial energy of the atom before such a transition, E_f is its final energy after the transition, and the photon's energy is $hf = hc/\lambda$, then conservation of energy gives

$$hf = \frac{hc}{\lambda} = E_i - E_f \qquad \text{(energy of emitted photon)} \tag{38.6}$$

38.7 An atom emitting a photon.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

For example, when a krypton atom emits a photon of orange light with wavelength $\lambda = 606$ nm, the corresponding photon energy is

$$E = \frac{hc}{\lambda} = \frac{(6.63 \times 10^{-34}\ \text{J}\cdot\text{s})(3.00 \times 10^{8}\ \text{m/s})}{606 \times 10^{-9}\ \text{m}}$$
$$= 3.28 \times 10^{-19}\ \text{J} = 2.05\ \text{eV}$$

This photon is emitted during a transition like that in Fig. 38.7 between two levels of the atom that differ in energy by 2.05 eV.

The Hydrogen Spectrum

By 1913 the spectrum of hydrogen, the simplest and least massive atom, had been studied intensively. In an electric discharge tube, atomic hydrogen emits the series of lines shown in Fig. 38.8. The visible line with longest wavelength, or lowest frequency, is in the red and is called H_α; the next line, in the blue-green, is called H_β; and so on. In 1885 the Swiss teacher Johann Balmer (1825–1898) found (by trial and error) a formula that gives the wavelengths of these lines, which are now called the *Balmer series*. We may write Balmer's formula as

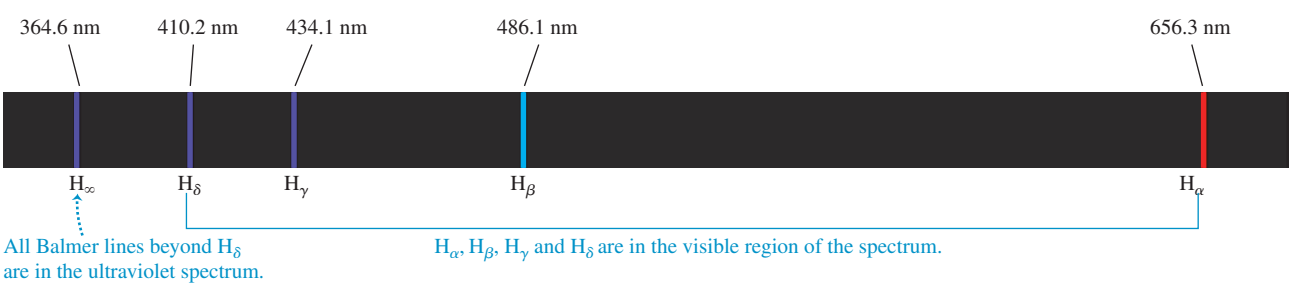
$$\frac{1}{\lambda} = R\left(\frac{1}{2^2} - \frac{1}{n^2}\right) \tag{38.7}$$

where λ is the wavelength, R is a constant called the **Rydberg constant** (chosen to make Eq. (38.7) fit the measured wavelengths), and n may have the integer values 3, 4, 5, ... If λ is in metres, the numerical value of R is

$$R = 1.097 \times 10^{7}\ \text{m}^{-1}$$

Letting $n = 3$ in Eq. (38.7), we obtain the wavelength of the H_α line:

$$\frac{1}{\lambda} = (1.097 \times 10^{7}\ \text{m}^{-1})\left(\frac{1}{4} - \frac{1}{9}\right) \qquad \text{or} \qquad \lambda = 656.3\ \text{nm}$$



For $n = 4$ we obtain the wavelength of the H_β line, and so on. For $n = \infty$ we obtain the *smallest* wavelength in the series, $\lambda = 364.6$ nm.

Balmer's formula has a very direct relationship to Bohr's hypothesis about energy levels. Using the relationship $E = hc/\lambda$, we can find the *photon energies* corresponding to the wavelengths of the Balmer series. Multiplying Eq. (38.7) by hc, we find

$$E = \frac{hc}{\lambda} = hcR\left(\frac{1}{2^2} - \frac{1}{n^2}\right) = \frac{hcR}{2^2} - \frac{hcR}{n^2} \tag{38.8}$$

Equations (38.6) and (38.8) for the photon's energy agree most simply if we identify $-hcR/n^2$ as the initial energy E_i of the atom and $-hcR/2^2$ as its final energy E_f, in a transition in which a photon with energy $E_i - E_f$ is emitted. The energies of the levels are negative because we choose the potential energy to be zero when the electron and nucleus are infinitely far apart. The Balmer (and other) series

38.8 The Balmer series of spectral lines for atomic hydrogen.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

suggest that the hydrogen atom has a series of energy levels, which we may call E_n, given by

$$E_n = -\frac{hcR}{n^2} \qquad (n = 1, 2, 3, 4, \ldots) \qquad \text{(energy levels of the hydrogen atom)} \qquad (38.9)$$

Each wavelength in the Balmer series corresponds to a transition from a level with n equal to 3 or greater to the level with $n = 2$.

The numerical value of the product hcR is

$$\begin{aligned} hcR &= (6.626 \times 10^{-34}\,\text{J}\cdot\text{s})(2.998 \times 10^{8}\,\text{m/s})(1.097 \times 10^{7}\,\text{m}^{-1}) \\ &= 2.179 \times 10^{-18}\,\text{J} = 13.60\,\text{eV} \end{aligned}$$

Thus the magnitudes of the energy levels given by Eq. (38.9) are -13.60 eV, -3.40 eV, -1.51 eV, -0.85 eV, and so on.

Other spectral series for hydrogen have been discovered. These are known, after their discoverers, as the Lyman, Paschen, Brackett and Pfund series. Their wavelengths can be represented by formulas similar to Balmer's formula:

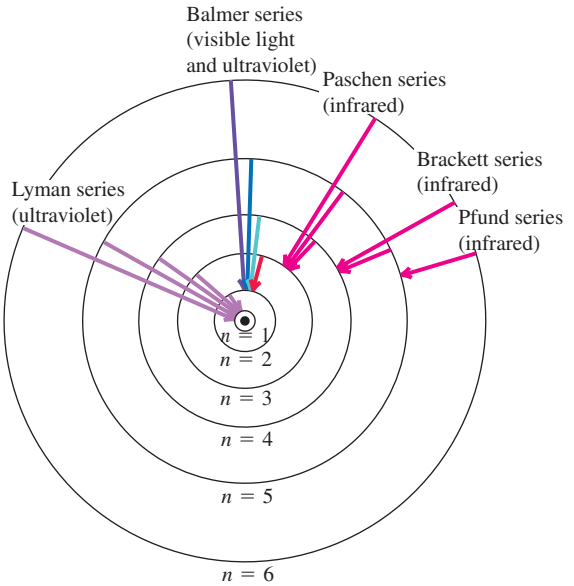
$$\begin{aligned} &\textit{Lyman series} && \frac{1}{\lambda} = R\left(\frac{1}{1^2} - \frac{1}{n^2}\right) && (n = 2, 3, 4, \ldots) \\ &\textit{Paschen series} && \frac{1}{\lambda} = R\left(\frac{1}{3^2} - \frac{1}{n^2}\right) && (n = 4, 5, 6, \ldots) \\ &\textit{Brackett series} && \frac{1}{\lambda} = R\left(\frac{1}{4^2} - \frac{1}{n^2}\right) && (n = 5, 6, 7, \ldots) \\ &\textit{Pfund series} && \frac{1}{\lambda} = R\left(\frac{1}{5^2} - \frac{1}{n^2}\right) && (n = 6, 7, 8, \ldots) \end{aligned}$$

The Lyman series is in the ultraviolet, and the Paschen, Brackett and Pfund series are in the infrared. We see that the Balmer series fits into the scheme between the Lyman and Paschen series.

Thus *all* the spectral series of hydrogen can be understood on the basis of Bohr's picture of transitions from one energy level (and corresponding electron orbit) to another, with the energy levels given by Eq. (38.9) with $n = 1, 2, 3, \ldots$. For the Lyman series the final level is always $n = 1$; for the Paschen series it is $n = 3$; and so on. The relationship of the various spectral series to the energy levels and to electron orbits is shown in Fig. 38.9. Taken together, these spectral series give very strong support to Bohr's picture of energy levels in atoms.

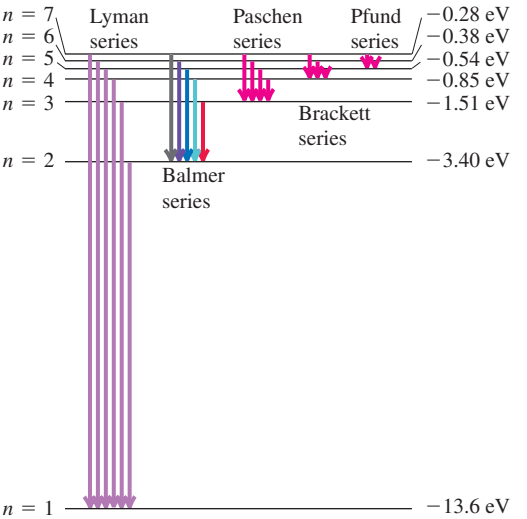
CAUTION **Producing a line spectrum** The lines of a spectrum, such as the hydrogen spectrum shown in Fig. 38.8, are *not* all produced by a single atom. The sample of hydrogen gas that produced the spectrum in Fig. 38.8 contained a large number of atoms; these were excited in an electric discharge tube to various energy levels. The spectrum of the gas shows the light emitted from all the different transitions that occurred in different atoms of the sample.

We haven't yet discussed any way to *predict* what the energy levels for a particular atom should be. Neither have we shown how to derive Eq. (38.9) from fundamental theory or to relate the Rydberg constant R to other fundamental constants. We'll return to these problems later.



The Franck-Hertz Experiment

In 1914, James Franck and Gustav Hertz found even more direct experimental evidence for the existence of atomic energy levels. Franck and Hertz studied the motion of electrons through mercury vapour under the action of an electric field.



Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

38.9 Two ways to represent the energy levels of the hydrogen atom and transitions between them.

(a) 'Permitted' orbits of an electron in the Bohr model of a hydrogen atom (not to scale). Arrows indicate the transitions responsible for some of the lines of various series.

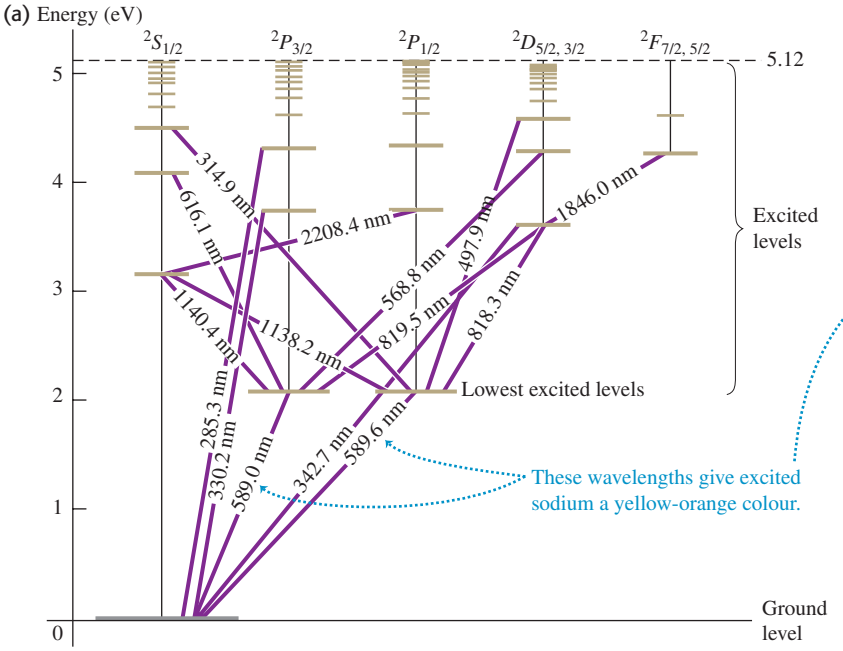
(b) Energy-level diagram for hydrogen, showing some transitions corresponding to the various series

They found that when the electron kinetic energy was 4.9 eV or greater, the vapour emitted ultraviolet light of wavelength 0.25 μm. Suppose mercury atoms have an energy level 4.9 eV above the lowest energy level. An atom can be raised to this level by collision with an electron; it later decays back to the lowest energy level by emitting a photon. According to Eq. (38.2), the wavelength of the photon should be

$$\lambda = \frac{hc}{E} = \frac{(4.136 \times 10^{-15}\ \text{eV} \cdot \text{s})(3.00 \times 10^{8}\ \text{m/s})}{4.9\ \text{eV}}$$
$$= 2.5 \times 10^{-7}\ \text{m} = 0.25\ \mu\text{m}$$

This is equal to the measured wavelength, confirming the existence of this energy level of the mercury atom. Similar experiments with other atoms yield the same kind of evidence for atomic energy levels.

Energy Levels



Only a few atoms and ions (such as hydrogen, singly ionised helium, doubly ionised lithium) have spectra whose wavelengths can be represented by a simple formula such as Balmer's. But it is *always* possible to analyse the more complicated spectra of other elements in terms of transitions among various energy levels and to deduce the numerical values of these levels from the measured spectrum wavelengths.

Every atom has a lowest energy level that includes the *minimum* internal energy state that the atom can have. This is called the *ground-state level*, or **ground level**, and all higher levels are called **excited levels**. A photon corresponding to a particular spectrum line is emitted when an atom makes a transition from a state in an excited level to a state in a lower excited level or the ground level.

Some energy levels for sodium are shown in Fig. 38.10a (next page). You may have noticed the yellow-orange light emitted by sodium vapour street lights. Sodium atoms emit this characteristic yellow-orange light with wavelengths 589.0 and 589.6 nm when they make transitions from the two closely spaced levels labelled *lowest excited levels* to the ground level. A standard test for the presence of

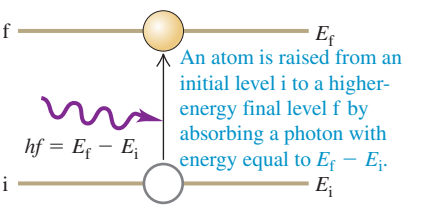
Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

38.10 (a) Energy levels of the sodium atom relative to the ground level. Numbers on the lines between levels are wavelengths. The column labels, such as $^2S_{1/2}$, refer to some quantum states of the valence electron (to be discussed in Chapter 41). (b) When a sodium compound is placed in a flame, sodium atoms are excited into the lowest excited levels. As they drop back to the ground level, the atoms emit photons of yellow-orange light with wavelengths 589.0 and 589.6 nm.

(b)

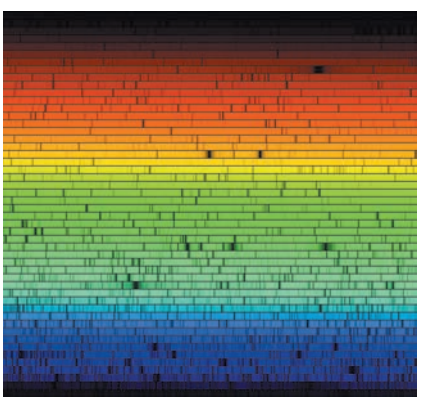
sodium compounds is to look for this yellow-orange light from a sample placed in a flame (Fig. 38.10b).

Photon Absorption



A sodium atom in the ground level can also *absorb* a photon with wavelength 589.0 or 589.6 nm. To demonstrate this process, we pass a beam of light from a sodium-vapour lamp through a bulb containing sodium vapour. The atoms in the vapour absorb the 589.0 nm or 589.6 nm photons from the beam, reaching the lowest excited levels; after a short time they return to the ground level, emitting photons in all directions and causing the sodium vapour to glow with the characteristic yellow light. The average time spent in an excited level is called the lifetime of the level; for the lowest excited levels of the sodium atom, the *lifetime* is about 1.6×10^{-8} s.

More generally, a photon *emitted* when an atom makes a transition from an excited level to a lower level can also be *absorbed* by a similar atom that is initially in the lower level (Fig. 38.11). If we pass white (continuous-spectrum) light through a gas and look at the *transmitted* light with a spectrometer, we find a series of dark lines corresponding to the wavelengths that have been absorbed, as shown in Fig. 38.12. This is called an **absorption spectrum**.



A related phenomenon is *fluorescence*. An atom absorbs a photon (often in the ultraviolet region) to reach an excited level and then drops back to the ground level in steps, emitting two or more photons with lower energy and longer wavelength. For example, the electric discharge in a fluorescent tube causes the mercury vapour in the tube to emit ultraviolet radiation. This radiation is absorbed by the atoms of the coating on the inside of the tube. The coating atoms then re-emit light in the longer-wavelength visible portion of the spectrum. Fluorescent lamps are more efficient than incandescent lamps in converting electrical energy to visible light because they do not waste as much energy producing (invisible) infrared photons.

The Bohr hypothesis established the relationship of wavelengths to energy levels, but it provided no general principles for *predicting* the energy levels of a particular atom. Bohr provided a partial analysis for the hydrogen atom; we will

38.11 An atom absorbing a photon. (Compare with Fig. 38.7.)

38.12 The absorption spectrum of the sun. (You should read the spectrum from left to right in each strip and then downward from one strip to the next, like words in a printed paragraph.) The relatively cool solar atmosphere selectively absorbs photons from the sun's glowing surface, producing dark absorption lines that indicate what kinds of atoms are present in the solar atmosphere.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

discuss this in Section 38.5. A more general understanding of atomic structure and energy levels rests on the concepts of *quantum mechanics*, which we will introduce in Chapters 39 and 40. Quantum mechanics provides all the principles needed to calculate energy levels from fundamental theory. Unfortunately, for many-electron atoms the calculations are so complex that they can be carried out only approximately.

Example 38.4 Emission and absorption spectra

A hypothetical atom has three energy levels: the ground level and 1.00 eV and 3.00 eV above the ground level. (a) Find the frequencies and wavelengths of the spectral lines that this atom can emit when excited. (b) What wavelengths can be absorbed by this atom if it is initially in its ground level?

SOLUTION

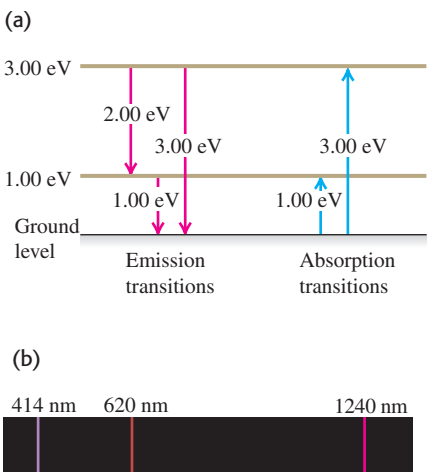
IDENTIFY: We use the idea that energy is conserved when a photon is emitted or absorbed.

SET UP: In each transition the photon energy is equal to the difference between the energies of the higher level and the lower level involved in the transition.

EXECUTE: (a) Figure 38.13a shows an energy-level diagram. The possible photon energies, corresponding to the transitions shown, are 1.00 eV, 2.00 eV, and 3.00 eV. For 1.00 eV we have, from Eq. (38.2),

$$f = \frac{E}{h} = \frac{1.00\ \text{eV}}{4.136 \times 10^{-15}\ \text{eV} \cdot \text{s}} = 2.42 \times 10^{14}\ \text{Hz}$$

For 2.00 eV and 3.00 eV, $f = 4.84 \times 10^{14}$ Hz and 7.25×10^{14} Hz, respectively. We can find the wavelengths using $\lambda = c/f$. For 1.00 eV,



$$\lambda = \frac{c}{f} = \frac{3.00 \times 10^{8}\ \text{m/s}}{2.42 \times 10^{14}\ \text{Hz}} = 1.24 \times 10^{-6}\ \text{m} = 1240\ \text{nm}$$

in the infrared region of the spectrum. For 2.00 eV and 3.00 eV the wavelengths are 620 nm (red) and 414 nm (violet), respectively (Fig. 38.13b).

(b) From the atom's ground level, only a 1.00-eV or 3.00-eV photon can be absorbed; a 2.00 eV photon cannot be because there is no energy level 2.00 eV above the ground level. As we have calculated, the wavelengths of 1.00 eV and 3.00 eV photons are 1240 nm and 414 nm, respectively. Passing light from a hot solid through a cool gas of these atoms would result in a continuous spectrum with dark absorption lines at 1240 nm and 414 nm.

EVALUATE: Note that if a gas of these atoms were at a high enough temperature, collisions would excite a number of atoms into the 1.00 eV energy level. Such excited atoms *can* absorb 2.00 eV photons, and an absorption line at 620 nm would appear in the spectrum. Thus the observed spectrum of a given substance depends on its energy levels and its temperature.

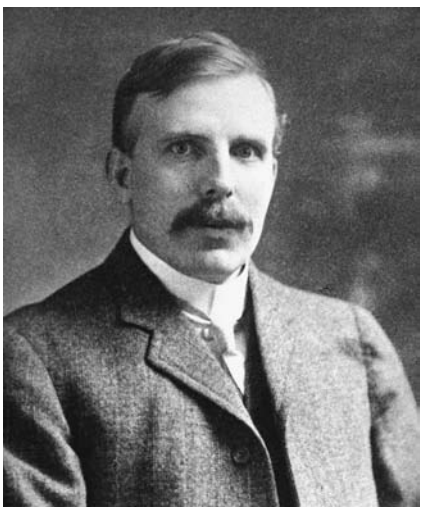
38.13 (a) Energy-level diagram, showing the possible transitions for emission from excited levels and for absorption from the ground level. (b) Emission spectrum of this hypothetical atom.

Test Your Understanding of Section 38.3 Would it be possible to excite the hypothetical atom in Example 38.4 from the ground level to the 1.00 eV level with a 1.50 eV photon?

38.4 The Nuclear Atom

Before we can make further progress in relating the energy levels of an atom to its internal structure, we need to have a better idea of what the inside of an atom is like. We know that atoms are much smaller than the wavelengths of visible light, so there is no hope of actually *seeing* an atom using that light. But we can still describe how the mass and electric charge are distributed throughout the volume of the atom.

Here's where things stood in 1910. J. J. Thomson had discovered the electron and measured its charge-to-mass ratio (e/m) in 1897; by 1909, Millikan had completed his first measurements of the electron charge $-e$. These and other experiments showed that almost all the mass of an atom had to be associated with



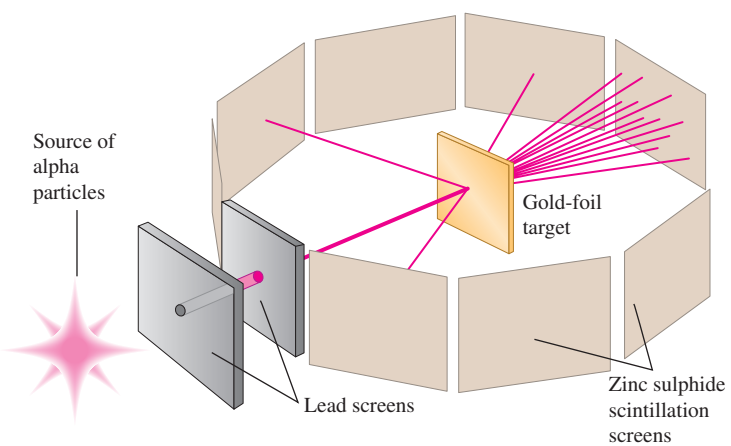
Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

the *positive* charge, not with the electrons. It was also known that the overall size of atoms is of the order of 10^{-10} m and that all atoms except hydrogen contain more than one electron. What was *not* known was how the mass and charge were distributed within the atom. Thomson had proposed a model in which the atom consisted of a sphere of positive charge, of the order of 10^{-10} m in diameter, with the electrons embedded in it like raisins in a more or less spherical muffin.

Rutherford's Exploration of the Atom

The first experiments designed to probe the interior structure of the atom were the **Rutherford scattering experiments**, carried out in 1910–1911 by Ernest Rutherford (Fig. 38.14) and two of his students, Hans Geiger and Ernest Marsden, at the University of Manchester in England. These experiments consisted of projecting charged particles at thin foils of the elements under study and observing the deflections of the particles. The particle accelerators that are now in common use in laboratories had not yet been invented, and Rutherford's projectiles were *alpha particles* emitted from naturally radioactive elements. Alpha particles are identical with the nuclei of most helium atoms: two protons and two neutrons bound together. They are ejected from unstable nuclei with speeds of the order of 10^7 m/s, and they can travel several centimetres through air or 0.1 mm or so through solid matter before they are brought to rest by collisions.

38.14 Born in New Zealand, Ernest Rutherford (1871–1937) spent his professional life in England and Canada. Before carrying out the experiments that established the existence of atomic nuclei, he shared (with Frederick Soddy) the 1908 Nobel Prize in chemistry for showing that radioactivity results from the disintegration of atoms.



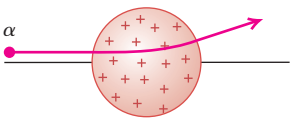
Activ Online Physics

19.1 Particle Scattering

Rutherford's experimental setup is shown schematically in Fig. 38.15. A radioactive substance at the left emits alpha particles. Thick lead screens stop all particles except those in a narrow beam defined by small holes. The beam then passes through a target consisting of a thin gold, silver or copper foil and strikes screens coated with zinc sulphide, similar in principle to the screen of a TV picture tube. A momentary flash, or *scintillation*, can be seen on the screen whenever it is struck by an alpha particle. Rutherford and his students counted the numbers of particles deflected through various angles.

Think of the atoms of the target material as being packed together like marbles in a box. An alpha particle can pass through a thin sheet of metal foil, so the alpha particle must be able actually to pass through the interiors of atoms. The *total* electric charge of the atom is zero, so outside the atom there is little force on the alpha particle. Within the atom there are electrical forces caused by the electrons and by the positive charge. But the mass of an alpha particle is about 7300 times that of an electron. Momentum considerations show that the alpha particle can be scattered only a very small amount by its interaction with the much lighter electrons. It's like throwing a pebble through a swarm of mosquitoes; the mosquitoes don't deflect the pebble very much. Only interactions with the *positive* charge, which is tied to almost all of the mass of the atom, can deflect the alpha particle appreciably.

In the Thomson model, the positive charge and the negative electrons are distributed through the whole atom. Hence the electric field inside the atom should



38.15 The scattering of alpha particles by a thin metal foil. The source of alpha particles is a radioactive element such as radium. The two lead screens with small holes form a narrow beam of alpha particles, which are scattered by the gold foil. The directions of the scattered particles are determined from the flashes on the scintillation screens.

38.16 (a) Thomson's model of the atom was ruled out by Rutherford's scattering experiments. (b) To account for his experimental results, Rutherford developed a nuclear model of the atom.

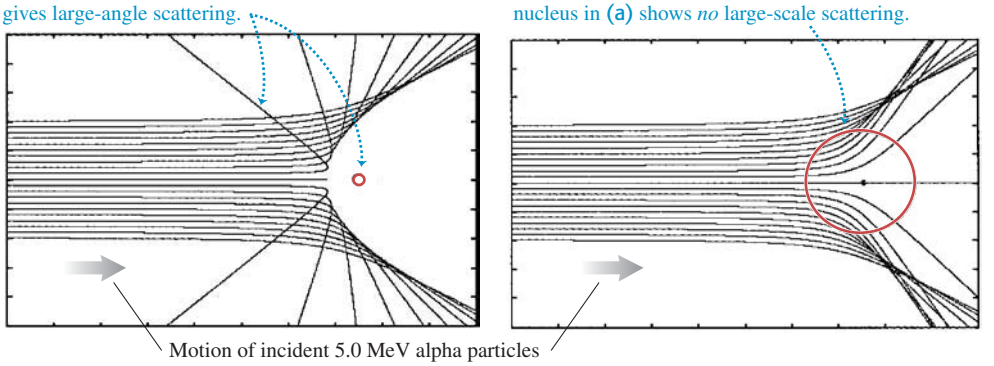
(a) Thomson's model of the atom: An alpha particle is scattered through only a small angle.

(b) Rutherford's model of the atom: An alpha particle can be scattered through a large angle by the compact, positively charged nucleus (not drawn to scale).

be quite small, and the electric force on an alpha particle that enters the atom should be quite weak. The maximum deflection to be expected is then only a few degrees (Fig. 38.16a).

The results were very different from this and were totally unexpected. Some alpha particles were scattered by nearly 180°—that is, almost straight backwards (Fig. 38.16b). Rutherford later wrote:

> It was quite the most incredible event that ever happened to me in my life. It was almost as incredible as if you had fired a 15 inch shell at a piece of tissue paper and it came back and hit you.



Back to the drawing board! Suppose the positive charge, instead of being distributed through a sphere with atomic dimensions (of the order of 10^{-10} m), is all concentrated in a much *smaller* space. Then it would act like a point charge down to much smaller distances. The maximum electric field repelling the alpha particle would be much larger, and the amazing large-angle scattering would be possible. Rutherford called this concentration of positive charge the **nucleus**. He again computed the numbers of particles expected to be scattered through various angles. Within the accuracy of his experiments, the computed and measured results agreed, down to distances of the order of 10^{-14} m. His experiments therefore established that the atom does have a nucleus, a very small, very dense structure, no larger than 10^{-14} m in diameter. The nucleus occupies only about 10^{-12} of the total volume of the atom or less, but it contains *all* the positive charge and at least 99.95% of the total mass of the atom.

Figure 38.17 shows a computer simulation of the scattering of 5.0 MeV alpha particles from a gold nucleus of radius 7.0×10^{-15} m (the actual value) and from a nucleus with a hypothetical radius ten times this great. In the second case there is *no* large-angle scattering. The presence of large-angle scattering in Rutherford's experiments thus attested to the small size of the nucleus.

38.17 Computer simulation of scattering of 5.0 MeV alpha particles from a gold nucleus. Each curve shows a possible alpha-particle trajectory. (a) The scattering curves match Rutherford's experimental data if a radius of 7.0×10^{-15} m is assumed for a gold nucleus. (b) A model with a much larger radius does not match the data.

(a) A gold nucleus with radius 7.0×10^{-15} m gives large-angle scattering.

(b) A nucleus with 10 times the radius of the nucleus in (a) shows *no* large-scale scattering.

Example 38.5 A Rutherford experiment

An alpha particle is aimed directly at a gold nucleus. An alpha particle has two protons and a charge of $2e = 2(1.60 \times 10^{-19}\,\text{C})$, while a gold nucleus has 79 protons and a charge of $79e = 79(1.60 \times 10^{-19}\,\text{C})$. What minimum initial kinetic energy must the alpha particle have to approach within 5.0×10^{-14} m of the centre of the gold nucleus? Assume that the gold nucleus, which has about 50 times the rest mass of an alpha particle, remains at rest.

SOLUTION

IDENTIFY: As the alpha particle approaches the gold nucleus, it slows down due to the repulsive electric force that acts on it. This is a conservative force, so the total mechanical energy (kinetic energy of the alpha particle plus electric potential energy of the system) is conserved.

Continued

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

SET UP: Let point 1 be very far from the gold nucleus (the initial position of the alpha particle), and let point 2 be 5.0×10^{-14} m from the centre of the gold nucleus. Our target variable is the kinetic energy of the alpha particle at point 1 that allows it to reach point 2. To find this we use the law of conservation of energy and Eq. (23.9) for electric potential energy, $U = qq_0/4\pi\epsilon_0 r$.

EXECUTE: The kinetic energy at point 1 is K_1 (the target variable), and the kinetic energy at point 2 (where the alpha particle comes momentarily to rest) is $K_2 = 0$. At point 1 the alpha particle and gold nucleus are so far apart that we can regard their separation r as infinite, so from Eq. (23.9) the electric potential energy at point 1 is $U_1 = 0$. At point 2, the potential is

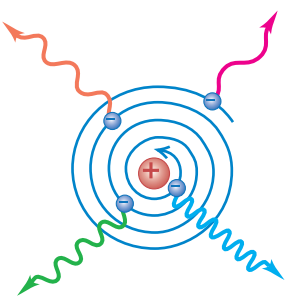
$$\begin{aligned} U_2 &= \frac{1}{4\pi\epsilon_0}\frac{qq_0}{r} \\ &= (9.0 \times 10^9\ \text{N}\cdot\text{m}^2/\text{C}^2)\frac{(2)(79)(1.60 \times 10^{-19}\ \text{C})^2}{5.0 \times 10^{-14}\ \text{m}} \\ &= 7.3 \times 10^{-13}\ \text{J} = 4.6 \times 10^6\ \text{eV} = 4.6\ \text{MeV} \end{aligned}$$

By energy conservation $K_1 + U_1 = K_2 + U_2$, so $K_1 = K_2 + U_2 - U_1 = 0 + 4.6\ \text{MeV} - 0 = 4.6\ \text{MeV}$. Thus, to approach to 5.0×10^{-14} m, the alpha particle must have 4.6 MeV when it is far away from the nucleus; to approach even closer, even greater kinetic energy is needed. In fact, alpha particles emitted from naturally occurring radioactive elements typically have energies in the range 4 to 6 MeV. For example, the common isotope of radium, ^{226}Ra, emits an alpha particle with energy 4.78 MeV.

EVALUATE: Was it valid to assume that the gold nucleus remains at rest? To find out, note that when the alpha particle stops momentarily, all of its initial momentum has been transferred to the gold nucleus. An alpha particle has a mass $m_\alpha = 6.64 \times 10^{-27}$ kg; if its initial kinetic energy $K_1 = \frac{1}{2}mv_1^2$ is 7.3×10^{-13} J, you can show that its initial speed is $v_1 = 1.5 \times 10^7$ m/s and its initial momentum is $p_1 = m_\alpha v_1 = 9.8 \times 10^{-20}$ kg · m/s. A gold nucleus (mass $m_{\text{Au}} = 3.27 \times 10^{-25}$ kg) with this much momentum has a much slower speed $v_{\text{Au}} = 3.0 \times 10^5$ m/s and a kinetic energy $K_{\text{Au}} = \frac{1}{2}m{v_{\text{Au}}}^2 = 1.5 \times 10^{-14}$ J = 0.092 MeV. This *recoil kinetic energy* of the gold nucleus is a small fraction of the total energy in this situation, so we are justified in neglecting it.

Test Your Understanding of Section 38.4 Suppose you repeated Rutherford's scattering experiment using a thin sheet of solid hydrogen in place of the gold foil. (Hydrogen is a solid at temperatures below 14.0 K.) Would you expect to observe large-angle scattering of alpha particles?

38.5 The Bohr Model



At the same time (1913) that Bohr established the relationship between spectral wavelengths and energy levels, he also proposed a model of the hydrogen atom. He developed his ideas while working in Rutherford's laboratory. Using this model, now known as the **Bohr model**, he was able to *calculate* the energy levels of hydrogen and obtain agreement with values determined from spectra.

Activ ONLINE Physics
18.1 The Bohr Model

Rutherford's discovery of the atomic nucleus raised a serious question. What kept the negatively charged electrons at relatively large distances $(\sim 10^{-10}\ \text{m})$ away from the very small $(\sim 10^{-14}\ \text{m})$, positively charged nucleus despite their electrostatic attraction? Rutherford suggested that perhaps the electrons *revolve* in orbits about the nucleus, just as the planets revolve around the sun.

But according to classical electromagnetic theory, any accelerating electric charge (either oscillating or revolving) radiates electromagnetic waves. An example is radiation from an oscillating point charge, shown in Fig. 32.2 (Section 32.1). The energy of an orbiting electron should therefore decrease continuously, its orbit should become smaller and smaller, and it should spiral rapidly into the nucleus (Fig. 38.18). Even worse, according to classical theory the *frequency* of the electromagnetic waves emitted should equal the frequency of revolution. As the electrons radiated energy, their angular speeds would change continuously, and they would emit a *continuous* spectrum (a mixture of all frequencies), not the *line* spectrum actually observed.

38.18 Classical physics predicts that an orbiting electron should continuously radiate electromagnetic waves and spiral into the nucleus. Because the electron's angular speed varies with its radius, classical physics predicts that the frequency of the emitted radiation should change continuously.

Stable Electron Orbits

To solve this problem, Bohr made a revolutionary proposal. He postulated that an electron in an atom can move around the nucleus in certain circular *stable orbits*, *without* emitting radiation, contrary to the predictions of classical electromagnetic theory. According to Bohr, there is a definite energy associated with each

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

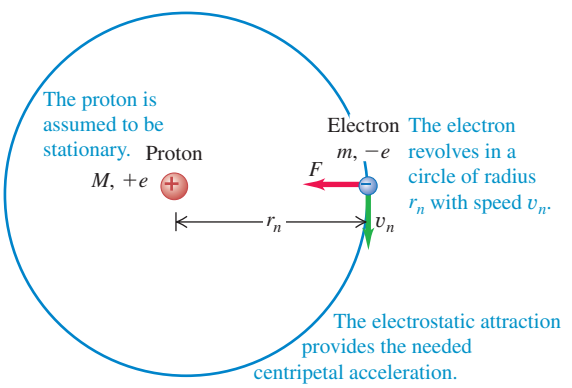
stable orbit, and an atom radiates energy only when it makes a transition from one of these orbits to another. The energy is radiated in the form of a photon with energy and frequency given by Eq. (38.6), $hf = E_i - E_f$.

As a result of a rather complicated argument that related the angular frequency of the light emitted to the angular speeds of the electron in highly excited energy levels, Bohr found that the magnitude of the electron's angular momentum is *quantised*, and that this magnitude for the electron must be an integral multiple of $h/2\pi$. (Note that because $1\ \text{J} = 1\ \text{kg} \cdot \text{m}^2/\text{s}^2$, the SI units of Planck's constant h, $\text{J} \cdot \text{s}$, are the same as the SI units of angular momentum, usually written as $\text{kg} \cdot \text{m}^2/\text{s}$.) From Section 10.5, Eq. (10.28), the magnitude of the angular momentum is $L = mvr$ for a particle with mass m moving with speed v in a circle of radius r (thus with $\phi = 90°$). So Bohr's argument led to

$$L = mvr = n\frac{h}{2\pi}$$

where $n = 1, 2, 3, \ldots$. Each value of n corresponds to a permitted value of the orbit radius, which we denote from now on by r_n, and a corresponding speed v_n. The value of n for each orbit is called the **principal quantum number** for the orbit. With this notation the above equation becomes

$$L_n = mv_n r_n = n\frac{h}{2\pi} \qquad \text{(quantisation of angular momentum)} \qquad (38.10)$$



Now let's consider a model of the hydrogen atom (Fig. 38.19) that is Newtonian in spirit but incorporates this quantisation assumption. This atom consists of a single electron with mass m and charge $-e$, revolving around a single proton with charge $+e$. The proton is nearly 2000 times as massive as the electron, so we have been assuming that the proton does not move. We learned in Section 5.4 that when a particle with mass m moves with speed v_n in a circular orbit with radius r_n, its radially inward acceleration is v_n^2/r_n. According to Newton's second law, a radially inward net force with magnitude $F = mv_n^2/r_n$ is needed to cause this acceleration. We discussed in Section 12.4 how the gravitational attraction provided that force for satellite orbits. In hydrogen the force F is provided by the electrical attraction between the positive proton and the negative electron. From Coulomb's law (Eq. 21.2),

$$F = \frac{1}{4\pi\epsilon_0}\frac{e^2}{r_n^2}$$

so Newton's second law states that

$$\frac{1}{4\pi\epsilon_0}\frac{e^2}{r_n^2} = \frac{mv_n^2}{r_n} \qquad (38.11)$$

38.19 Bohr model of the hydrogen atom.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

When we solve Eqs (38.10) and (38.11) simultaneously for r_n and v_n, we get

$$r_n = \epsilon_0 \frac{n^2 h^2}{\pi m e^2} \qquad \text{(orbit radii in the Bohr model)} \tag{38.12}$$

$$v_n = \frac{1}{\epsilon_0}\frac{e^2}{2nh} \qquad \text{(orbital speeds in the Bohr model)} \tag{38.13}$$

Equation (38.12) shows that the orbit radius r_n is proportional to n^2; the smallest orbit radius corresponds to $n = 1$. We'll denote this minimum radius, called the *Bohr radius*, as a_0:

$$a_0 = \epsilon_0 \frac{h^2}{\pi m e^2} \tag{38.14}$$

Then Eq. (38.12) can be written as

$$r_n = n^2 a_0 \tag{38.15}$$

The permitted orbits have radii a_0, $4a_0$, $9a_0$, and so on.

The numerical values of the quantities on the right side of Eq. (38.14) are given in Appendix F. Using these values, we find that the radius a_0 of the smallest Bohr orbit is

$$\begin{aligned} a_0 &= \frac{(8.854 \times 10^{-12}\,\mathrm{C^2/N \cdot m^2})(6.626 \times 10^{-34}\,\mathrm{J \cdot s})^2}{(3.142)(9.109 \times 10^{-31}\,\mathrm{kg})(1.602 \times 10^{-19}\,\mathrm{C})^2} \\ &= 5.29 \times 10^{-11}\,\mathrm{m} \end{aligned}$$

This result, giving an atomic diameter of about $10^{-10}\,\mathrm{m} = 0.1\,\mathrm{nm}$, is consistent with atomic dimensions estimated by other methods.

We can use Eq. (38.13) to find the orbital *speed* of the electron. We leave this calculation to you (see Exercise 38.27); the result is that for the $n = 1$ state, $v_1 = 2.19 \times 10^6\,\mathrm{m/s}$. This, the greatest possible speed of the electron in the hydrogen atom, is less than 1% of the speed of light, showing that relativistic considerations aren't significant.

Hydrogen Energy Levels in the Bohr Model

We can use Eqs (38.13) and (38.12) to find the kinetic and potential energies K_n and U_n when the electron is in the orbit with quantum number n:

$$K_n = \frac{1}{2}mv_n^2 = \frac{1}{\epsilon_0^2}\frac{me^4}{8n^2h^2} \tag{38.16}$$

$$U_n = -\frac{1}{4\pi\epsilon_0}\frac{e^2}{r_n} = -\frac{1}{\epsilon_0^2}\frac{me^4}{4n^2h^2} \tag{38.17}$$

The total energy E_n is the sum of the kinetic and potential energies:

$$E_n = K_n + U_n = -\frac{1}{\epsilon_0^2}\frac{me^4}{8n^2h^2} \tag{38.18}$$

The potential energy has a negative sign because we have taken the potential energy to be zero when the electron is infinitely far from the nucleus. We are interested only in energy *differences*, so the reference position doesn't matter.

The orbits and energy levels are depicted in Fig. 38.9 (Section 38.3). The possible energy levels of the atom are labelled by values of the quantum number n. For each value of n there are corresponding values of orbit radius r_n, speed v_n, angular momentum $L_n = nh/2\pi$, and total energy E_n. The energy of the atom is least when $n = 1$ and E_n has its most negative value. This is the *ground level* of the atom; it is the level with the smallest orbit, with radius a_0. For $n = 2, 3, \ldots,$

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

the absolute value of E_n is smaller and the energy is progressively larger (less negative). The orbit radius increases as n^2, as shown by Eqs (38.12) and (38.15), while the speed decreases as $1/n$, as shown by Eq. (38.13).

Comparing the expression for E_n in Eq. (38.18) with Eq. (38.9) (deduced from the measured spectrum of hydrogen), we see that they agree only if the coefficients are equal:

$$hcR = \frac{1}{\epsilon_0^2}\frac{me^4}{8h^2} \qquad \text{or} \qquad R = \frac{me^4}{8\epsilon_0^2 h^3 c} \tag{38.19}$$

This equation therefore shows us how to *calculate* the value of the Rydberg constant from the fundamental physical constants m, c, e, h and ϵ_0, all of which can be determined quite independently of the Bohr theory. When we substitute the numerical values of these quantities, we obtain the value $R = 1.097 \times 10^7\ \text{m}^{-1}$. To four significant figures, this is the value determined from wavelength measurements. This agreement provides very strong and direct confirmation of Bohr's theory. You should substitute numerical values into Eq. (38.19) and compute the value of R to confirm these statements.

The *ionisation energy* of the hydrogen atom is the energy required to remove the electron completely. Ionisation corresponds to a transition from the ground level $(n = 1)$ to an infinitely large orbit radius $(n = \infty)$ and thus equals $-E_1$. Substituting the constants from Appendix F into Eq. (38.18) gives an ionisation energy of 13.606 eV. The ionisation energy can also be measured directly; the result is 13.60 eV. These two values agree within 0.1%.

Example 38.6 Exploring the Bohr model

Find the kinetic, potential and total energies of the hydrogen atom in the first excited level, and find the wavelength of the photon emitted in the transition from the first excited level to the ground level.

SOLUTION

IDENTIFY: This problem uses the ideas of the Bohr model discussed in this section.

SET UP: We use Eqs (38.16), (38.17) and (38.18) to find the energies of the atom. To find the photon wavelength λ we use Eq. (38.6), which relates the energy and wavelength of an emitted photon to the energies of the initial and final levels of the atom.

EXECUTE: We could evaluate Eqs (38.16), (38.17) and (38.18) for the nth level by substituting the values of m, e, ϵ_0 and h. But we can simplify the calculation by comparing with Eq. (38.19), which shows that the constant that appears in Eqs (38.14), (38.15) and (38.16) is equal to hcR and is experimentally equal to 13.60 eV:

$$\frac{me^4}{8\epsilon_0^2 h^2} = hcR = 13.60\ \text{eV}$$

Using this expression, we can rewrite Eqs (38.16), (38.17) and (38.18) as

$$K_n = \frac{13.60\ \text{eV}}{n^2} \qquad U_n = \frac{-27.20\ \text{eV}}{n^2} \qquad E_n = \frac{-13.60\ \text{eV}}{n^2}$$

The first excited level is the $n = 2$ level, which has $K_2 = 3.40$ eV, $U_2 = -6.80$ eV, and $E_2 = -3.40$ eV.

The ground level is the $n = 1$ level, for which the energy is $E_1 = -13.60$ eV. The energy of the emitted photon is $E_2 - E_1 = -3.40\ \text{eV} - (-13.60\ \text{eV}) = 10.20$ eV. The photon energy equals hc/λ, so we find

$$\lambda = \frac{hc}{E_2 - E_1} = \frac{(4.136 \times 10^{-15}\ \text{eV}\cdot\text{s})(3.00 \times 10^8\ \text{m/s})}{10.20\ \text{eV}}$$
$$= 1.22 \times 10^{-7}\ \text{m} = 122\ \text{nm}$$

This is the wavelength of the 'Lyman alpha' line, the longest-wavelength line in the Lyman series of ultraviolet lines in the hydrogen spectrum (see Fig. 38.9).

EVALUATE: Our results show that the total mechanical energy is negative and equal to one-half the potential energy. Remarkably, we found the same energy relationship for satellite orbits in Section 12.4. The reason for the similarity between the two situations is that both the electrostatic force and the gravitational force are inversely proportional to $1/r^2$.

Nuclear Motion and the Reduced Mass of an Atom

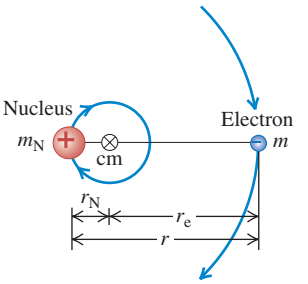
The values of the Rydberg constant R and the ionisation energy of hydrogen predicted by Bohr's analysis are within 0.1% of the measured values. The agreement would be even better if we had not assumed that the nucleus (a proton) remains at

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

rest. Rather, the proton and electron both revolve in circular orbits about their common *centre of mass* (see Section 8.5), as shown in Fig. 38.20. It turns out that we can take this motion into account very simply by using in Bohr's equations not the electron rest mass m but a quantity called the **reduced mass** m_r of the system. For a system composed of two bodies of masses m_1 and m_2, the reduced mass is defined as

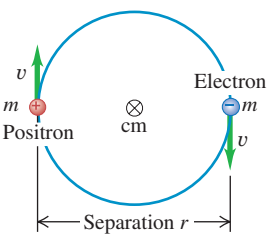
$$m_r = \frac{m_1 m_2}{m_1 + m_2} \tag{38.20}$$

For ordinary hydrogen we let m_1 equal m and m_2 equal the proton mass, $m_p = 1836.2m$. Thus the proton-electron system of ordinary hydrogen has a reduced mass of



$$m_r = \frac{m(1836.2m)}{m + 1836.2m} = 0.99946m$$

When this value is used instead of the electron mass m in the Bohr equations, the predicted values agree very well with the measured values.



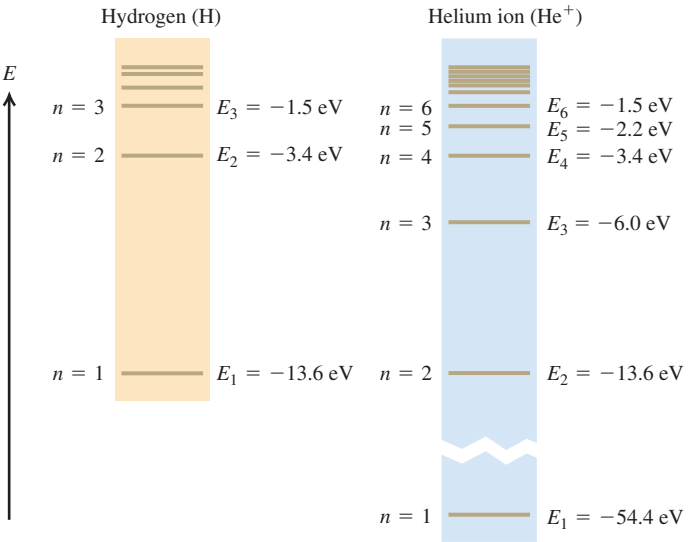
In an atom of deuterium, also called *heavy hydrogen*, the nucleus is not a single proton but a proton and a neutron bound together to form a composite body called the *deuteron*. The reduced mass of the deuterium atom turns out to be $0.99973m$. Equations (38.6) and (38.18) (with m replaced by m_r) show that all energies and frequencies are proportional to m_r, while all wavelengths are inversely proportional to m_r. Thus the spectral wavelengths of deuterium should be those of hydrogen divided by $(0.99973m)/(0.99946m) = 1.00027$. This is a small effect but well within the precision of modern spectrometers. This small wavelength shift led the American scientist Harold Urey to the discovery of deuterium in 1932, an achievement that earned him the 1934 Nobel Prize in chemistry.

The concept of reduced mass has other applications. A *positron* has the same rest mass as an electron but a charge $+e$. A positronium 'atom' (Fig. 38.21) consists of an electron and a positron, each with mass m, in orbit around their common centre of mass. This structure lasts only about 10^{-6} s before the two particles annihilate one another and disappear, but this is enough time to study the positronium spectrum. The reduced mass is $m/2$, so the energy levels and photon frequencies have exactly half the values for the simple Bohr model with infinite proton mass. The existence of positronium atoms was confirmed by observation of the corresponding spectrum lines.

38.20 The nucleus and the electron revolve around their common centre of mass. The distance r_N has been exaggerated for clarity; for ordinary hydrogen it actually equals $r_e/1836.2$.

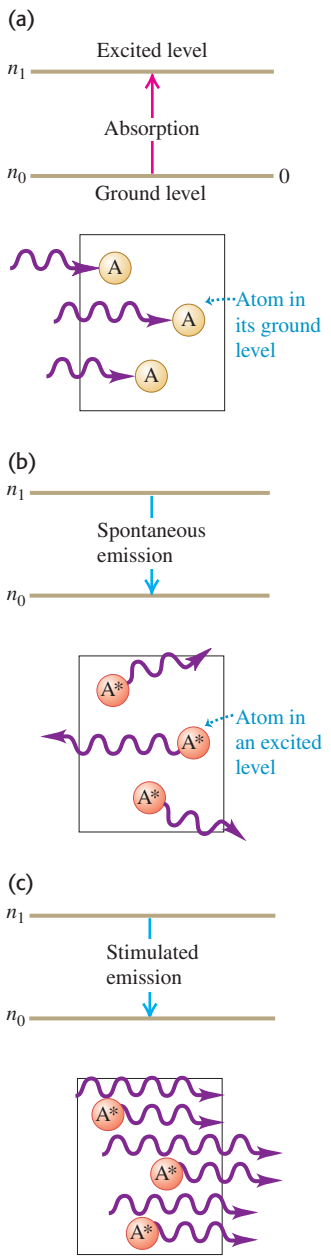
38.21 Applying the Bohr model to positronium. The electron and the positron revolve about their common centre of mass, which is located midway between them because they have equal mass. Their separation is twice either orbit radius.

Hydrogenlike Atoms



We can extend the Bohr model to other one-electron atoms, such as singly ionised helium (He^+), doubly ionised lithium (Li^{2+}), and so on. Such atoms are called *hydrogenlike* atoms. In such atoms, the nuclear charge is not e but Ze, where Z is the *atomic number*, equal to the number of protons in the nucleus. The effect in the previous analysis is to replace e^2 everywhere by Ze^2. In particular, the orbit radii r_n given by Eq. (38.12) become smaller by a factor of Z, and the energy levels E_n given by Eq. (38.18) are multiplied by Z^2. We invite you to verify these statements. The reduced-mass correction in these cases is even less than 0.1% because the nuclei are more massive than the single proton of ordinary hydrogen. Figure 38.22 compares the energy levels for H and for He^+, which has $Z = 2$.

Atoms of the *alkali* metals have one electron outside a core consisting of the nucleus and the inner electrons, with net core charge $+e$. These atoms are approximately hydrogenlike, especially in excited levels. Even trapped electrons and electron vacancies in semiconducting solids act somewhat like hydrogen atoms.



Although the Bohr model predicted the energy levels of the hydrogen atom correctly, it raised as many questions as it answered. It combined elements of classi-

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

38.22 Energy levels of H and He^+. The energy expression, Eq. (38.18), is multiplied by $Z^2 = 4$ for He^+, so the energy of an He^+ ion with a given n is almost exactly four times that of an H atom with the same n. (There are small differences of the order of 0.05% because the reduced masses are slightly different.)

38.23 Three processes in which an atom interacts with electromagnetic waves. In part (a), A denotes an atom in its ground level; in parts (b) and (c), A* denotes an atom in an excited level.

cal physics with new postulates that were inconsistent with classical ideas. The model provided no insight into what happens during a transition from one orbit to another; the angular speeds of the electron motion were not in general the angular frequencies of the emitted radiation, a result that is contrary to classical electrodynamics. Attempts to extend the model to atoms with two or more electrons were not successful. An electron moving in one of Bohr's circular orbits forms a current loop and should produce a magnetic moment. However, a hydrogen atom in its ground level has no magnetic moment due to orbital motion. In Chapters 39 and 40 we will find that an even more radical departure from classical concepts was needed before the understanding of atomic structure could progress further.

Test Your Understanding of Section 38.5 Consider the wavelengths in the spectrum of light emitted by excited He^+ ions. Are any of these wavelengths nearly equal to any of the wavelengths emitted by excited H atoms?

38.6 The Laser

The **laser** is a light source that produces a beam of highly coherent and very nearly monochromatic light as a result of cooperative emission from many atoms. The name 'laser' is an acronym for 'light amplification by stimulated emission of radiation.' We can understand the principles of laser operation on the basis of photons and atomic energy levels. During the discussion we'll also introduce two new concepts: *stimulated emission* and *population inversion*.

Spontaneous and Stimulated Emission

If an atom has an excited level an energy E above the ground level, the atom in its ground level can absorb a photon with frequency f given by $E = hf$. This process is shown schematically in Fig. 38.23a, which shows a gas in a transparent container. Three atoms A each absorb a photon, reaching an excited level and being denoted as A*. Some time later, the excited atoms return to the ground level by each emitting a photon with the same frequency as the one originally absorbed. This process is called *spontaneous emission*; the direction and phase of the emitted photons are random (Fig. 38.23b).

In **stimulated emission** (Fig. 38.23c), each incident photon encounters a previously excited atom. A kind of resonance effect induces each atom to emit a second photon with the same frequency, direction, phase and polarisation as the

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

incident photon, which is not changed by the process. For each atom there is one photon before a stimulated emission and two photons after—thus the name *light amplification*. Because the two photons have the same phase, they emerge together as *coherent* radiation. The laser makes use of stimulated emission to produce a beam consisting of a large number of such coherent photons.

To discuss stimulated emission from atoms in excited levels, we need to know something about how many atoms are in each of the various energy levels. First, we need to make the distinction between the terms *energy level* and *state*. A system may have more than one way to attain a given energy level; each different way is a different **state**. For instance, there are two ways of putting an ideal unstretched spring in a given energy level. Remembering that $U = \frac{1}{2}kx^2$, we could compress the spring by $x = -b$ or we could stretch it by $x = +b$ to get the same $U = \frac{1}{2}kb^2$. The Bohr model had only one state in each energy level, but we will find in Section 41.4 that the hydrogen atom actually has two states in its –13.60 eV ground level, eight states in its –3.40 eV first exited level, and so on.

ALEKSANDR PROKHOROV

Born in the small town of Peeramon in the Atherton Tablelands, Queensland, Aleksandr Prokhorov lived in Australia until the age of seven when his father decided to return to Russia following the October Revolution of 1917. He graduated with a Ph.D. from the P. N. Lebedev Physical Institute, of which he subsequently became the director. In the 1950s he began research in the field of radio spectroscopy which later led to his work in the new field of quantum electronics. He won the 1964 Nobel Prize in Physics with his colleague Nicolay Basov and the American physicist Charles Townes for fundamental work in the field of quantum electronics which led to the construction of masers (microwave amplification by simulated emission of radiation) and lasers (light amplification by simulated emission of radiation).

FRONTIERS OF RESEARCH

The Maxwell-Boltzmann distribution function (see Section 18.5) determines the number of atoms in a given state in a gas. The function tells us that when the gas is in thermal equilibrium at absolute temperature T, the number n_i of atoms in a state with energy E_i equals $Ae^{-E_i/kT}$, where k is Boltzmann's constant and A is another constant determined by the total number of atoms in the gas. (In Section 18.5, E was the kinetic energy $\frac{1}{2}mv^2$ of a gas molecule; here we're talking about the internal energy of an atom.) Because of the negative exponent, fewer atoms are in higher-energy states, as we should expect. If E_g is a ground-state energy and E_{ex} is the energy of an excited state, then the ratio of numbers of atoms in the two states is

$$\frac{n_{ex}}{n_g} = \frac{Ae^{-E_{ex}/kT}}{Ae^{-E_g/kT}} = e^{-(E_{ex}-E_g)/kT} \tag{38.21}$$

For example, suppose $E_{ex} - E_g = 2.0\text{ eV} = 3.2 \times 10^{-19}\text{ J}$, the energy of a 620 nm visible-light photon. At $T = 3000\text{ K}$ (the temperature of the filament in an incandescent light bulb),

$$\frac{E_{ex} - E_g}{kT} = \frac{3.2 \times 10^{-19}\text{ J}}{(1.38 \times 10^{-23}\text{ J/K})(3000\text{ K})} = 7.73$$

and

$$e^{-(E_{ex}-E_g)/kT} = e^{-7.73} = 0.00044$$

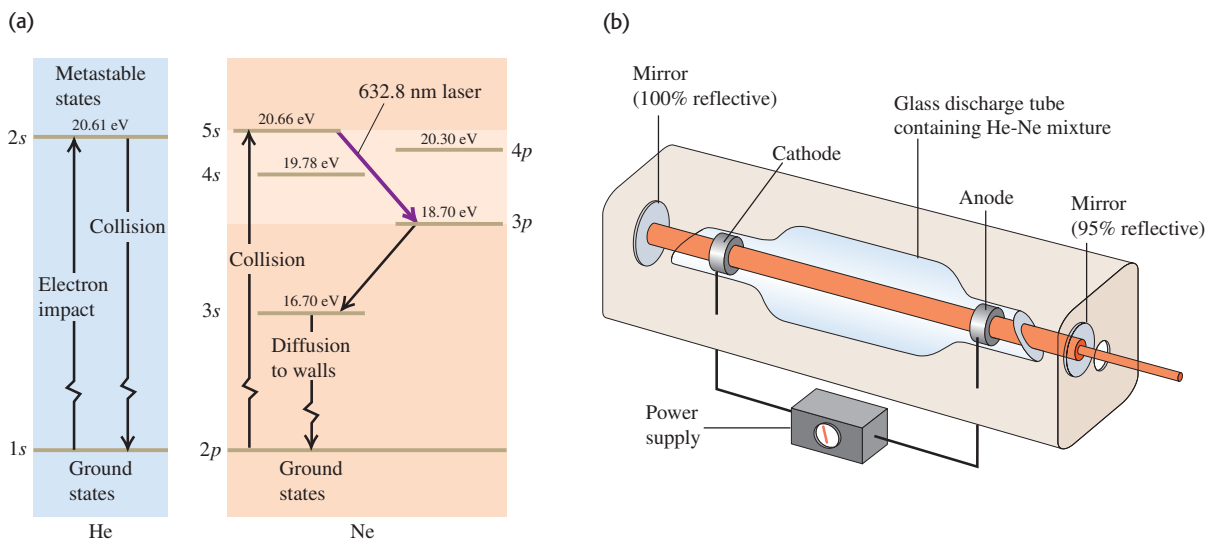
That is, the fraction of atoms in a state 2.0 eV above a ground state is extremely small, even at this high temperature. The point is that at any reasonable temperature there aren't enough atoms in excited states for any appreciable amount of stimulated emission from these states to occur. Rather, absorption is much more probable.

Enhancing Stimulated Emission: Population Inversions

We could try to enhance the number of atoms in excited states by sending through the container a beam of radiation with frequency $f = E/h$ corresponding to the energy difference $E = E_{ex} - E_g$. Some of the atoms absorb photons of energy E and are raised to the excited state, and the population ratio n_{ex}/n_g momentarily increases. But because n_g is originally so much larger than n_{ex}, an enormously intense beam of light would be required to momentarily increase n_{ex}

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

to a value comparable to n_g. The rate at which energy is *absorbed* from the beam by the n_g ground-state atoms far exceeds the rate at which energy is added to the beam by stimulated emission from the relatively rare (n_{ex}) excited atoms.



We need to create a nonequilibrium situation in which the number of atoms in a higher-energy state is greater than the number in a lower-energy state. Such a situation is called a **population inversion**. Then the rate of energy radiation by stimulated emission can *exceed* the rate of absorption, and the system acts as a net *source* of radiation with photon energy E. Furthermore, because the photons are the result of stimulated emission, they all have the same frequency, phase, polarisation and direction of propagation. The resulting radiation is therefore very much more coherent than light from ordinary sources, in which the emissions of individual atoms are not coordinated. This coherent emission is exactly what happens in a laser.

The necessary population inversion can be achieved in a variety of ways. A familiar example is the helium-neon laser, a common and inexpensive laser that is available in many undergraduate laboratories. A mixture of helium and neon, typically at a pressure of the order of 10^2 Pa $(10^{-3}$ atm$)$, is sealed in a glass enclosure provided with two electrodes. When a sufficiently high voltage is applied, an electric discharge occurs. Collisions between ionised atoms and electrons carrying the discharge current excite atoms to various energy states.

Figure 38.24a shows an energy-level diagram for the system. The labels for the various energy levels, such as 1*s*, 3*p* and 5*s*, refer to states of the electrons in the levels. (We'll discuss this notation in Chapter 41; we don't need detailed knowledge of the nature of the states to understand laser action.) Because of restrictions imposed by conservation of angular momentum, a helium atom with an electron excited to a 2*s* state cannot return to a ground $(1s)$ state by emitting a 20.61 eV photon, as you might expect it to do. Such a state, in which single-photon emission is impossible, has an unusually long lifetime and is called a **metastable state**. Helium atoms 'pile up' in the metastable 2*s* states, creating a population inversion relative to the ground states.

However, excited helium atoms *can* lose energy by energy-exchange collisions with neon atoms that are initially in a ground state. A helium atom, excited to a 2*s* state 20.61 eV above its ground states and possessing a little additional kinetic energy, can collide with a neon atom in a ground state, exciting the *neon* atom to a 5*s* excited state at 20.66 eV and dropping the *helium* atom back to a ground state. Thus we have the necessary mechanism for a population inversion in neon, with more neon atoms per 5*s* state than per 3*p* state.

38.24 (a) Energy-level diagram for a helium-neon laser. (b) Operation of a helium-neon laser. The light emitted by electrons returning to lower-energy states is reflected between mirrors, so it continues to stimulate emission of more coherent light. One mirror is partially transmitting and allows the high-intensity light beam to escape.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

Stimulated emissions during transitions from a $5s$ to a $3p$ state then result in the emission of highly coherent light at 632.8 nm, as shown in Fig. 38.24a. In practice the beam is sent back and forth through the gas many times by a pair of parallel mirrors (Fig. 38.24b), so as to stimulate emission from as many excited atoms as possible. One of the mirrors is partially transparent, so a portion of the beam emerges as an external beam. The net result of all these processes is a beam of light that can be quite intense, has parallel rays, is highly monochromatic and is spatially *coherent* at all points within a given cross-section.

Other types of lasers use different processes to achieve the necessary population inversion. In a semiconductor laser the inversion is obtained by driving electrons and holes to a *p-n* junction (to be discussed in Section 42.7) with a steady electric field. In one type of *chemical* laser a chemical reaction forms molecules in metastable excited states. In a carbon dioxide gas dynamic laser the population inversion results from rapid expansion of the gas. A *maser* (acronym for 'microwave amplification by stimulated emission of radiation') operates on the basis of population inversions in molecules, using closely spaced energy levels. The corresponding emitted radiation is in the microwave range. Maser action even occurs naturally in interstellar molecular clouds.

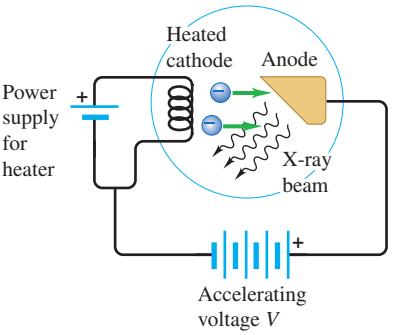
Lasers have found a wide variety of practical applications. A high-intensity laser beam can drill a very small hole in a diamond for use as a die in drawing very small-diameter wire. Surveyors often use lasers, especially in situations requiring great precision such as drilling a long tunnel from both ends; the laser beam has parallel rays that can travel long distances without appreciable spreading.

Lasers are widely used in medicine. A laser with a very narrow intense beam can be used in the treatment of a detached retina; a short burst of radiation damages a small area of the retina, and the resulting scar tissue 'welds' the retina back to the membrane from which it has become detached (see Fig. 33.2). Laser beams are used in surgery; blood vessels cut by the beam tend to seal themselves off, making it easier to control bleeding. Lasers are also used for selective destruction of tissue, as in the removal of tumours.

Lasers are also used in communications since a light beam carries a million times more information than a radio wave. An interesting application of lasers is in the seach for extra-terrestrial intelligence (ETI). The Australian Optical SETI (OZ OSETI) Project at the University of Western Sydney is carrying out a search for nanosecond laser pulses from ETI civilisations. It is the only dedicated optical search program in the southern hemisphere.

Test Your Understanding of Section 38.6 An ordinary neon light fixture (like those used in advertising signs) emits red light with the same 632.8 nm wavelength as a helium-neon laser. The light emitted by a neon light fixture is (i) spontaneous emission; (ii) stimulated emission; (iii) both spontaneous and stimulated emission.

Australian Research



The Australian Optical SETI Project conducted by Dr Ragbir Bhathal at the University of Western Sydney uses optical telescopes and specialised equipment to detect nanosecond laser pulsed signals from outer space.

38.7 X-ray Production and Scattering

The production and scattering of x-rays provide additional examples of the quantum nature of electromagnetic radiation. X-rays are produced when rapidly moving electrons that have been accelerated through a potential difference of the order of 10^3 to 10^6 V strike a metal target. They were first produced in 1895 by Wilhelm Röntgen (1845–1923), using an apparatus similar in principle to the setup shown in Fig. 38.25. Electrons are 'boiled off' from the heated cathode by thermionic emission and are accelerated towards the anode (the target) by a large potential difference V_{AC}. The bulb is evacuated (residual pressure 10^{-7} atm or less), so the electrons can travel from the cathode to the anode without colliding with air molecules. When V_{AC} is a few thousand volts or more, a very penetrating radiation is emitted from the anode surface.

38.25 An apparatus used to produce x-rays, similar to Röntgen's 1895 apparatus.

Electrons are emitted thermionically from the heated cathode and are accelerated towards the anode; when they strike it, x-rays are produced.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

X-ray Photons

Because they are emitted by accelerated charges, it is clear that x-rays are electromagnetic waves. Like light, x-rays are governed by quantum relationships in their interaction with matter. Thus we can talk about x-ray photons or quanta, and the energy of an x-ray photon is related to its frequency and wavelength in the same way as for photons of light, $E = hf = hc/\lambda$. Typical x-ray wavelengths are 0.001 to 1 nm $(10^{-12}$ to 10^{-9} m$)$. X-ray wavelengths can be measured quite precisely by crystal diffraction techniques, which we discussed in Section 36.6.

X-ray emission is the inverse of the photoelectric effect. In photoelectric emission there is a transformation of the energy of a photon into the kinetic energy of an electron; in x-ray production there is a transformation of the kinetic energy of an electron into the energy of a photon. The energy relationships are similar. In x-ray production we usually neglect the work function of the target and the initial kinetic energy of the 'boiled-off' electrons because they are very small in comparison to the other energies.

Two distinct processes are involved in x-ray emission. In the first process, some electrons are slowed down or stopped by the target, and part or all of their kinetic energy is converted directly to a continuous spectrum of photons, including x-rays. This process is called *bremsstrahlung* (German for 'braking radiation'). Classical physics is completely unable to explain why the x-rays that are emitted in a bremsstrahlung process have a maximum frequency f_{max} and a corresponding minimum wavelength λ_{min}, much less predict their values. With quantum concepts it is easy. An electron has charge $-e$ and gains kinetic energy eV_{AC} when accelerated through a potential increase V_{AC}. The most energetic photon (highest frequency and shortest wavelength) is produced when all the electron's kinetic energy goes to produce one photon; that is,

$$eV_{AC} = hf_{max} = \frac{hc}{\lambda_{min}} \qquad \text{(bremsstrahlung)} \tag{38.22}$$

Note that the maximum frequency and minimum wavelength in the bremsstrahlung process do *not* depend on the target material.

The second process gives peaks in the x-ray spectrum at characteristic frequencies and wavelengths that *do* depend on the target material. Other electrons, if they have enough kinetic energy, can transfer that energy partly or completely to individual atoms within the target. These atoms are left in excited levels; when they decay back to their ground levels, they may emit x-ray photons. Since each element has a unique set of atomic energy levels, each also has a characteristic x-ray spectrum. The energy levels associated with x-rays are rather different in character from those associated with visible spectra. They involve vacancies in the inner electron configurations of complex atoms. The energy differences between these levels can be hundreds or thousands of electron volts, rather than a few electron volts as is typical for optical spectra. We will return to energy levels and spectra associated with x-rays in Section 41.5.

Example 38.7 Producing x-rays

Electrons in an x-ray tube are accelerated by a potential difference of 10.0 kV. If an electron produces one photon on impact with the target, what is the minimum wavelength of the resulting x-rays? Answer using both SI units and electron volts.

SOLUTION

IDENTIFY: To produce an x-ray photon with minimum wavelength and hence maximum energy, all of the kinetic energy of an electron must go into producing a single x-ray photon.

SET UP: We use Eq. (38.22) to determine the wavelength in this situation.

EXECUTE: From Eq. (38.22), using SI units we find

$$\lambda_{min} = \frac{hc}{eV_{AC}} = \frac{(6.626 \times 10^{-34}\ \text{J}\cdot\text{s})(3.00 \times 10^{8}\ \text{m/s})}{(1.602 \times 10^{-19}\ \text{C})(10.0 \times 10^{3}\ \text{V})}$$
$$= 1.24 \times 10^{-10}\ \text{m} = 0.124\ \text{nm}$$

Continued

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

Using electron volts, we have

$$\lambda_{\text{min}} = \frac{hc}{eV_{\text{AC}}} = \frac{(4.136 \times 10^{-15}\ \text{eV} \cdot \text{s})(3.00 \times 10^{8}\ \text{m/s})}{e(10.0 \times 10^{3}\ \text{V})}$$
$$= 1.24 \times 10^{-10}\ \text{m} = 0.124\ \text{nm}$$

Note that the 'e' in the unit eV is canceled by the *'e'* for the magnitude of the electron charge, because the electron volt (eV) is the magnitude of the electron charge e times one volt (1 V).

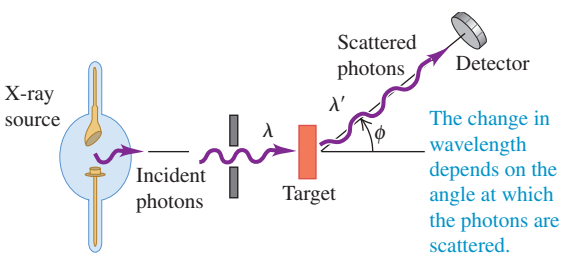
EVALUATE: To check our result, recall from Example 38.6 (Section 38.5) that a photon of energy 10.2 eV has a wavelength of 122 nm. In the present example the electron energy, and therefore the energy of the x-ray photon, is 10.0×10^{3} eV = 10.0 keV (about 10^{3} times greater than in Example 38.6) and the wavelength is about 10^{-3} times as great as in Example 38.6. This makes sense, since wavelength and photon energy are inversely proportional.

Compton Scattering

17.4 Compton Scattering

A phenomenon called **Compton scattering**, first explained in 1923 by the American physicist Arthur H. Compton, provides additional direct confirmation of the quantum nature of x-rays. When x-rays strike matter, some of the radiation is *scattered*, just as visible light falling on a rough surface undergoes diffuse reflection. Compton and others discovered that some of the scattered radiation has smaller frequency (longer wavelength) than the incident radiation and that the change in wavelength depends on the angle through which the radiation is scattered. Specifically, if the scattered radiation emerges at an angle ϕ with respect to the incident direction (Fig. 38.26) and if λ and λ' are the wavelengths of the incident and scattered radiation, respectively, we find that

$$\lambda' - \lambda = \frac{h}{mc}(1 - \cos\phi) \qquad \text{(Compton scattering)} \qquad (38.23)$$

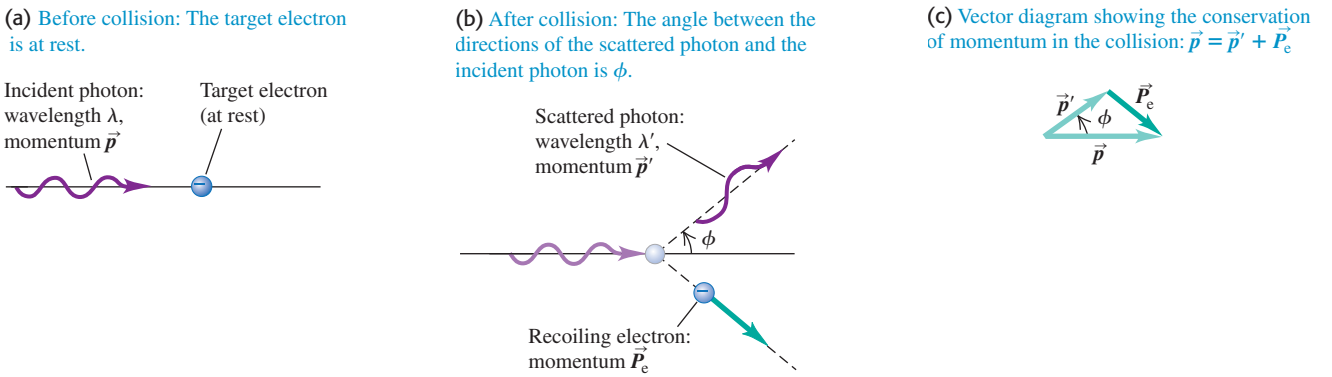


where m is the electron rest mass. The quantity h/mc that appears in Eq. (38.23) has units of length. Its numerical value is

$$\frac{h}{mc} = \frac{6.626 \times 10^{-34}\ \text{J} \cdot \text{s}}{(9.109 \times 10^{-31}\ \text{kg})(2.998 \times 10^{8}\ \text{m/s})} = 2.426 \times 10^{-12}\ \text{m}$$

We cannot explain Compton scattering using classical electromagnetic theory, which predicts that the scattered wave has the same wavelength as the incident wave. However, the quantum theory provides a beautifully clear explanation. We imagine the scattering process as a collision of two *particles*, the incident photon and an electron that is initially at rest, as in Fig. 38.27a. The incident photon disappears, giving part of its energy and momentum to the electron, which recoils as a result of this impact. The remainder goes to a new scattered photon that therefore has less energy, smaller frequency, and longer wavelength than the incident one (Fig. 38.27b).

We can derive Eq. (38.23) from the principles of conservation of energy and momentum. We outline the derivation below; we invite you to fill in the details (see Exercise 38.41). The electron recoil energy may be in the relativistic range, so we have to use the relativistic energy–momentum relationships, Eqs (37.39) and (37.40). The incident photon has momentum $\vec{\boldsymbol{p}}$, with magnitude p and energy pc. The scattered photon has momentum $\vec{\boldsymbol{p}}'$, with magnitude p' and energy $p'c$. The electron is initially at rest, so its initial momentum is zero and its initial energy is its rest energy mc^2. The final electron momentum $\vec{\boldsymbol{P}}_e$ has magnitude P_e, and the final electron energy is given by $E_e^2 = (mc^2)^2 + (P_e c)^2$. Then energy conservation gives us the relationship



$$pc + mc^2 = p'c + E_e$$

38.26 A Compton-effect experiment.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

38.27 Schematic diagram of Compton scattering.

Rearranging, we find

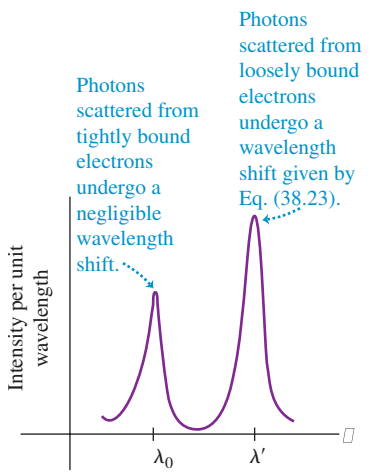
$$(pc - p'c + mc^2)^2 = E_e^2 = (mc^2)^2 + (P_e c)^2 \tag{38.24}$$

We can eliminate the electron momentum $\vec{P}_e$ from Eq. (38.24) by using momentum conservation (Fig. 38.27c):

$$\vec{p} = \vec{p}' + \vec{P}_e \quad \text{or} \quad \vec{P}_e = \vec{p} - \vec{p}' \tag{38.25}$$

By taking the scalar product of each side of Eq. (38.25) with itself or by using the law of cosines with the vector diagram in Fig. 38.27c, we find

$$P_e^2 = p^2 + p'^2 - 2pp'\cos\phi \tag{38.26}$$



We now substitute this expression for P_e^2 into Eq. (38.24) and multiply out the left side. We divide out a common factor c^2; several terms cancel, and when the resulting equation is divided through by (pp'), the result is

$$\frac{mc}{p'} - \frac{mc}{p} = 1 - \cos\phi \tag{38.27}$$

Finally, we substitute $p' = h/\lambda'$ and $p = h/\lambda$, then multiply by h/mc to obtain Eq. (38.23).

When the wavelengths of x-rays scattered at a certain angle are measured, the curve of intensity per unit wavelength as a function of wavelength has two peaks (Fig. 38.28). The longer-wavelength peak represents Compton scattering. The shorter-wavelength peak, labelled λ_0, is at the wavelength of the incident x-rays and corresponds to x-ray scattering from tightly bound electrons. In such scattering processes the entire atom must recoil, so the m in Eq. (38.23) is the mass of the entire atom rather than of a single electron. The resulting wavelength shifts are negligible.

38.28 Intensity as a function of wavelength for photons scattered at an angle of 135° in a Compton scattering experiment.

Example 38.8 Compton scattering

You use the x-ray photons in Example 38.7 (with $\lambda = 0.124$ nm) in a Compton scattering experiment. (a) At what angle is the wavelength of the scattered x-rays 1.0% longer than that of the incident x-rays? (b) At what angle is it 0.050% longer?

SOLUTION

IDENTIFY: This problem uses the relationship between scattering angle and wavelength shift in the Compton effect.

SET UP: In each case our target variable is the angle ϕ shown in Fig. 38.27b. We solve for it using Eq. (38.23).

EXECUTE: (a) In Eq. (38.23) we want $\Delta\lambda = \lambda' - \lambda$ to be 1.0% of 0.124 nm. That is, $\Delta\lambda = 0.00124\text{ nm} = 1.24 \times 10^{-12}$ m. Using the value $h/mc = 2.426 \times 10^{-12}$ m, we find

$$\Delta\lambda = \frac{h}{mc}(1 - \cos\phi)$$

$$\cos\phi = 1 - \frac{\Delta\lambda}{h/mc} = 1 - \frac{1.24 \times 10^{-12}\text{ m}}{2.426 \times 10^{-12}\text{ m}} = 0.4889$$

$$\phi = 60.7°$$

Continued

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

(b) For $\Delta\lambda$ to be 0.050% of 0.124 nm, or 6.2×10^{-14} m,

$$\cos\phi = 1 - \frac{6.2 \times 10^{-14}\ \text{m}}{2.426 \times 10^{-12}\ \text{m}} = 0.9744$$

$$\phi = 13.0°$$

EVALUATE: Comparing our results for parts (a) and (b) shows that smaller angles give smaller wavelength shifts. Thus in a grazing collision the photon energy loss and the electron recoil energy are smaller than when the scattering angle is larger. This is just what we would expect for an elastic collision, whether between a photon and an electron or between two billiard balls.

Applications of X-rays

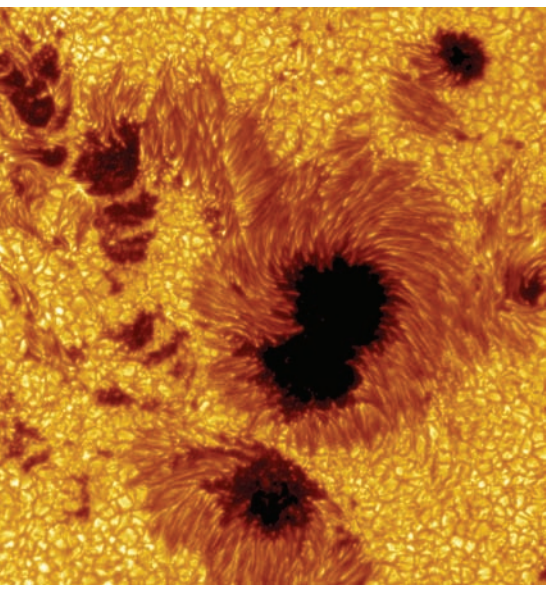
X-rays have many practical applications in medicine and industry. Because x-ray photons are of such high energy, they can penetrate several centimetres of solid matter and so can be used to visualise the interiors of materials that are opaque to ordinary light, such as broken bones or defects in structural steel. The object to be visualised is placed between an x-ray source and a large sheet of photographic film; the darkening of the film is proportional to the radiation exposure. A crack or air bubble allows greater transmission and shows as a dark area. Bones appear lighter than the surrounding soft tissue because they contain greater proportions of elements with higher atomic number (and greater absorption); in the soft tissue the light elements carbon, hydrogen and oxygen predominate.

A widely used and vastly improved x-ray technique is *computed tomography*; the corresponding instrument is called a *CT scanner*. The x-ray source produces a thin, fan-shaped beam that is detected on the opposite side of the subject by an array of several hundred detectors in a line. Each detector measures absorption along a thin line through the subject. The entire apparatus is rotated around the subject in the plane of the beam during a few seconds. The changing photon-counting rates of the detectors are recorded digitally; a computer processes this information and reconstructs a picture of absorption over an entire cross-section of the subject (Fig. 38.29). Differences as small as 1% can be detected with CT scans and tumours and other anomalies that are much too small to be seen with older x-ray techniques can be detected.

X-rays cause damage to living tissues. As x-ray photons are absorbed in tissues, their energy breaks molecular bonds and creates highly reactive free radicals (such as neutral H and OH), which in turn can disturb the molecular structure of proteins and especially genetic material. Young and rapidly growing cells are particularly susceptible; thus x-rays are useful for selective destruction of cancer cells. Conversely, however, a cell may be damaged by radiation but survive, continue dividing and produce generations of defective cells; thus x-rays can *cause* cancer.

Even when the organism itself shows no apparent damage, excessive radiation exposure can cause changes in the organism's reproductive system that will affect its offspring. A careful assessment of the balance between risks and benefits of radiation exposure is essential in each individual case.

38.29 Radiologists operate a CT scanner from a separate room to avoid repeated exposure to x-rays.



Test Your Understanding of Section 38.7 If you used visible-light photons in the experiment shown in Fig. 38.26, would the photons undergo a wavelength shift in the scattering? If so, is it possible to detect the shift with the human eye?

38.8 Continuous Spectra

Line spectra are emitted by matter in the gaseous state, in which the atoms are so far apart that interactions between them are negligible and each atom behaves as an isolated system. Hot matter in condensed states (solid or liquid) nearly always emits radiation with a *continuous* distribution of wavelengths rather than a line spectrum. An ideal surface that absorbs all wavelengths of electromagnetic radiation incident upon it is also the best possible emitter of electromagnetic radiation at

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

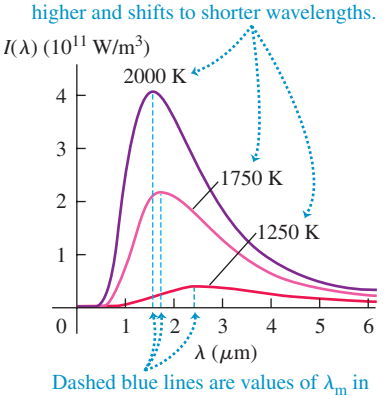
38.30 Large field-of-view image of sunspots in Active Region 10030 observed on 15 July 2002. The temperatures of the dark sunspots and the surrounding solar material are 4000 K and 4800 K respectively. From the Stefan-Boltzmann law, the intensity from a given area of sunspot is only $(4000\ \text{K}/5800\ \text{K})^4 = 0.23$ as great as the intensity from the same area of the surrounding material—which is why sunspots appear dark. The image has been cololured yellow for aesthetic reasons.

any wavelength. Such an ideal surface is called a *blackbody*, and the continuous-spectrum radiation that it emits is called **blackbody radiation**. By 1900 this radiation had been studied extensively, and two characteristics had been established.

First, the total intensity I (the average rate of radiation of energy per unit surface area or average power per area) emitted from the surface of an ideal radiator is proportional to the fourth power of the absolute temperature (Fig. 38.30). We studied this relationship in Section 17.7 during our study of heat transfer mechanisms. This total intensity I emitted at absolute temperature T is given by the **Stefan-Boltzmann law**:

$$I = \sigma T^4 \qquad \text{(Stefan-Boltzmann law for a blackbody)} \qquad (38.28)$$

where σ is a fundamental physical constant called the *Stefan-Boltzmann constant*. In SI units,



$$\sigma = 5.670400(40) \times 10^{-8} \frac{\text{W}}{\text{m}^2 \cdot \text{K}^4}$$

Second, the intensity is not uniformly distributed over all wavelengths. Its distribution can be measured and described by the intensity per wavelength interval $I(\lambda)$, called the *spectral emittance*. Thus $I(\lambda)\,d\lambda$ is the intensity corresponding to wavelengths in the interval from λ to $\lambda + d\lambda$. The *total* intensity I, given by Eq. (38.28), is the *integral* of the distribution function $I(\lambda)$ over all wavelengths, which equals the area under the $I(\lambda)$ versus λ curve:

$$I = \int_0^\infty I(\lambda)\,d\lambda \qquad (38.29)$$

CAUTION **Spectral emittance vs intensity** Although we use the symbol $I(\lambda)$ for spectral emittance, keep in mind that spectral emittance is *not* the same thing as intensity I. Intensity is power per unit area, with units W/m^2; spectral emittance is power per unit area per unit wavelength interval, with units W/m^3.

38.31 Spectral emittance $I(\lambda)$ for radiation from a blackbody at three different temperatures.

Measured spectral emittances $I(\lambda)$ for three different temperatures are shown in Fig. 38.31. Each has a peak wavelength λ_m at which the emitted intensity per wavelength interval is largest. Experiment shows that λ_m is inversely proportional to T, so their product is constant. This result is called the **Wien displacement law**. The experimental value of the constant is $2.90 \times 10^{-3}\ \text{m} \cdot \text{K}$:

$$\lambda_m T = 2.90 \times 10^{-3}\ \text{m} \cdot \text{K} \qquad \text{(Wien displacement law)} \qquad (38.30)$$

As the temperature rises, the peak of $I(\lambda)$ becomes higher and shifts to shorter wavelengths. A body that glows yellow is hotter and brighter than one that glows red; yellow light has shorter wavelengths than red light. Finally, experiments show that the *shape* of the distribution function is the same for all temperatures; we can make a curve for one temperature fit any other temperature by simply changing the scales on the graph.

Rayleigh and the 'Ultraviolet Catastrophe'

During the last decade of the 19th century, many attempts were made to *derive* these empirical results from basic principles. In one attempt, the English physicist Lord Rayleigh considered light enclosed in a rectangular box with perfectly reflecting sides. Such a box has a series of possible *normal modes* for electromagnetic waves, as discussed in Section 32.5. It seemed reasonable to assume that the distribution of energy among the various modes was given by the

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

equipartition principle (see Section 18.4), which had been successfully used in the analysis of heat capacities. A small hole in the box would behave as an ideal blackbody radiator.

Including both the electric- and magnetic-field energies, Rayleigh assumed that the total energy of each normal mode was equal to kT. Then by computing the *number* of normal modes corresponding to a wavelength interval $d\lambda$, Rayleigh could predict the distribution of wavelengths in the radiation within the box. Finally, he could compute the intensity distribution $I(\lambda)$ of the radiation emerging from a small hole in the box. His result was quite simple:

$$I(\lambda) = \frac{2\pi ckT}{\lambda^4} \tag{38.31}$$

At large wavelengths this formula agrees quite well with the experimental results shown in Fig. 38.31, but there is serious disagreement at small wavelengths. The experimental curve falls towards zero at small λ, but Rayleigh's curve goes the opposite direction, approaching infinity as $1/\lambda^4$, a result that was called in Rayleigh's time the 'ultraviolet catastrophe'. Even worse, the integral of Eq. (38.31) over all λ is infinite, indicating an infinitely large *total* radiated intensity. Clearly, something is wrong.

Planck and the Quantum Hypothesis

Finally, in 1900, the German physicist Max Planck succeeded in deriving a function, now called the **Planck radiation law**, that agreed very well with experimental intensity distribution curves. In his derivation he made what seemed at the time to be a crazy assumption. Planck assumed that electromagnetic oscillators (electrons) in the walls of Rayleigh's box vibrating at a frequency f could have only certain values of energy equal to nhf, where $n = 0, 1, 2, 3, \ldots$ and h turned out to be the constant that now bears Planck's name. These oscillators were in equilibrium with the electromagnetic waves in the box. His assumption gave quantised energy levels and was in sharp contrast to Rayleigh's point of view, which was that each normal mode could have any amount of energy.

Planck was not comfortable with this *quantum hypothesis*; he regarded it as a calculational trick rather than a fundamental principle. In a letter to a friend, he called it 'an act of desperation' into which he was forced because 'a theoretical explanation had to be found at any cost, whatever the price'. But five years later, Einstein identified the energy change hf between levels as the energy of a photon to explain the photoelectric effect (see Section 38.2), and other evidence quickly mounted. By 1915 there was little doubt about the validity of the quantum concept and the existence of photons. By discussing atomic spectra *before* continuous spectra, we have departed from the historical order of things. The credit for inventing the concept of quantisation of energy levels goes to Planck, even though he didn't believe it at first.

We won't go into the details of Planck's derivation of the intensity distribution. Here is his result:

$$I(\lambda) = \frac{2\pi hc^2}{\lambda^5\left(e^{hc/\lambda kT} - 1\right)} \qquad \text{(Planck radiation law)} \tag{38.32}$$

where h is Planck's constant, c is the speed of light, k is Boltzmann's constant, T is the *absolute* temperature and λ is the wavelength. This function turns out to agree well with experimental intensity curves such as those in Fig. 38.31.

The Planck radiation law also contains the Wien displacement law and the Stefan-Boltzmann law as consequences. To derive the Wien law, we take the derivative of Eq. (38.32) and set it equal to zero to find the value of λ at which

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

$I(\lambda)$ is maximum. We leave the details as a problem (see Exercise 38.47); the result is

$$\lambda_m = \frac{hc}{4.965kT} \tag{38.33}$$

To obtain this result, you have to solve the equation

$$5 - x = 5e^{-x} \tag{38.34}$$

The root of this equation, found by trial and error or more sophisticated means, is 4.965 to four significant figures. You should evaluate the constant $hc/4.965k$ and show that it agrees with the experimental value of $2.90 \times 10^{-3}\ \text{m} \cdot \text{K}$ given in Eq. (38.30).

We can obtain the Stefan-Boltzmann law for a blackbody by integrating Eq. (38.32) over all λ to find the *total* radiated intensity (see Problem 38.77). This is not a simple integral; the result is

$$I = \int_0^\infty I(\lambda)\, d\lambda = \frac{2\pi^5 k^4}{15c^2h^3}T^4 = \sigma T^4 \tag{38.35}$$

in agreement with Eq. (38.28). This result also shows that the constant σ in that law can be expressed as a combination of other fundamental constants:

$$\sigma = \frac{2\pi^5 k^4}{15c^2h^3} \tag{38.36}$$

You should substitute the values of k, c and h from Appendix F and verify that you obtain the Stefan-Boltzmann constant $\sigma = 5.6704 \times 10^{-8}\ \text{W/m}^2 \cdot \text{K}^4$.

The general form of Eq. (38.33) is what we should expect from kinetic theory. If photon energies are typically of the order of kT, as suggested by the equipartition theorem, then for a typical photon we would expect

$$E \approx kT \approx \frac{hc}{\lambda} \qquad \text{and} \qquad \lambda \approx \frac{hc}{kT} \tag{38.37}$$

Indeed, a photon with wavelength given by Eq. (38.33) has an energy $E = 4.965kT$.

The Planck radiation law, Eq. (38.32), looks so different from the unsuccessful Rayleigh expression, Eq. (38.31), that it may seem unlikely that they would agree at large values of λ. But when λ is large, the exponent in the denominator of Eq. (38.32) is very small. We can then use the approximation $e^x \approx 1 + x$ $(\text{for } x \ll 1)$. You should verify that when this is done, the result approaches Eq. (38.31), showing that the two expressions do agree in the limit of very large λ. We also note that the Rayleigh expression does not contain h. At very long wavelengths and correspondingly very small photon energies, quantum effects become unimportant.

Example 38.9 Light from the sun

The surface of the sun has a temperature of approximately 5800 K. To a good approximation we may treat it as a blackbody. (a) What is the peak-intensity wavelength λ_m? (b) What is the total radiated power per unit area of surface?

SOLUTION

IDENTIFY: This problem involves the Wien displacement law (which relates the temperature T of a blackbody and its peak-intensity wavelength λ_m) and the Stefan-Boltzmann law (which relates the blackbody temperature and the radiated power per area I).

SET UP: We use Eq. (38.30) to determine λ_m and Eq. (38.28) to calculate I.

EXECUTE: (a) From Eq. (38.30),

$$\lambda_m = \frac{2.90 \times 10^{-3}\ \text{m} \cdot \text{K}}{T} = \frac{2.90 \times 10^{-3}\ \text{m} \cdot \text{K}}{5800\ \text{K}}$$
$$= 0.500 \times 10^{-6}\ \text{m} = 500\ \text{nm}$$

Continued

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

(b) From Eq. (38.28),

$$I = \sigma T^4 = (5.67 \times 10^{-8}\ \mathrm{W/m^2 \cdot K^4})(5800\ \mathrm{K})^4$$
$$= 6.42 \times 10^7\ \mathrm{W/m^2} = 64.2\ \mathrm{MW/m^2}$$

EVALUATE: The wavelength found in part (b) is near the middle of the visible spectrum. This is not a surprising result: The human eye evolved to take maximum advantage of natural light.

The enormous value of I found in part (b) is the intensity at the *surface* of the sun. When the radiated power reaches the earth, the intensity drops to about $1.4\ \mathrm{kW/m^2}$ because the power spreads out over the much larger area of a sphere with a radius equal to that of the earth's orbit.

Example 38.10 A slice of sunlight

Find the power per unit area radiated from the surface of the sun in the wavelength range 600.0 to 605.0 nm.

SOLUTION

IDENTIFY: This question concerns the power emitted by a blackbody over a narrow range of wavelengths, and so involves the spectral emittance (intensity distribution) $I(\lambda)$.

SET UP: For an exact result we should integrate Eq. (38.32) between the limits 600.0 and 605.0 nm, finding the area under the $I(\lambda)$ curve between these limits. This integral can't be evaluated in terms of familiar functions, so we *approximate* the area by the height of the curve at the median wavelength $\lambda = 602.5$ nm multiplied by the width of the interval $(\Delta\lambda = 5.0\ \mathrm{nm})$.

EXECUTE: To obtain the height of the $I(\lambda)$ curve at $\lambda = 602.5\ \mathrm{nm} = 6.025 \times 10^{-7}\ \mathrm{m}$, we first evaluate the quantity $hc/\lambda kT$ for this value of λ and for $T = 5800$ K (the temperature of the solar surface; see Example 38.9). We then substitute the result into Eq. (38.32):

$$\frac{hc}{\lambda kT} = \frac{(6.626 \times 10^{-34}\ \mathrm{J \cdot s})(2.998 \times 10^8\ \mathrm{m/s})}{(6.025 \times 10^{-7}\ \mathrm{m})(1.381 \times 10^{-23}\ \mathrm{J/K})(5800\ \mathrm{K})}$$
$$= 4.116$$

$$I(\lambda) = \frac{2\pi(6.626 \times 10^{-34}\ \mathrm{J \cdot s})(2.998 \times 10^8\ \mathrm{m/s})^2}{(6.025 \times 10^{-7}\ \mathrm{m})^5(e^{4.116} - 1)}$$
$$= 7.81 \times 10^{13}\ \mathrm{W/m^3}$$

The intensity in the 5.0 nm range from 600.0 to 605.0 nm is then approximately

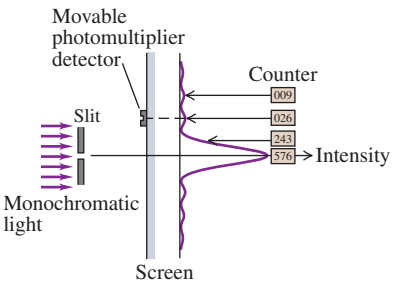
$$I(\lambda)\Delta\lambda = (7.81 \times 10^{13}\ \mathrm{W/m^3})(5.0 \times 10^{-9}\ \mathrm{m})$$
$$= 3.9 \times 10^5\ \mathrm{W/m^2} = 0.39\ \mathrm{MW/m^2}$$

EVALUATE: We see from this result and from part (b) of Example 38.9 (in which we found the power radiated per unit area at *all* wavelengths) that about 0.6% of the total power radiated from the sun is in the wavelength range from 600 to 605 nm. Had we found that more power is radiated in this range than the total calculated in Example 38.9, something would have been very wrong with our calculations!

Test Your Understanding of Section 38.8 (a) Does a blackbody at 2000 K emit x-rays? (b) Does it emit radio waves?

38.9 Wave–Particle Duality

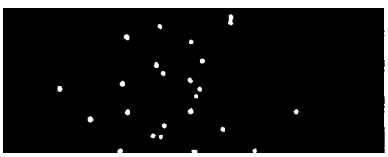
We have studied many examples of the behaviour of light and other electromagnetic radiation. Some, including the interference and diffraction effects described in Chapters 35 and 36, demonstrate conclusively the *wave* nature of light. Others, the subject of the present chapter, point with equal force to the *particle* nature of light. At first glance these two aspects seem to be in direct conflict. How can light be a wave and a particle at the same time?



We can find the answer to this apparent wave–particle conflict in the **principle of complementarity**, first stated by Niels Bohr in 1928. The wave descriptions and the particle descriptions are complementary. That is, we need both descriptions to complete our model of nature, but we will never need to use both descriptions at the same time to describe a single part of an occurrence.

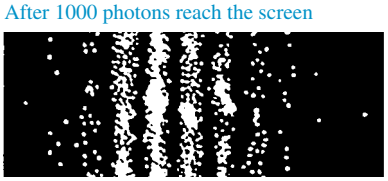
Diffraction and Interference in the Photon Picture

Let's start by considering again the diffraction pattern for a single slit, which we analysed in Sections 36.2 and 36.3. Instead of recording the pattern on photographic film, we use a detector called a *photomultiplier* that can actually detect

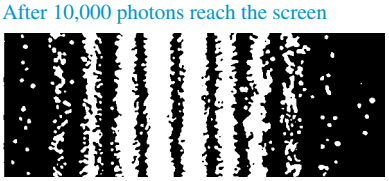


Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

38.32 Single-slit diffraction pattern observed with a movable photomultiplier. The curve shows the intensity distribution predicted by the wave picture. The photon distribution is shown by the numbers of photons counted at various positions.



38.33 These images record the positions where individual photons in a two-slit interference experiment strike the screen. As more photons reach the screen, a recognisable interference pattern appears.



After 21 photons reach the screen

After 1000 photons reach the screen

After 10,000 photons reach the screen

individual photons. Using the setup shown in Fig. 38.32, we place the photomultiplier at various positions for equal time intervals, count photons at each position, and plot out the intensity distribution.

We find that, on average, the distribution of photons agrees with our predictions from Section 36.3. At points corresponding to the maxima of the pattern, we count many photons; at minimum points, we count almost none, and so on. The graph of the counts at various points gives us the same diffraction pattern that we predicted with Eq. (36.7).

But suppose we now reduce the intensity to the point at which only a few photons per second pass through the slit. With only a few photons we can't expect to get the smooth diffraction curve that we found with very large numbers. In fact, there is no way to predict exactly where any individual photon will go. To reconcile the wave and particle aspects of this pattern, we have to regard the pattern as a *statistical* distribution that tells us how many photons, on average, go various places, or the *probability* for an individual photon to land in each of several places. But we can't predict exactly where an individual photon will go.

Now let's take a brief look at a quantum interpretation of a *two-slit* optical interference pattern, which we studied in Section 35.2. We can again trace out the pattern using a photomultiplier and a counter. We reduce the light intensity to a level of a few photons per second (Fig. 38.33). Again we can't predict exactly where an individual photon will go; the interference pattern is a *statistical distribution*.

How does the principle of complementarity apply to these diffraction and interference experiments? The wave description, not the particle description, explains the single- and double-slit patterns. But the particle description, not the wave description, explains why the photomultiplier measures the pattern to be built up by discrete packages of energy. The two descriptions complete our understanding of the results.

In these experiments, light goes through a slit or slits, and photons are detected at various positions on a screen. Suppose we ask the following question: 'We just detected a photon at a certain position; when the photon went through the slit, how did it know which way to go?' The problem with the question is that it is asked in terms of a *particle* description. The wave nature of light, not the particle nature, determines the distribution of photons. Asking that question is trying to force a particle description (the photon being somehow directed which way to go) on a wave phenomenon (the formation of the pattern).

Quantum Electrodynamics

We know from experiments that sending electromagnetic waves through slits gives interference patterns and that these patterns are built up by individual photons. But if we didn't know the experimental results, how would we predict when to apply the wave description and when to apply the particle description? We need a theory that includes both these descriptions and predicts as well as explains both types of behaviour. Such a comprehensive theory is called *quantum electrodynamics* (QED). In this theory the concept of energy levels of an atomic system is extended to electromagnetic fields. Just as an atom exists only in certain definite energy states, so the electromagnetic field has certain well-defined energy states, corresponding to the presence of various numbers of photons with assorted energies, momenta and polarisations. QED came to full flower 50 years after Planck's quantum hypothesis of 1900 gave quantum mechanics its conceptual birth.

In the following chapters we will find that particles such as electrons also have a dual wave–particle personality. One of the great achievements of quantum mechanics has been to reconcile these apparently incompatible aspects of behaviour of photons, electrons and other constituents of matter.

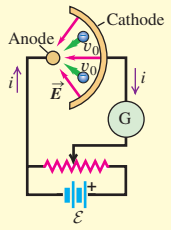
CHAPTER 38 SUMMARY

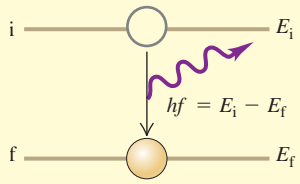


Photons: Electromagnetic radiation behaves as both waves and particles. The energy in an electromagnetic wave is carried in units called photons. The energy E of one photon is proportional to the wave frequency f and inversely proportional to the wavelength λ, and is proportional to a universal quantity h called Planck's constant. The momentum of a photon has magnitude E/c. (See Example 38.1.)

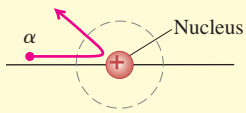
$$E = hf = \frac{hc}{\lambda} \tag{38.2}$$

$$p = \frac{E}{c} = \frac{hf}{c} = \frac{h}{\lambda} \tag{38.5}$$

The photoelectric effect: In the photoelectric effect, a surface can eject an electron by absorbing a photon whose energy hf is greater than or equal to the work function ϕ of the material. The stopping potential V_0 is the voltage required to stop a current of ejected electrons from reaching an anode. (See Examples 38.2 and 38.3.)



$$eV_0 = hf - \phi \tag{38.4}$$

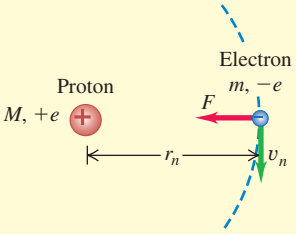


Atomic line spectra and energy levels: When an atom makes a transition from an energy level E_i to a lower level E_f, the energy of the emitted photon is equal to $E_i - E_f$. The energy levels of the hydrogen atom are given by Eq. (38.9), where R is the Rydberg constant. All of the observed spectral series of hydrogen can be understood in terms of these levels. (See Example 38.4.)

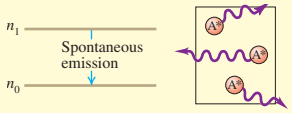
$$hf = \frac{hc}{\lambda} = E_i - E_f \tag{38.6}$$

$$E_n = -\frac{hcR}{n^2} = -\frac{13.60\ \text{eV}}{n^2} \quad (n = 1, 2, 3, \ldots) \tag{38.9}$$

The nuclear atom: The Rutherford scattering experiments show that at the centre of an atom is a dense nucleus, much smaller than the overall size of the atom but containing all of the positive charge and most of the mass. (See Example 38.5.)



The Bohr model: In the Bohr model of the hydrogen atom, the permitted values of angular momentum are integral multiples of $h/2\pi$. The integer multiplier n is called the principal quantum number for the level. The orbital radii are proportional to n^2 and the orbital speeds are proportional to $1/n$. (See Example 38.6.)

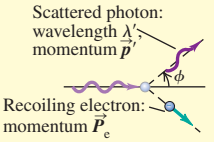


$$L_n = mv_n r_n = n\frac{h}{2\pi} \quad n = 1, 2, 3, \ldots \tag{38.10}$$

$$r_n = \epsilon_0 \frac{n^2 h^2}{\pi m e^2} = n^2 a_0 = n^2(5.29 \times 10^{-11}\ \text{m}) \tag{38.12}$$

$$v_n = \frac{1}{\epsilon_0}\frac{e^2}{2nh} = \frac{2.19 \times 10^6\ \text{m/s}}{n} \tag{38.13}$$

The laser: The laser operates on the principle of stimulated emission, by which many photons with identical wavelength and phase are emitted. Laser operation requires a nonequilibrium condition called a population inversion, in which more atoms are in a higher-energy state than are in a lower-energy state.

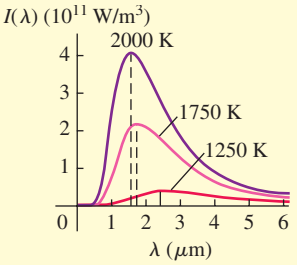


Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

X-ray production and scattering: X-rays can be produced by electron impact on a target. If electrons are accelerated through a potential increase V_{AC}, the maximum frequency and minimum wavelength that they can produce are given by Eq. (38.22). (See Example 38.7.) Compton scattering is scattering of x-ray photons by electrons. For free electrons (mass m), the wavelengths of incident and scattered photons are related to the photon scattering angle ϕ by Eq. (38.23). (See Example 38.8.)

$$eV_{AC} = hf_{max} = \frac{hc}{\lambda_{min}} \qquad (38.22)$$

$$\lambda' - \lambda = \frac{h}{mc}(1 - \cos\phi) \qquad (38.23)$$



Blackbody radiation: The total radiated intensity (average power radiated per area) from a blackbody surface is proportional to the fourth power of the absolute temperature T. The quantity $\sigma = 5.67 \times 10^{-8}\ \mathrm{W/m^2 \cdot K^4}$ is called the Stefan-Boltzmann constant. The wavelength λ_m at which a blackbody radiates most strongly is inversely proportional to T. The Planck radiation law gives the spectral emittance $I(\lambda)$ (intensity per wavelength interval in blackbody radiation). (See Examples 38.9 and 38.10.)

$$I = \sigma T^4 \qquad (38.28)$$
(Stefan-Boltzmann law)

$$\lambda_m T = 2.90 \times 10^{-3}\ \mathrm{m \cdot K} \qquad (38.30)$$
(Wien displacement law)

$$I(\lambda) = \frac{2\pi hc^2}{\lambda^5 (e^{hc/\lambda kT} - 1)} \qquad (38.32)$$
(Planck radiation law)

Answer to Chapter Opening Question ?

A photon of wavelength 656.3 nm (the H_α line in Fig. 38.8) is emitted when the electron in a hydrogen atom drops from the $n = 3$ energy level to the $n = 2$ level. The fact that we observe this tells us that the hydrogen gas in the Lagoon Nebula is very highly excited. (If the gas were not excited, all of the atoms would be in the lowest energy level and could not emit photons.) The gas is excited by high-energy ultraviolet photons coming from hot, luminous stars within the Lagoon Nebula.

Answers to Test Your Understanding Questions

38.2 Answers: (i) and (ii) From Eq. (38.2), a photon of energy $E = 1.14$ eV has wavelength $\lambda = hc/E = (4.136 \times 10^{-15}\ \mathrm{eV}) \cdot (3.00 \times 10^8\ \mathrm{m/s})/(1.14\ \mathrm{eV}) = 1.09 \times 10^{-6}\ \mathrm{m} = 1090$ nm. This is in the infrared part of the spectrum. Since wavelength is inversely proportional to photon energy, the *minimum* photon energy of 1.14 eV corresponds to the *maximum* wavelength that causes photoconductivity in silicon. Thus the wavelength must be 1090 nm or less.

38.3 Answer: no For the atom to absorb a photon, the photon energy must be precisely equal to the energy difference between the initial and final energy levels of the atom (see Fig. 38.11).

38.4 Answer: no The nucleus of a hydrogen atom is a proton (mass 1.67×10^{-27} kg), which has only about one-fourth of the mass of an alpha particle $(6.64 \times 10^{-27}\ \mathrm{kg})$. Because the alpha particle is more massive, it won't bounce back in even a head-on collision with a proton. It's like a bowling ball colliding with a ping-pong ball at rest (see Fig. 8.22b). Thus there would be no large-angle scattering in this case. In Rutherford's experiment, by contrast, there *was* large-angle scattering because a gold nucleus is more massive than an alpha particle. The analogy there is a ping-pong ball hitting a bowling ball at rest (see Fig. 8.22a).

38.5 Answer: yes Figure 38.22 shows that many (though not all) of the energy levels of He^+ are the same as those of H. Hence photons emitted during transitions between corresponding pairs of levels in He^+ and H have the same energy E and the same wavelength $\lambda = hc/E$. For example, a H atom that drops from the $n = 2$ level to the $n = 1$ level emits a photon of energy 10.20 eV and wavelength 122 nm (see Example 38.6); a He^+ ion emits a photon

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

of the same energy and wavelength when it drops from the $n = 4$ level to the $n = 2$ level.

38.6 Answer: (i) In a neon light fixture, a large potential difference is applied between the ends of a neon-filled glass tube. This ionises some of the neon atoms, allowing a current of electrons to flow through the gas. Some of the neon atoms are struck by fast-moving electrons, exciting the atoms to the 5s level shown in Fig. 38.24a. From this level the atoms transition spontaneously to the 3*p* level and emit 632.8-nm photons in the process. The photons escape out of the sides of the glass tube. This process is *spontaneous* emission, as depicted in Fig. 38.23b. No population inversion occurs and the photons are not trapped by mirrors as shown in Fig. 38.24b, so there is no stimulated emission. Hence there is no laser action.

38.7 Answer: yes, no Equation (38.23) shows that the wavelength shift $\Delta\lambda = \lambda' - \lambda$ depends only on the photon scattering angle ϕ, not on the wavelength of the incident photon. So a visible-light photon scattered through an angle ϕ undergoes the same wavelength shift as an x-ray photon. Equation (38.23) also shows that this shift is of the order of $h/mc = 2.426 \times 10^{-12}$ m = 0.002426 nm. This is a few percent of the wavelength of x-rays (see Example 38.8), so the effect is noticeable in x-ray scattering. However, h/mc is a tiny fraction of the wavelength of visible light (between 400 and 700nm). The human eye cannot distinguish such minuscule differences in wavelength (that is, differences in colour).

38.8 Answer: (a) yes, (b) yes The Planck radiation law, Eq. (38.32), shows that an ideal blackbody emits radiation at *all* wavelengths: The spectral emittance $I(\lambda)$ is equal to zero only for $\lambda = 0$ and in the limit $\lambda \to \infty$. So a blackbody at 2000 K does indeed emit both x-rays and radio waves. However, Fig. 38.31 shows that the spectral emittance for this temperature is very low for wavelengths much shorter than 1 μm (including x-rays) and for wavelengths much longer than a few μm (including radio waves). Hence such a blackbody emits very little in the way of x-rays or radio waves.

PROBLEMS

Exercises

Section 38.2 The Photoelectric Effect

38.1. The graph in Figure 38.34 shows the stopping potential as a function of the frequency of the incident light falling on a metal surface, (a) Find the photoelectric work function for this metal. (b) What value of Planck's constant does the graph yield? (c) Why does the graph *not* extend below the *x*-axis? (d) If a different metal were used, what characteristics of the graph would you expect to be the same and which ones to be different?

Figure **38.34** Exercise 38.1.

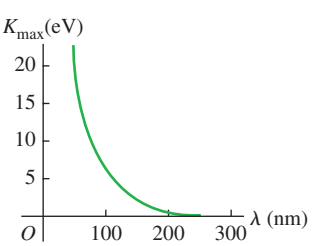
38.2. The human eye is most sensitive to green light of wavelength 505 nm. Experiments have found that when people are kept in a dark room until their eyes adapt to the darkness, a *single* photon of green light will trigger receptor cells in the rods of the retina. (a) What is the frequency of this photon? (b) How much energy (in joules and electron volts) does it deliver to the receptor cells? (c) to appreciate what a small amount of energy this is, calculate how fast a typical bacterium of mass 9.5×10^{-12} g would move if it had that much energy.

38.3. A photon of green light has a wavelength of 520 nm. Find the photon's frequency, magnitude of momentum and energy. Express the energy in both joules and electron volts.

38.4. A laser used to weld detached retinas emits light with a wavelength of 652 nm in pulses that are 20.0 ms in duration. The average power during each pulse is 0.600 W. (a) How much energy is in each pulse in joules? In electron volts? (b) What is the energy of one photon in joules? In electron volts? (c) How many photons are in each pulse?

38.5. An excited nucleus emits a gamma-ray photon with an energy of 2.45 MeV. (a) What is the photon frequency? (b) What is the photon wavelength? (c) How does the wavelength compare with a typical nuclear diameter of 10^{-14} m?

38.6. The photoelectric threshold wavelength of a tungsten surface is 272 nm. Calculate the maximum kinetic energy of the electrons ejected from this tungsten surface by ultraviolet radiation of frequency 1.45×10^{15} Hz. Express the answer in electron volts.



38.7. A clean nickel surface is exposed to light of wavelength 235 nm. What is the maximum speed of the photoelectrons emitted from this surface? Use Table 38.1.

38.8. What would the minimum work function for a metal have to be for visible light (400–700 mn) to eject photoelectrons?

38.9. A 75 W light source consumes 75 W of electrical power. Assume all this energy goes into emitted light of wavelength 600 nm. (a) Calculate the frequency of the emitted light. (b) How many photons per second does the source emit? (c) Are the answers to parts (a) and (b) the same? Is the frequency of the light the same thing as the number of photons emitted per second? Explain.

38.10. In a photoelectric-effect experiment, the maximum kinetic energy of the ejected photoelectrons is measured for various wavelengths of the incident light. Figure 38.35 shows a graph of this maximum kinetic energy, K_{max}, as a function of the wavelength λ of the light falling on the surface of the metal. What are (a) the threshold frequency and (b) the work function (in electron volts) for this metal? (c) Data from experiments like this are often

Figure **38.35** Exercise 38.10.

graphed showing K_{max} as a function of $1/\lambda$. Make a *qualitative* (no numbers) sketch of what this graph would look like. Identify the threshold wavelength (λ_0) on your sketch. What advantages are there to graphing the data this way?

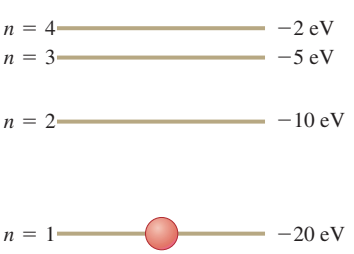
38.11. (a) A proton is moving at a speed much slower than the speed of light. It has kinetic energy K_1 and momentum p_1. If the momentum of the proton is doubled, so $p_2 = 2p_1$, how is its new kinetic energy K_2 related to K_1? (b) A photon with energy E_1 has momentum p_1. If another photon has momentum p_2 that is twice p_1, how is the energy E_2 of the second photon related to E_1?

38.12. The photoelectric work function of potassium is 2.3 eV. If light having a wavelength of 250 nm falls on potassium, find (a) the stopping potential in volts; (b) the kinetic energy in electron volts of the most energetic electrons ejected; (c) the speed of these electrons.

38.13. When ultraviolet light with a wavelength of 254 nm falls on a clean copper surface, the stopping potential necessary to stop emission of photoelectrons is 0.181 V. (a) What is the photoelectric threshold wavelength for this copper surface? (b) What is the work function for this surface, and how does your calculated value compare with that given in Table 38.1?

38.14. A photon has momentum of magnitude $8.24 \times 10^{-28}\,\text{kg} \cdot \text{m/s}$. (a) What is the energy of this photon? Give your answer in joules and in electron volts. (b) What is the wavelength of this photon? In what region of the electromagnetic spectrum does it lie?

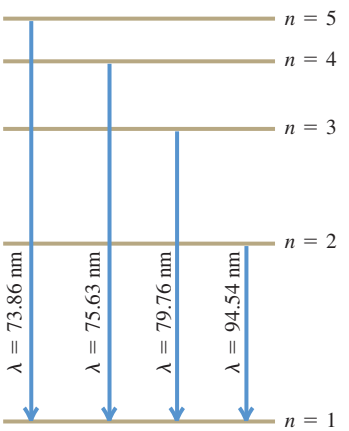
Section 38.3 Atomic Line Spectra and Energy Levels



38.15. Use Balmer's formula to calculate (a) the wavelength, (b) the frequency, and (c) the photon energy for the H_γ line of the Balmer series for hydrogen.

38.16. Find the longest and shortest wavelengths in the Lyman and Paschen series for hydrogen. In what region of the electromagnetic spectrum does each series lie?

38.17. (a) An atom initially in an energy level with $E = -6.52$ eV absorbs a photon that has wavelength 860 nm. What is the internal energy of the atom after it absorbs the photon? (b) An atom initially in an energy level with $E = -2.68$ eV emits a photon that has wavelength 420 nm. What is the internal energy of the atom after it emits the photon?



38.18. The energy-level scheme for the hypothetical one-electron element Searsium is shown in Fig. 38.36. The potential energy is taken to be zero for an electron at an infinite distance from the nucleus. (a) How much energy (in electron volts) does it take to ionise an electron from the ground level? (b) An 18 eV photon is absorbed by a Searsium atom in its ground level. As the atom returns to its ground level, what possible energies can the emitted photons have? Assume that there can be transitions between all pairs of levels. (c) What will happen if a photon with an energy of 8 eV strikes a Searsium atom in its ground level? Why? (d) Photons emitted in the Searsium transitions $n = 3 \rightarrow n = 2$ and $n = 3 \rightarrow n = 1$ will eject photoelectrons from an unknown metal, but the photon emitted from the transition $n = 4 \rightarrow n = 3$ will not. What are the limits (maximum and minimum possible values) of the work function of the metal?

Figure 38.36 Exercise 38.18.

38.19. In a set of experiments on a hypothetical one-electron atom, you measure the wavelengths of the photons emitted from transitions ending in the ground state $(n = 1)$, as shown in the energy-level diagram in Fig. 38.37. You also observe that it takes 17.50 eV to ionise this atom. (a) What is the energy of the atom in each of the levels $(n = 1, n = 2,$ etc.) shown in the figure? (b) If an electron made a transition from the $n = 4$ to the $n = 2$ level what wavelength of light would it emit?

Figure 38.37 Exercise 38.19.

Section 38.4 The Nuclear Atom

38.20. A 4.78 MeV alpha particle from a ^{226}Ra decay makes a head-on collision with a uranium nucleus. A uranium nucleus has 92 protons. (a) What is the distance of closest approach of the alpha particle to the centre of the nucleus? Assume that the uranium nucleus remains at rest and that the distance of closest approach is much greater than the radius of the uranium nucleus. (b) What is the force on the alpha particle at the instant when it is at the distance of closest approach?

38.21. A beam of alpha particles is incident on a target of lead. A particular alpha particle comes in 'head-on' to a particular lead nucleus and stops 6.50×10^{-14} m away from the centre of the nucleus. (This point is well outside the nucleus.) Assume that the lead nucleus, which has 82 protons, remains at rest. The mass of the alpha particle is 6.64×10^{-27} kg. (a) Calculate the electrostatic potential energy at the instant that the alpha particle stops. Express your result in joules and in MeV. (b) What initial kinetic energy (in joules and in MeV) did the alpha particle have? (c) What was the initial speed of the alpha particle?

Section 38.5 The Bohr Model

38.22. (a) What is the angular momentum L of the electron in a hydrogen atom, with respect to an origin at the nucleus, when the atom is in its lowest energy level? (b) Repeat part (a) for the ground level of He^+. Compare to the answer in part (a).

38.23. A hydrogen atom is in a state with energy -1.51 eV. In the Bohr model, what is the angular momentum of the electron in the atom, with respect to an axis at the nucleus?

38.24. A hydrogen atom initially in the ground level absorbs a photon, which excites it to the $n = 4$ level. Determine the wavelength and frequency of the photon.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

38.25. A triply ionised beryllium ion, Be^{3+} (a beryllium atom with three electrons removed), behaves very much like a hydrogen atom except that the nuclear charge is four times as great. (a) What is the ground-level energy of Be^{3+}? How does this compare to the ground-level energy of the hydrogen atom? (b) What is the ionisation energy of Be^{3+}? How does this compare to the ionisation energy of the hydrogen atom? (c) For the hydrogen atom the wavelength of the photon emitted in the $n = 2$ to $n = 1$ transition is 122 nm (see Example 38.6). What is the wavelength of the photon emitted when a Be^{3+} ion undergoes this transition? (d) For a given value of n, how does the radius of an orbit in Be^{3+} compare to that for hydrogen?

38.26. A hydrogen atom undergoes a transition from the $n = 5$ to the $n = 2$ state. (a) What are the energy and wavelength of the photon that is emitted? (b) If the angular momentum is conserved and if the Bohr model is used to describe the atom, what must the angular momentum be of the photon that is emitted? (As we will see in Chapter 41, the modern quantum-mechanical description of the hydrogen atom gives a different result.)

38.27. (a) Using the Bohr model, calculate the speed of the electron in a hydrogen atom in the $n = 1$, 2 and 3 levels. (b) Calculate the orbital period in each of these levels. (c) The average lifetime of the first excited level of a hydrogen atom is 1.0×10^{-8} s. In the Bohr model, how many orbits does an electron in the $n = 2$ level complete before returning to the ground level?

38.28. (a) Show that, as n gets very large, the energy levels of the hydrogen atom get closer and closer together in energy. (b) Do the radii of these energy levels also get closer together?

Section 38.6 The Laser

38.29. How many photons per second are emitted by a 7.50 mW CO_2 laser that has a wavelength of 10.6 μm?

38.30. Photorefractive keratectomy (PRK) is a laser-based surgical procedure that corrects near- and farsightedness by removing part on the lens of the eye to change its curvature and hence focal length. This procedure can remove layers 0.25 μm thick using pulses lasting 12.0 ns from a laser beam of wavelength 193 nm. Low-intensity beams can be used because each individual photon has enough energy to break the covalent bonds of the tissue. (a) In what part of the electromagnetic spectrum does this light lie? (b) What is the energy of a single photon? (c) If a 1.50 mW beam is used, how many photons are delivered to the lens in each pulse?

38.31. A large number of neon atoms are in thermal equilibrium. What is the ratio of the number of atoms in a 5s state to the number in a 3p state at (a) 300 K; (b) 600 K; (c) 1200 K? The energies of these states are shown in Fig. 38.24a. (d) At any of these temperatures, the rate at which a neon gas will spontaneously emit 632.8-nm radiation is quite low. Explain why.

38.32. Figure 38.10 a shows the energy levels of the sodium atom. The two lowest excited levels are shown in columns labelled $^2P_{3/2}$ and $^2P_{1/2}$. Find the ratio of the number of atoms in a $^2P_{3/2}$ state to the number in a $^2P_{1/2}$ state for a sodium gas in thermal equilibrium at 500 K. In which state are more atoms found?

Section 38.7 X-ray Production and Scattering

38.33. Protons are accelerated from rest by a potential difference of 4.00 kV and strike a metal target. If a proton produces one photon on impact, what is the minimum wavelength of the resulting x-rays? How does your answer compare to the minimum wavelength if 4.00-keV electrons are used instead? Why do x-ray tubes use electrons rather than protons to produce x-rays?

38.34. (a) What is the minimum potential difference between the filament and the target of an x-ray tube if the tube is to produce x-rays with a wavelength of 0.150 nm? (b) What is the shortest wavelength produced in an x-ray tube operated at 30.0 kV?

38.35. Accelerating voltages in cathode-ray-tube (CRT) TVs are about 25.0 kV. What are (a) the highest frequency and (b) the shortest wavelength (in nm) of the x-rays that such a TV screen could produce? (c) What assumptions did you need to make? (CRT televisions contain shielding to absorb these x-rays.)

38.36. x-rays are produced in a tube operating at 18.0 kV. After emerging from the tube, x-rays with the minimum wavelength produced strike a target and are Compton-scattered through an angle of 45.0°. (a) What is the original x-ray wavelength? (b) What is the wavelength of the scattered x-rays? (c) What is the energy of the scattered x-rays (in electron volts)?

38.37. x-rays with initial wavelength 0.0665 nm undergo Compton scattering. What is the longest wavelength found in the scattered x-rays? At which scattering angle is this wavelength observed?

38.38. A beam of x-rays with wavelength 0.0500 nm is Compton-scattered by the electrons in a sample. At what angle from the incident beam should you look to find x-rays with a wavelength of (a) 0.0542 nm; (b) 0.0521 nm; (c) 0.0500 nm?

38.39. If a photon of wavelength 0.04250 nm strikes a free electron and is scattered at an angle of 35.0° from its original direction, find (a) the change in the wavelength of this photon; (b) the wavelength of the scattered light; (c) the change in energy of the photon (is it a loss or a gain?); (d) the energy gained by the electron.

38.40. A photon scatters in the backward direction ($\phi = 180°$) from a free proton that is initially at rest. What must the wavelength of the incident photon be if it is to undergo a 10.0% change in wavelength as a result of the scattering?

38.41. Complete the derivation of the Compton-scattering formula, Eq. (38.23), following the outline given in Eqs (38.24) through (38.27).

Section 38.8 Continuous Spectra

38.42. Determine λ_m, the wavelength at the peak of the Planck distribution, and the corresponding frequency f, at these temperatures: (a) 3.00 K; (b) 300 K; (c) 3000 K.

38.43. A 100 W incandescent light bulb has a cylindrical tungsten filament 30.0 cm long, 0.40 mm in diameter, and with an emissivity of 0.26. (a) What is the temperature of the filament? (b) For what wavelength does the spectral emittance of the bulb peak? (c) Incandescent light bulbs are not very efficient sources of visible light. Explain why this is so.

38.44. The shortest visible wavelength is about 400 nm. What is the temperature of an ideal radiator whose spectral emittance peaks at this wavelength?

38.45. Radiation has been detected from space that is characteristic of an ideal radiator at $T = 2.728$ K. (This radiation is a relic of the Big Bang at the beginning of the universe.) For this temperature, at what wavelength does the Planck distribution peak? In what part of the electromagnetic spectrum is this wavelength?

38.46. Two stars, both of which behave like ideal blackbodies, radiate the same total energy per second. The cooler one has a surface temperature T and 3.0 times the diameter of the hotter star. (a) What is the temperature of the hotter star in terms of T? (b) What is the ratio of the peak-intensity wavelength of the hot star to the peak-intensity wavelength of the cool star?

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

38.47. (a) Show that the maximum in the Planck distribution, Eq. (38.32), occurs at a wavelength λ_m given by $\lambda_m = hc/4.965kT$ (Eq. 38.33). As discussed in the text, 4.965 is the root of Eq. (38.34). (b) Evaluate the constants in the expression derived in part (a) to show that $\lambda_m T$ has the numerical value given in the Wien displacement law, Eq. (38.30).

38.48. The brightest star in the sky is Sirius, the Dog Star. It is actually a binary system of two stars, the smaller one (Sirius B) being a white dwarf. Spectral analysis of Sirius B indicates that its surface temperature is 24 000 K and that it radiates energy at a total rate of 1.0×10^{25} W. Assume that it behaves like an ideal blackbody. (a) What is the total radiated intensity of Sirius B? (b) What is the peak-intensity wavelength? Is this wavelength visible to humans? (c) What is the radius of Sirius B? Express your answer in kilometres and as a fraction of our sun's radius. (d) Which star radiates more *total* energy per second, the hot Sirius B or the (relatively) cool sun with a surface temperature of 5800 K? To find out, calculate the ratio of the total power radiated by our sun to the power radiated by Sirius B.

38.49. Show that for large values of λ the Planck distribution, Eq. (38.32), agrees with the Rayleigh distribution, Eq. (38.31).

38.50. A typical blue supergiant star (the type that explode and leave behind black holes) has a surface temperature of 30 000 K and a visual luminosity 100 000 times that of our sun. Our sun radiates at the rate of 3.86×10^{26} W. (Visual luminosity is the total power radiated at visible wavelengths.) (a) Assuming that this star behaves like an ideal blackbody, what is the principal wavelength it radiates? Is this light visible? Use your answer to explain why these stars are blue. (b) If we assume that the power radiated by the star is also 100 000 times that of our sun, what is the radius of this star? Compare its size to that of our sun, which has a radius of 6.96×10^5 km. (c) Is it really correct to say that the visual luminosity is proportional to the total power radiated? Explain.

Problems

38.51. The light-sensitive compound on most photographic films is silver bromide, AgBr. A film is 'exposed' when the light energy absorbed dissociates this molecule into its atoms. (The actual process is more complex, but the quantitative result does not differ greatly.) The energy of dissociation of AgBr is 1.00×10^5 J/mol. For a photon that is just able to dissociate a molecule of silver bromide, find (a) the photon energy in electron volts; (b) the wavelength of the photon; (c) the frequency of the photon. (d) What is the energy in electron volts of a photon having a frequency of 100 MHz? (e) Light from a firefly can expose photographic film, but the radiation from an FM station broadcasting 50 000 W at 100 MHz cannot. Explain why this is so.

38.52. An atom with mass m emits a photon of wavelength λ. (a) What is the recoil speed of the atom? (b) What is the kinetic energy K of the recoiling atom? (c) Find the ratio K/E, where E is the energy of the emitted photon. If this ratio is much less than unity, the recoil of the atom can be neglected in the emission process. Is the recoil of the atom more important for small or large atomic masses? For long or short wavelengths? (d) Calculate K (in electron volts) and K/E for a hydrogen atom (mass 1.67×10^{-27} kg) that emits an ultraviolet photon of energy 10.2 eV. Is recoil an important consideration in this emission process?

38.53. When a certain photoelectric surface is illuminated with light of different wavelengths, the following stopping potentials are observed:

Wavelength (nm)	Stopping potential (V)
366	1.48
405	1.15
436	0.93
492	0.62
546	0.36
579	0.24

Plot the stopping potential on the vertical axis against the frequency of the light on the horizontal axis. Determine (a) the threshold frequency; (b) the threshold wavelength; (c) the photoelectric work function of the material (in electron volts); (d) the value of Planck's constant h (assuming that the value of e is known).

38.54. (a) If the average frequency emitted by a 200 W light bulb is 5.00×10^{14} Hz, and 10.0% of the input power is emitted as visible light, approximately how many visible-light photons are emitted per second? (b) At what distance would this correspond to 1.00×10^{11} visible-light photons per square centimetre per second if the light is emitted uniformly in all directions?

38.55. (a) The wavelength of light incident on a metal surface is reduced from λ_1 to λ_2. (Both λ_1 and λ_2 are less than the threshold wavelength for the surface.) When the wavelength is reduced in this way, what is the change in the stopping potential for photoelectrons emitted from the surface? (b) Evaluate the change in stopping potential for $\lambda_1 = 295$ nm and $\lambda_2 = 265$ nm.

38.56. A 2.50 W beam of light of wavelength 124 nm falls on a metal surface. You observe that the maximum kinetic energy of the ejected electrons is 4.16 eV. Assume that each photon in the beam ejects a photoelectron. (a) What is the work function (in electron volts) of this metal? (b) How many photoelectrons are ejected each second from this metal? (c) If the power of the light beam, but not its wavelength, were reduced by half, what would be the answer to part (b)? (d) If the wavelength of the beam, but not its power, were reduced by half, what would be the answer to part (b)?

38.57. A pulsed dye laser emits light of wavelength 585 nm in 450 μs pulses. Because this wavelength is strongly absorbed by the haemoglobin in the blood, the method is especially effective for removing various types of blemishes due to blood, such as port-wine–coloured birth-marks. To get a reasonable estimate of the power required for such laser surgery, we can model the blood as having the same specific heat and heat of vaporisation as water $(4190\ \text{J/kg} \cdot \text{K}, 2.256 \times 10^6\ \text{J/kg})$. Suppose that each pulse must remove 2.0 μg of blood by evaporating it, starting at 33°C. (a) How much energy must each pulse deliver to the blemish? (b) What must be the power output of this laser? (c) How many photons does each pulse deliver to the blemish?

38.58. The photoelectric work functions for particular samples of certain metals are as follows: cesium, 2.1 eV; copper, 4.7 eV; potassium, 2.3 eV; and zinc, 4.3 eV. (a) What is the threshold wavelength for each metal surface? (b) Which of these metals could *not* emit photoelectrons when irradiated with visible light (400–700 nm)?

38.59. The negative muon has a charge equal to that of an electron but a mass that is 207 times as great. Consider a hydrogenlike atom consisting of a proton and a muon. (a) What is the reduced mass of the atom? (b) What is the ground-level energy (in electron volts)? (c) What is the wavelength of the radiation emitted in the transition from the $n = 2$ level to the $n = 1$ level?

38.60. An incident x-ray photon is scattered from a free electron that is initially at rest. The photon is scattered straight back at an angle of 180° from its initial direction. The wavelength of the

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

scattered photon is 0.0830 nm. (a) What is the wavelength of the incident photon? (b) What is the magnitude of the momentum of the electron after the collision? (c) What is the kinetic energy of the electron after the collision?

38.61. An incident x-ray photon of wavelength 0.0900 nm is scattered in the backward direction from a free electron that is initially at rest. (a) What is the magnitude of the momentum of the scattered photon? (b) What is the kinetic energy of the electron after the photon is scattered?

38.62. A 20.0 kg satellite circles the earth once every 2.00 h in an orbit having a radius of 8060 km. (a) Assuming that Bohr's angular-momentum result $(L = nh/2\pi)$ applies to satellites just as it does to an electron in the hydrogen atom, find the quantum number n of the orbit of the satellite. (b) Show from Bohr's angular momentum result and Newton's law of gravitation that the radius of an earth-satellite orbit is directly proportional to the square of the quantum number, $r = kn^2$, where k is the constant of proportionality. (c) Using the result from part (b), find the distance between the orbit of the satellite in this problem and its next 'allowed' orbit. (Calculate a numerical value.) (d) Comment on the possibility of observing the separation of the two adjacent orbits. (e) Do quantised and classical orbits correspond for this satellite? Which is the 'correct' method for calculating the orbits?

38.63. (a) What is the smallest amount of energy in electron volts that must be given to a hydrogen atom initially in its ground level so that it can emit the H_α line in the Balmer series? (b) How many different possibilities of spectral-line emissions are there for this atom when the electron starts in the $n = 3$ level and eventually ends up in the ground level? Calculate the wavelength of the emitted photon in each case.

38.64. A large number of hydrogen atoms are in thermal equilibrium. Let n_2/n_1 be the ratio of the number of atoms in an $n = 2$ excited state to the number of atoms in an $n = 1$ ground state. At what temperature is n_2/n_1 equal to (a) 10^{-12}; (b) 10^{-8}; (c) 10^{-4}? (d) Like the sun, other stars have continuous spectra with dark absorption lines (see Fig. 38.12). The absorption takes place in the star's atmosphere, which in all stars is composed primarily of hydrogen. Explain why the Balmer absorption lines are relatively weak in stars with low atmospheric temperatures such as the sun (atmosphere temperature 5800 K) but strong in stars with higher atmospheric temperatures.

38.65. A sample of hydrogen atoms is irradiated with light with wavelength 85.5 nm, and electrons are observed leaving the gas. (a) If each hydrogen atom were initially in its ground level, what would be the maximum kinetic energy in electron volts of these photoelectrons? (b) A few electrons are detected with energies as much as 10.2 eV greater than the maximum kinetic energy calculated in part (a). How can this be?

38.66. Light from an ideal spherical blackbody 15.0 cm in diameter is analysed using a diffraction grating having 3850 lines/cm. When you shine this light through the grating, you observe that the peak-intensity wavelength forms a first-order bright fringe at $\pm 11.6°$ from the central bright fringe. (a) What is the temperature of the blackbody? (b) How long will it take this sphere to radiate 12.0 MJ of energy?

38.67. The red giant Betelgeuse has a surface temperature of 3000 K and is 600 times the diameter of our sun. (If our sun were that large, we would be inside it!) Assume that it radiates like an ideal blackbody. (a) If Betelgeuse were to radiate all of its energy at the peak-intensity wavelength, how many photons per second would it radiate? (b) Find the ratio of the power radiated by Betelgeuse to the power radiated by our sun (at 5800 K).

38.68. An ideal spherical blackbody 24.0 cm in diameter is maintained at 225°C by an internal electrical heater and is immersed in a very large open-faced tank of water that is kept boiling by the energy radiated by the sphere. You can neglect any heat transferred by conduction and convection. Consult Table 17.4 as needed. (a) At what rate, in g/s, is water evapourating from the tank? (b) If a physics-wise thermophile organism living in the hot water is observing this process, what will it measure for the peak-intensity (i) wavelength and (ii) frequency of the electromagnetic waves emitted by the sphere?

38.69. What must be the temperature of an ideal blackbody so that photons of its radiated light having the peak-intensity wavelength can excite the electron in the Bohr-model hydrogen atom from the ground state to the third excited state?

38.70. An x-ray tube is operating at voltage V and current I. (a) If only a fraction p of the electric power supplied is converted into x-rays, at what rate is energy being delivered to the target? (b) If the target has mass m and specific heat capacity c (in $J/kg \cdot K$), at what average rate would its temperature rise if there were no thermal losses? (c) Evaluate your results from parts (a) and (b) for an x-ray tube operating at 18.0 kV and 60.0 mA that converts 1.0% of the electric power into x-rays. Assume that the 0.250 kg target is made of lead $(c = 130\ J/kg \cdot K)$. (d) What must the physical properties of a practical target material be? What would be some suitable target elements?

38.71. When a photon is emitted by an atom, the atom must recoil to conserve momentum. This means that the photon and the recoiling atom share the transition energy. (a) For an atom with mass m, calculate the correction $\Delta\lambda$ due to recoil to the wavelength of an emitted photon. Let λ be the wavelength of the photon if recoil is not taken into consideration. (*Hint:* The correction is very small, as Problem 38.52 suggests, so $|\Delta\lambda|/\lambda \ll 1$. Use this fact to obtain an approximate but very accurate expression for $\Delta\lambda$.) (b) Evaluate the correction for a hydrogen atom in which an electron in the nth level returns to the ground level. How does the answer depend on n?

38.72. (a) Derive an expression for the total shift in photon wavelength after two successive Compton scatterings from electrons at rest. The photon is scattered by an angle θ_1 in the first scattering and by θ_2 in the second. (b) In general, is the total shift in wavelength produced by two successive scatterings of an angle $\theta/2$ the same as by a single scattering of θ? If not, are there any specific values of θ, other than $\theta = 0°$, for which the total shifts are the same? (c) Use the result of part (a) to calculate the total wavelength shift produced by two successive Compton scatterings of 30.0° each. Express your answer in terms of h/mc. (d) What is the wavelength shift produced by a single Compton scattering of 60.0°? Compare to the answer in part (c).

38.73. Nuclear fusion reactions at the centre of the sun produce gamma-ray photons with energies of order 1 MeV $(10^6\ eV)$. By contrast, what we see emanating from the sun's surface are visible-light photons with wavelengths of order 500 nm. A simple model that explains this difference in wavelength is that a photon undergoes Compton scattering many times—in fact, about 10^{26} times, as suggested by models of the solar interior—as it travels from the centre of the sun to its surface. (a) Estimate the increase in wavelength of a photon in an average Compton-scattering event. (b) Find the angle in degrees through which the photon is scattered in the scattering event described in part (a). (*Hint:* A useful approximation is $\cos\phi \approx 1 - \phi^2/2$, which is valid for $\phi \ll 1$. Note that ϕ is in radians in this expression.) (c) It is estimated that a photon takes about 10^6 years to travel from the core to the surface of the sun. Find the average distance that light can travel within the

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

interior of the sun without being scattered. (This distance is roughly equivalent to how far you could see if you were inside the sun and could survive the extreme temperatures there. As your answer shows, the interior of the sun is *very* opaque.)

38.74. An x-ray photon is scattered from a free electron (mass m) at rest. The wavelength of the scattered photon is λ', and the final speed of the struck electron is v. (a) What was the initial wavelength λ of the photon? Express your answer in terms of λ', v, and m. (*Hint:* Use the relativistic expression for the electron kinetic energy.) (b) Through what angle ϕ is the photon scattered? Express your answer in terms of λ, λ', and m. (c) Evaluate your results in parts (a) and (b) for a wavelength of 5.10×10^{-3} nm for the scattered photon and a final electron speed of 1.80×10^8 m/s. Give ϕ in degrees.

38.75. A photon with wavelength 0.1100 nm collides with a free electron that is initially at rest. After the collision the wavelength is 0.1132 nm. (a) What is the kinetic energy of the electron after the collision? What is its speed? (b) If the electron is suddenly stopped (for example, in a solid target), all of its kinetic energy is used to create a photon. What is the wavelength of this photon?

38.76. (a) Calculate the maximum increase in photon wavelength that can occur during Compton scattering. (b) What is the energy (in electron volts) of the lowest-energy x-ray photon for which Compton scattering could result in doubling the original wavelength?

38.77. (a) Write the Planck distribution law in terms of the frequency f rather than the wavelength λ, to obtain $I(f)$. (b) Show that

$$\int_0^\infty I(\lambda)\, d\lambda = \frac{2\pi^5 k^4}{15c^2h^3}\, T^4$$

where $I(\lambda)$ is the Planck distribution formula of Eq. (38.32). (*Hint:* Change the integration variable from λ to f.) You will need to use the following tabulated integral:

$$\int_0^\infty \frac{x^3}{e^{\alpha x} - 1}\, dx = \frac{1}{240}\left(\frac{2\pi}{\alpha}\right)^4$$

(c) The result of (b) is I and has the form of the Stefan-Boltzmann law, $I = \sigma T^4$ (Eq. 38.28). Evaluate the constants in (b) to show that σ has the value given in Section 38.8.

38.78. A large cavity with a very small hole and maintained at a temperature T is a good approximation to an ideal radiator or blackbody. Radiation can pass into or out of the cavity only through the hole. The cavity is a perfect absorber, since any radiation incident on the hole becomes trapped inside the cavity. Such a cavity at 200°C has a hole with area 4.00 mm^2. How long does it take for the cavity to radiate 100 J of energy through the hole?

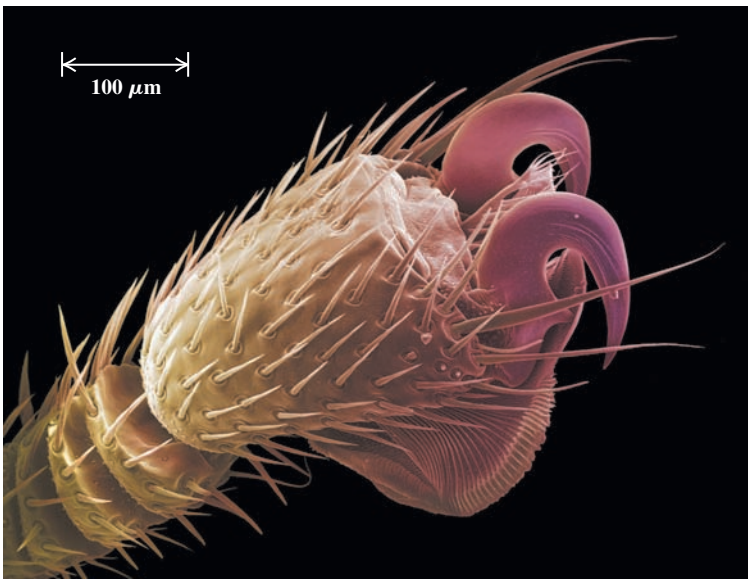
Challenge Problems

38.79. (a) Show that in the Bohr model, the frequency of revolution of an electron in its circular orbit around a stationary hydrogen nucleus is $f = me^4/4\epsilon_0^2 n^3 h^3$. (b) In classical physics, the frequency of revolution of the electron is equal to the frequency of the radiation that it emits. Show that when n is very large, the frequency of revolution does indeed equal the radiated frequency calculated from Eq. (38.6) for a transition from $n_1 = n + 1$ to $n_2 = n$. (This illustrates Bohr's *correspondence principle*, which is often used as a check on quantum calculations. When n is small, quantum physics gives results that are very different from those of classical physics. When n is large, the differences are not significant, and the two methods then 'correspond.' In fact, when Bohr first tackled the hydrogen atom problem, he sought to determine f as a function of n such that it would correspond to classical results for large n.)

38.80. Consider a beam of monochromatic light with intensity I incident on a perfectly absorbing surface oriented perpendicular to the beam. Use the photon concept to show that the radiation pressure exerted by the light on the surface is given by I/c.

38.81. Consider Compton scattering of a photon by a *moving* electron. Before the collision the photon has wavelength λ and is moving in the $+x$-direction, and the electron is moving in the $-x$-direction with total energy E (including its rest energy mc^2). The photon and electron collide head-on. After the collision, both are moving in the $-x$-direction (that is, the photon has been scattered by 180°). (a) Derive an expression for the wavelength λ' of the scattered photon. Show that if $E \gg mc^2$, where m is the rest mass of the electron, your result reduces to

$$\lambda' = \frac{hc}{E}\left(1 + \frac{m^2c^4\lambda}{4hcE}\right)$$



(b) A beam of infrared radiation from a CO_2 laser $(\lambda = 10.6\ \mu\text{m})$ collides head-on with a beam of electrons, each of total energy $E = 10.0$ GeV $(1\ \text{GeV} = 10^9\ \text{eV})$. Calculate the wavelength λ' of the scattered photons, assuming a 180° scattering angle. (c) What kind of scattered photons are these (infrared, microwave, ultraviolet, etc.)? Can you think of an application of this effect?

39 THE WAVE NATURE OF PARTICLES

? This image of the foot of a bat fly (*Streblidae*) was made using a beam of electrons rather than a light beam. What properties of electrons make them useful for imaging such fine details?

LEARNING GOALS

By studying this chapter, you will be able to explain:

- de Broglie's proposal that electrons, protons and other particles can behave like waves.
- How electron diffraction experiments provided evidence for de Broglie's ideas.
- How the Heisenberg uncertainty principle imposes fundamental limits on what can be measured.
- How electron microscopes can provide much higher magnification than visible-light microscopes.
- About the wave functions that describe the behaviour of particles and the Schrödinger equation that these functions must satisfy.

In preceding chapters we've seen one aspect of nature's wave–particle duality: Light and other electromagnetic radiation sometimes act like waves and sometimes like particles. Interference and diffraction demonstrate wave behaviour, while emission and absorption of photons demonstrate the particle behaviour.

A complete theory should also be able to *predict*, on theoretical grounds, the energy levels of any particular atom. The 1913 Bohr model of the hydrogen atom was a step in this direction. But it combined classical principles with new ideas that were inconsistent with classical theory, and it raised as many questions as it answered. More drastic departures from classical concepts were needed.

A successful drastic departure is *quantum mechanics*, a theory that began to emerge in the 1920s. Besides waves that sometimes act like particles, quantum mechanics extends the concept of wave–particle duality to include particles that sometimes show *wavelike* behaviour. In these situations a particle is modelled as an inherently spread-out entity that can't be described as a point with a perfectly definite position and velocity.

In this chapter we will explore the wavelike nature of matter and some of its applications. We'll also introduce the *Schrödinger equation*, which is as fundamental to quantum mechanics as Newton's laws are to mechanics or as Maxwell's equations are to electromagnetism. In Chapter 40 we'll see how to use this equation to find the possible energy levels of a quantum-mechanical system.

Quantum mechanics is the key to understanding atoms and molecules, including their structure, spectra, chemical behaviour and many other properties. It has the happy effect of restoring unity and symmetry to our description of both particles and radiation. We will learn about quantum mechanics and use its results throughout the remainder of this book.

39.1 de Broglie Waves

A major advance in the understanding of atomic structure began in 1924 with a proposition made by a French physicist and nobleman, Prince Louis de Broglie (pronounced 'de broy'). His reasoning, freely paraphrased, went like this: Nature loves symmetry. Light is dualistic in nature, behaving in some situations like waves and in others like particles. If nature is symmetric, this duality should also hold for matter. Electrons and protons, which we usually think of as *particles*, may in some situations behave like *waves*.

If a particle acts like a wave, it should have a wavelength and a frequency. De Broglie (Fig. 39.1) postulated that a free particle with rest mass m, moving with nonrelativistic speed v, should have a wavelength λ related to its momentum $p = mv$ in exactly the same way as for a photon, as expressed by Eq. (38.5): $\lambda = h/p$. The **de Broglie wavelength** of a particle is then

$$\lambda = \frac{h}{p} = \frac{h}{mv} \qquad \text{(de Broglie wavelength of a particle)} \qquad (39.1)$$

where h is Planck's constant. If the particle's speed is an appreciable fraction of the speed of light c, we use Eq. (37.27) to replace mv in Eq. (39.1) with $\gamma mv = mv/\sqrt{1 - v^2/c^2}$. The frequency f, according to de Broglie, is also related to the particle's energy E in the same way as for a photon, namely,

$$E = hf \qquad (39.2)$$

Thus the relationships of wavelength to momentum and of frequency to energy, in de Broglie's hypothesis, are exactly the same for particles as for photons.

39.1 Louis-Victor de Broglie, the seventh Duke de Broglie (1892–1987), broke with family tradition by choosing a career in physics rather than as a diplomat. His revolutionary proposal that particles have wave characteristics—for which de Broglie won the 1929 Nobel Prize in physics—was published in his doctoral thesis.

CAUTION **Not all photon equations apply to particles with mass** The relationship $E = hf$ must be carefully applied to particles with nonzero rest mass, such as electrons and protons. Unlike a photon, they do *not* travel at speed c, so neither the equation $f = c/\lambda$ nor $E = pc$ applies to them!

To appreciate the enormous significance of de Broglie's proposal, we have to realise that at the time there was no direct experimental evidence that particles have wave characteristics. It is one thing to suggest a new hypothesis to explain experimental observations; it is quite another to propose such a radical departure from established concepts on theoretical grounds alone. But it was clear that a radical idea was needed. The dual nature of electromagnetic radiation had led to adoption of the photon concept, also a radical idea. The limited success in understanding atomic structure indicated that a similar revolution was needed in the mechanics of particles.

De Broglie's hypothesis was the beginning of that revolution. Within a few years after 1924 it was developed by Heisenberg, Schrödinger, Dirac, Born and many others into a detailed theory called **quantum mechanics**. This development was well under way even before direct experimental evidence for the wave properties of particles was found.

Quantum mechanics involves sweeping revisions of our fundamental concepts of the description of matter. A particle is not a geometric point but an entity that is spread out in space. The spatial distribution of a particle is defined by a function called a **wave function**, which is closely analogous to the wave functions we used for mechanical waves in Chapter 15 and for electromagnetic waves in Chapter 32. The wave function for a *free* particle with definite energy has a recurring wave pattern with definite wavelength and frequency. The wave and particle aspects are not inconsistent; the *principle of complementarity*, which we discussed in Section 38.9, tells us that we need both the particle model and the wave model for a complete description of nature.

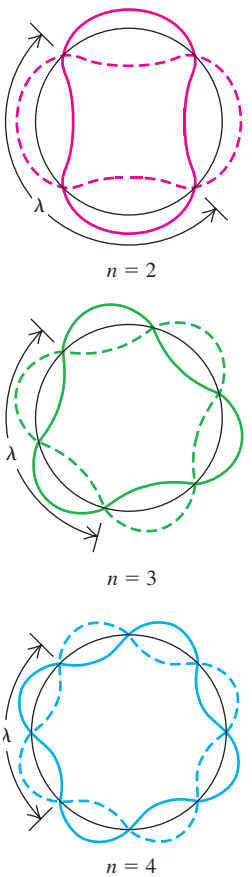
The Bohr Model and de Broglie Waves

In the Bohr model, we pictured the energy levels of the hydrogen atom in terms of definite electron orbits, as shown in Fig. 38.9. This is an oversimplification and should not be taken literally. But the most important idea in Bohr's theory was the existence of discrete energy levels and their relationship to the frequencies of emitted photons. The new quantum mechanics still assigns only certain allowed energy states to an atom, but with a more general description of the electron motion in terms of wave functions. In the hydrogen atom the energy levels predicted by quantum mechanics turn out to be the same as those given by Bohr's theory. In more complicated atoms, for which the Bohr theory does not work, the quantum-mechanical picture is in excellent agreement with observation.

The de Broglie wave hypothesis has an interesting relationship to the Bohr model. We can use Eq. (39.1) to obtain the Bohr quantum condition that the angular momentum $L = mvr$ must be an integer multiple of Planck's constant h. The method is analogous to determining the normal-mode frequencies of standing waves. We discussed this problem in Sections 15.8 and 32.5; the central idea was to satisfy the **boundary conditions** for the waves. For example, for standing waves on a string that is fixed at both ends, the ends are always nodes, and there will be additional nodes along the string for all but the fundamental mode. For the boundary conditions to be satisfied, the total length of the string must equal some *integral* number of half-wavelengths.

A standing wave on a string transmits no energy, and electrons in Bohr's orbits radiate no energy. So think of an electron as a standing wave fitted around a circle in one of the Bohr orbits. For the wave to 'come out even' and join onto itself smoothly, the circumference of this circle must include some *whole number* of wavelengths, as suggested by Fig. 39.2. For an orbit with radius r and circumference $2\pi r$, we must have $2\pi r = n\lambda$, where $n = 1, 2, 3, \ldots$. According to the de Broglie relationship, Eq. (39.1), the wavelength λ of a particle with rest mass m, moving with nonrelativistic speed v, is $\lambda = h/mv$. Combining $2\pi r = n\lambda$ and $\lambda = h/mv$, we find $2\pi r = nh/mv$, or



$$mvr = n\frac{h}{2\pi} \tag{39.3}$$

We recognise Eq. (39.3) as being identical to Eq. (38.10), Bohr's result that the magnitude of the angular momentum $L = mvr$ must equal an integer n times $h/2\pi$. Thus a wave-mechanical picture leads naturally to the quantisation of the electron's angular momentum.

The idea of fitting a standing wave around a circular orbit is a rather vague notion. But the agreement of Eq. (39.3) with Bohr's result is much too remarkable to be a coincidence. It strongly suggests that the wave properties of electrons do indeed have something to do with atomic structure.

Later we will learn how wave functions for specific systems are determined by solution of a wave equation called the Schrödinger equation. Boundary conditions play a central role in finding solutions of this equation and thus in determining possible energy levels, values of angular momentum and other properties.

39.2 Diagrams showing the idea of fitting a standing wave around a circular orbit. For the wave to join onto itself smoothly, the circumference of the orbit must be an integral number n of wavelengths. Examples are shown for $n = 2$, $n = 3$ and $n = 4$.

Problem-Solving Strategy 39.1 Particles and Waves

IDENTIFY *the relevant concepts*: Jarring as it may seem, both particles and light have wavelike properties as well as particlelike properties. The wavelength of a particle is inversely proportional to the momentum, and the frequency is proportional to the energy. These concepts will help you solve many problems involving the wave character of matter.

SET UP *the problem*: As always, determine the target variable and decide which equations you will use to calculate it.

EXECUTE *the solution* as follows:

1. Use Eq. (39.1) to relate the momentum p to the wavelength λ, and use Eq. (39.2) to relate the energy E to the frequency f.

Continued

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

2. Nonrelativistic kinetic energy may be expressed as either $K = \frac{1}{2}mv^2$ or (because $p = mv$) $K = p^2/2m$. The latter form is often useful in calculations involving the de Broglie wavelength.
3. Be careful to use consistent units. Lengths, such as wavelengths, are always in metres if you use the other quantities consistently in SI units. If you want a length in nanometres or some other units, don't forget to convert. As in Chapter 38, energies may be expressed in either joules or electron volts. Depending on your choice, you can use either $h = 6.626 \times 10^{-34}\ \text{J} \cdot \text{s}$ or $h = 4.136 \times 10^{-15}\ \text{eV} \cdot \text{s}$.

EVALUATE *your answer*: To check your numerical results, it helps to remember some typical orders of magnitude for quantities on the atomic scale:

Size of an atom: 10^{-10} m

Mass of an atom: 10^{-26} kg

Mass of an electron: 10^{-30} kg

Energy magnitude of an atomic state: 1 to 10 eV (10^{-19} to 10^{-18} J) (but some interaction energies are much smaller)

Speed of an electron in the Bohr model of a hydrogen atom: 10^6 m/s

Electron charge magnitude: 10^{-19} C

kT at room temperature: $\frac{1}{40}$ eV

You may want to add items to this list. These approximate values will also help you in Chapter 43, in which we will deal with magnitudes that are characteristic of *nuclear* structure rather than atomic structure; these are often different by factors of 10^4 to 10^6.

Example 39.1 Energy of a thermal neutron

Find the speed and kinetic energy of a neutron ($m = 1.675 \times 10^{-27}$ kg) that has a de Broglie wavelength $\lambda = 0.200$ nm, approximately the atomic spacing in many crystals. Compare the energy with the average translational kinetic energy of a gas molecule at room temperature ($T = 20°\text{C} = 293$ K).

SOLUTION

IDENTIFY: This problem uses several relationships: between the wavelength and speed of a particle, between particle speed and kinetic energy, and between the temperature of a gas and the average kinetic energy of a gas molecule.

SET UP: Our target variables are the speed v and kinetic energy K. We determine v using Eq. (39.1), and then calculate the kinetic energy using $K = \frac{1}{2}mv^2$. To find the average kinetic energy of a molecule at temperature T, we use the results of our discussion of kinetic theory in Section 18.3.

EXECUTE: From Eq. (39.1),

$$v = \frac{h}{\lambda m} = \frac{6.626 \times 10^{-34}\ \text{J} \cdot \text{s}}{(0.200 \times 10^{-9}\ \text{m})(1.675 \times 10^{-27}\ \text{kg})} = 1.98 \times 10^3\ \text{m/s}$$

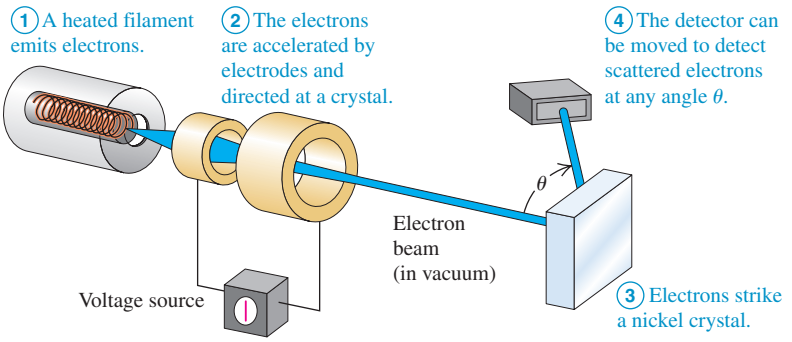
The kinetic energy is

$$K = \frac{1}{2}mv^2 = \frac{1}{2}(1.675 \times 10^{-27}\ \text{kg})(1.98 \times 10^3\ \text{m/s})^2 = 3.28 \times 10^{-21}\ \text{J} = 0.0204\ \text{eV}$$

The average translational kinetic energy of a molecule of an ideal gas is given by Eq. (18.16):

$$\frac{1}{2}m(v^2)_{\text{av}} = \frac{3}{2}kT = \frac{3}{2}(1.38 \times 10^{-23}\ \text{J/K})(293\ \text{K}) = 6.07 \times 10^{-21}\ \text{J} = 0.0397\ \text{eV}$$

The two energies are comparable in magnitude. In fact, a neutron with kinetic energy in this range is called a *thermal neutron*. Diffraction of thermal neutrons, which we'll discuss in the next section, is used to study crystal and molecular structure in the same way as x-ray diffraction. Neutron diffraction has proved to be especially useful in the study of large organic molecules.



EVALUATE: Note that the calculated neutron speed is much less than the speed of light. This justifies our use of the nonrelativistic form of Eq. (39.1).

Test Your Understanding of Section 39.1 A proton has a slightly smaller mass than a neutron. Compared to the neutron described in Example 39.1, would a proton of the same wavelength have (i) more kinetic energy; (ii) less kinetic energy; or (iii) the same kinetic energy?

39.2 Electron Diffraction

De Broglie's wave hypothesis, radical though it seemed, almost immediately received experimental confirmation. The first direct evidence involved a diffraction experiment with electrons that was analogous to the x-ray diffraction experiments that we described in Section 36.6. In those experiments, atoms in a crystal act as a three-dimensional diffraction grating for x-rays. An x-ray beam is strongly reflected when it strikes a crystal at an angle that gives constructive interference among the waves scattered from the various atoms in the crystal. These interference effects demonstrate the *wave* nature of x-rays.

39.3 An apparatus similar to that used by Davisson and Germer to discover electron diffraction.

Observing the Wave Nature of Electrons

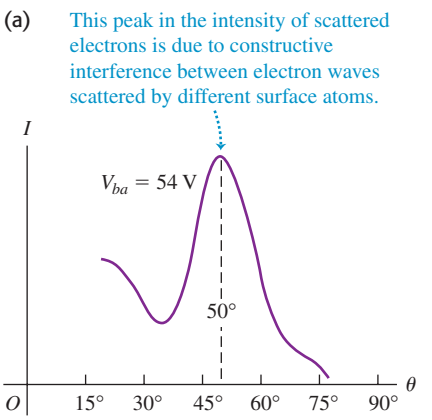
In 1927, Clinton Davisson and Lester Germer, working at the Bell Telephone Laboratories, were studying the surface of a piece of nickel by directing a beam of *electrons* at the surface and observing how many electrons bounced off at various angles. Figure 39.3 shows an experimental setup like theirs. The specimen was *polycrystalline*: Like many ordinary metals, it consisted of many microscopic crystals bonded together with random orientations. The experimenters expected that even the smoothest surface attainable would still look rough to an electron and that the electron beam would be diffusely reflected, with a smooth distribution of intensity as a function of the angle θ.

During the experiment an accident occurred that permitted air to enter the vacuum chamber, and an oxide film formed on the metal surface. To remove this film, Davisson and Germer baked the specimen in a high-temperature oven, almost hot enough to melt it. Unknown to them, this had the effect of creating large single-crystal regions with crystal planes that were continuous over the width of the electron beam.

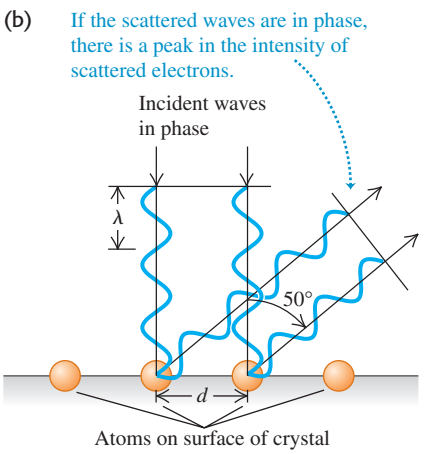
When the observations were repeated, the results were quite different. Strong maxima in the intensity of the reflected electron beam occurred at specific angles (Fig. 39.4a), in contrast to the smooth variation of intensity with angle that Davisson and Germer had observed before the accident. The angular positions of the maxima depended on the accelerating voltage V_{ba} used to produce the electron beam. Davisson and Germer were familiar with de Broglie's hypothesis, and they noticed the similarity of this behaviour to x-ray diffraction. This was not the effect they had been looking for, but they immediately recognised that the electron beam was being *diffracted*. They had discovered a very direct experimental confirmation of the wave hypothesis.

Davisson and Germer could determine the speeds of the electrons from the accelerating voltage, so they could compute the de Broglie wavelength from Eq. (39.1). The electrons were scattered primarily by the planes of atoms at the surface of the crystal. Atoms in a surface plane are arranged in rows, with a distance d that can be measured by x-ray diffraction techniques. These rows act like a reflecting diffraction grating; the angles at which strong reflection occurs are the same as for a grating with centre-to-centre distance d between its slits (Fig. 39.4b). From Eq. (36.13) the angles of maximum reflection are given by

$$d\sin\theta = m\lambda \qquad (m = 1, 2, 3, \ldots) \tag{39.4}$$



where θ is the angle shown in Fig. 39.3. The angles predicted by this equation, using the de Broglie wavelength, were found to agree with the observed values (Fig. 39.4a). Thus the accidental discovery of **electron diffraction** was the first direct evidence confirming de Broglie's hypothesis.



The de Broglie wavelength of a nonrelativistic particle is $\lambda = h/p = h/mv$. We can also express λ in terms of the particle's kinetic energy. For example, consider an electron freely accelerated from rest at point a to point b through a

17.5 Electron Interference

39.4 (a) A graph of intensity of the scattered electron beam shown in Fig. 39.3 as a function of the scattering angle θ. (b) Constructive interference of electron waves scattered from two adjacent atoms occurs when $d\sin\theta = m\lambda$. In the case shown here, $\theta = 50°$ and $m = 1$.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

potential increase $V_b - V_a = V_{ba}$. The work done on the electron eV_{ba} equals its kinetic energy K. Using $K = p^2/2m$, we have

$$eV_{ba} = \frac{p^2}{2m} \qquad p = \sqrt{2meV_{ba}}$$

and the de Broglie wavelength of the electron is

$$\lambda = \frac{h}{p} = \frac{h}{\sqrt{2meV_{ba}}} \qquad \text{(de Broglie wavelength of an electron)} \quad (39.5)$$

Example 39.2 An electron-diffraction experiment

In a particular electron-diffraction experiment using an accelerating voltage of 54 V, an intensity maximum occurs when the angle θ in Fig. 39.3 is 50° (see Fig. 39.4a). The initial kinetic energy of the electrons is negligible. The rows of atoms have been found by x-ray diffraction to have a separation $d = 2.15 \times 10^{-10}$ m = 0.215 nm. Find the electron wavelength.

SOLUTION

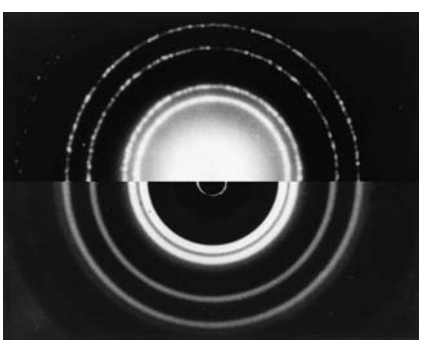
IDENTIFY: This problem uses the relationships among accelerating voltage, electron wavelength, spacing between atoms and angle of maximum reflection for an electron-diffraction experiment.

SET UP: We are given the accelerating voltage $V_{ba} = 54$ V, so we can determine the wavelength λ using Eq. (39.5). We are also given the atomic spacing d and the angle θ for an intensity maximum, so we can also determine λ using Eq. (39.4).

EXECUTE: From Eq. (39.5), the electron wavelength is

$$\lambda = \frac{6.626 \times 10^{-34}\ \text{J} \cdot \text{s}}{\sqrt{2(9.109 \times 10^{-31}\ \text{kg})(1.602 \times 10^{-19}\ \text{C})(54\ \text{V})}} = 1.7 \times 10^{-10}\ \text{m}$$

Alternatively, using Eq. (39.4) and assuming $m = 1$,



$$\lambda = d\sin\theta = (2.15 \times 10^{-10}\ \text{m})\sin 50° = 1.7 \times 10^{-10}\ \text{m}$$

EVALUATE: The two numbers agree within the accuracy of the experimental results, which gives us an excellent check on our calculations. Note that this electron wavelength is less than the spacing between the atoms.

Diffraction of Electrons and Other Particles

39.5 X-ray and electron diffraction. The upper half of the photo shows the diffraction pattern for 71-pm x-rays passing through aluminium foil. The lower half, with a different scale, shows the diffraction pattern for 600 eV electrons from aluminium.

Top: x-ray diffraction

Bottom: electron diffraction

In 1928, just a year after the Davisson-Germer discovery, the English physicist G. P. Thomson carried out electron-diffraction experiments using a thin polycrystalline metallic foil as a target. Debye and Sherrer had used a similar technique several years earlier to study x-ray diffraction from polycrystalline specimens. Because of the random orientations of the individual microscopic crystals in his foil, the diffraction pattern consisted of intensity maxima forming rings around the direction of the incident beam. Thomson's results again confirmed the de Broglie relationship. Figure 39.5 shows both x-ray and electron diffraction patterns for a polycrystalline aluminium foil. (G. P. Thomson was the son of J. J. Thomson, who 31 years earlier had performed the definitive experiment to establish the *particle* nature of electrons.)

Additional experiments were soon carried out in many laboratories. In Germany, Estermann and Stern demonstrated diffraction of alpha particles. Diffraction experiments have also been performed with various ions and low-energy neutrons (see Example 39.1). Thus the wave nature of particles, so strange in 1924, became firmly established in the years that followed.

Test Your Understanding of Section 39.2 Example 39.2 shows that to give electrons a wavelength of 1.7×10^{-10} m, they must be accelerated from rest through a voltage of 54 V and so acquire a kinetic energy of 54 eV. Does a photon of this same energy also have a wavelength of 1.7×10^{-10} m?

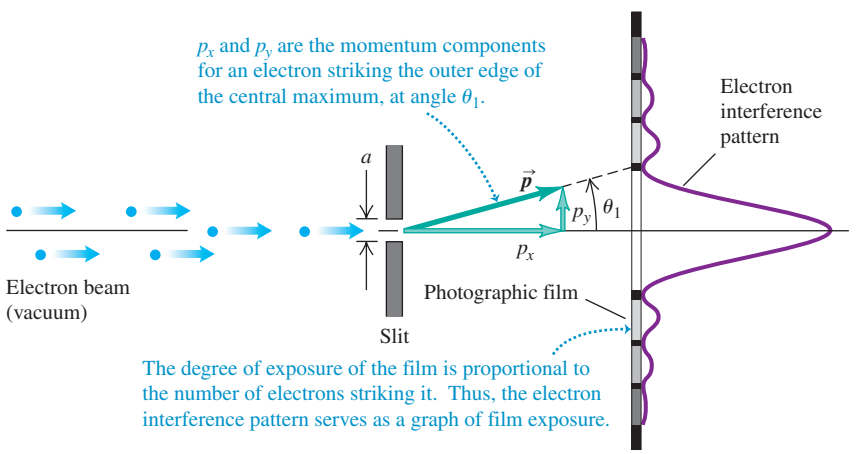
Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

39.3 Probability and Uncertainty

The discovery of the dual wave–particle nature of matter has forced us to reevaluate the kinematic language we use to describe the position and motion of a particle. In classical Newtonian mechanics we think of a particle as a point. We can describe its location and state of motion at any instant with three spatial coordinates and three components of velocity. But in general such a specific description is not possible. When we look on a small enough scale, there are fundamental limitations on the precision with which we can determine the position and velocity of a particle. Many aspects of a particle's behaviour can be stated only in terms of *probabilities*.

17.6 Uncertainty Principle

Single-Slit Diffraction



To try to get some insight into the nature of the problem, let's review the single-slit diffraction of light described in Section 36.2. Suppose the wavelength λ is much less than the slit width a. Then most (85%) of the light in the diffraction pattern is concentrated in the central maximum, bounded on either side by the first intensity minimum. We use θ_1 to denote the angle between the central maximum and the first minimum. Using Eq. (36.2) with $m = 1$, we find that θ_1 is given by $\sin\theta_1 = \lambda/a$. Since we assume $\lambda \ll a$, it follows that θ_1 is very small, $\sin\theta_1$ is very nearly equal to θ_1 (in radians), and

$$\theta_1 = \frac{\lambda}{a} \tag{39.6}$$

Now we perform the same experiment again, but using a beam of *electrons* instead of a beam of monochromatic light (Fig. 39.6). We have to do the experiment in vacuum (10^{-7} atm or less) so that the electrons don't bounce off air molecules. We can produce the electron beam with a setup that is similar in principle to the electron gun in a cathode-ray tube. This produces a narrow beam of electrons that all have very nearly the same direction and speed and therefore also the same de Broglie wavelength.

The result of this experiment, recorded on photographic film or by use of more sophisticated detectors, is a diffraction pattern identical to the one shown in Fig. 39.6. This pattern gives us additional direct evidence of the *wave* nature of electrons. About 85% of the electrons strike the film within the central maximum; the remainder strike the film within the subsidiary maxima on both sides.

If we believe that electrons are waves, the wave behaviour in this experiment isn't surprising. But if we try to interpret it in terms of *particles*, we run into very serious problems. First, the electrons don't all follow the same path, even though they all have the same initial state of motion. In fact, we can't predict the exact

39.6 An electron-diffraction experiment.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

trajectory of any individual electron from knowledge of its initial state. The best we can do is to say that *most* of the electrons go to a certain region, *fewer* go to other regions, and so on. That is, we can describe only the *probability* that an individual electron will strike each of various areas on the film. This fundamental indeterminacy has no counterpart in Newtonian mechanics, in which the motion of a particle can always be well predicted if we know the initial position and motion with sufficient accuracy.

Second, there are fundamental *uncertainties* in both the position and the momentum of an individual particle, and these two uncertainties are related inseparably. To clarify this point, let's go back to Fig. 39.6. An electron that strikes the film at the outer edge of the central maximum, at angle θ_1, must have a component of momentum p_y in the y-direction, as well as a component p_x in the x-direction, despite the fact that initially the beam was directed along the x-axis. From the geometry of the situation the two components are related by $p_y/p_x = \tan\theta_1$. Since θ_1 is small, we may use the approximation $\tan\theta_1 = \theta_1$, and

$$p_y = p_x\theta_1 \tag{39.7}$$

Substituting Eq. (39.6), $\theta_1 = \lambda/a$, we have

$$p_y = p_x\frac{\lambda}{a} \tag{39.8}$$

For the 85% of the electrons that strike the film within the central maximum (that is, at angles between $-\lambda/a$ and $+\lambda/a$), we see that the y-component of momentum is spread out over a range from $-p_x\lambda/a$ to $+p_x\lambda/a$. Now let's consider *all* the electrons that pass through the slit and strike the film. Again, they may hit above or below the centre of the pattern, so their component p_y may be positive or negative. However the symmetry of the diffraction pattern shows us the average value $(p_y)_{\text{av}} = 0$. There will be an *uncertainty* Δp_y in the y-component of momentum at least as great as $p_x\lambda/a$. That is,

$$\Delta p_y \geq p_x\frac{\lambda}{a} \tag{39.9}$$

The narrower the slit width a, the broader is the diffraction pattern and the greater is the uncertainty in the y-component of momentum p_y.

The electron wavelength λ is related to the momentum $p_x = mv_x$ by the de Broglie relationship Eq. (39.1), which we can rewrite as $\lambda = h/p_x$. Using this relationship in Eq. (39.9) and simplifying, we find

$$\begin{aligned}\Delta p_y &\geq p_x\frac{h}{p_x a} = \frac{h}{a}\\ \Delta p_y a &\geq h\end{aligned} \tag{39.10}$$

What does this result mean? The slit width a represents an uncertainty in the y-component of the *position* of an electron as it passes through the slit. We don't know exactly *where* in the slit each particle passes through. So both the y-position and the y-component of momentum have uncertainties, and the two uncertainties are related by Eq. (39.10). We can reduce the *momentum* uncertainty Δp_y only by reducing the width of the diffraction pattern. To do this, we have to increase the slit width a, which increases the *position* uncertainty. Conversely, when we *decrease* the position uncertainty by narrowing the slit, the diffraction pattern broadens and the corresponding momentum uncertainty *increases*.

You may protest that it doesn't seem to be consistent with common sense for a particle not to have a definite position and momentum. We reply that what we call *common sense* is based on familiarity gained through experience. Our usual

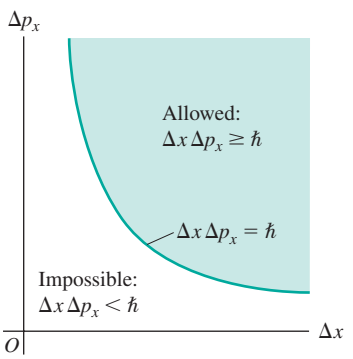
Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

experience includes very little contact with the microscopic behaviour of particles. Sometimes we have to accept conclusions that violate our intuition when we are dealing with areas that are far removed from everyday experience.

The Uncertainty Principle

In more general discussions of uncertainty relationships, the uncertainty of a quantity is usually described in terms of the statistical concept of *standard deviation*, which is a measure of the spread or dispersion of a set of numbers around their average value. Suppose we now begin to describe uncertainties in this way [neither Δp_y nor a in Eq. (39.10) is a standard deviation]. If a coordinate x has an uncertainty Δx and if the corresponding momentum component p_x has an uncertainty Δp_x, then those standard-deviation uncertainties are found to be related in general by the inequality

$$\Delta x \Delta p_x \geq \hbar \qquad \text{(Heisenberg uncertainty principle for position and momentum)} \tag{39.11}$$



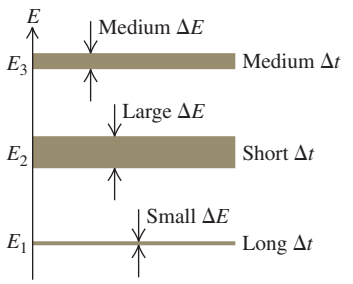
In this expression the quantity $\hbar$ (pronounced 'h-bar') is Planck's constant divided by 2π:

$$\hbar = \frac{h}{2\pi} = 1.05457168(18) \times 10^{-34}\ \text{J} \cdot \text{s} \tag{39.12}$$

We will use this quantity frequently to avoid writing a lot of factors of 2π in later equations.

Equation (39.11) is one form of the **Heisenberg uncertainty principle**, first discovered by the German physicist Werner Heisenberg (1901–1976). It states that, in general, neither the position nor the momentum of a particle can be determined with arbitrarily great precision, as classical physics would predict. Instead, the uncertainties in the two quantities play complementary roles, as we have described. Figure 39.7 shows the relationship between the two uncertainties.

39.7 The Heisenberg uncertainty principle for position and momentum components. It is impossible for the product $\Delta x \Delta p_x$ to be less than $\hbar = h/2\pi$.



It is tempting to suppose that we could get greater precision by using more sophisticated detectors of position and momentum. This turns out not to be possible. To detect a particle, the detector must *interact* with it, and this interaction unavoidably changes the state of motion of the particle, introducing uncertainty about its original state. For example, if we were to bounce shorter-wavelength photons off a particle to better locate its position, the larger photon momentum h/λ would make the particle recoil more, giving us greater uncertainty in its momentum. A more detailed analysis of such hypothetical experiments shows that the uncertainties we have described are fundamental and intrinsic. They *cannot* be circumvented *even in principle* by any experimental technique, no matter how sophisticated.

There is nothing special about the x-axis. In a three-dimensional situation with coordinates (x, y, z) there is an uncertainty relationship for each coordinate and its corresponding momentum component: $\Delta x \Delta p_x \geq \hbar$, $\Delta y \Delta p_y \geq \hbar$ and $\Delta z \Delta p_z \geq \hbar$. However, the uncertainty in one coordinate is *not* related to the uncertainty in a different component of momentum. For example, Δx is not related directly to Δp_y.

For a particle moving along a radius, we can replace x in Eq. (39.11) with r, giving $\Delta r \Delta p_r \geq \hbar$. In the Bohr model, an electron moves in a circle of exact radius r, giving $\Delta r = 0$ and $\Delta p_r = 0$. Thus the Bohr model violates the Heisenberg uncertainty principle. We'll give a more correct description of atomic structure in Chapter 41; happily, it turns out that the energy-level predictions of the Bohr model *are* correct.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

39.8 The longer the lifetime Δt of a state, the smaller is its spread in energy (shown by the width of the energy levels).

Uncertainty in Energy

There is also an uncertainty principle for *energy*. It turns out that the energy of a system also has inherent uncertainty. The uncertainty ΔE depends on the *time interval* Δt during which the system remains in the given state. The relationship is

$$\Delta E \Delta t \geq \hbar \qquad \begin{matrix}\text{(Heisenberg uncertainty principle}\\ \text{for energy and time interval)}\end{matrix} \qquad (39.13)$$

A system that remains in a metastable state for a very long time (large Δt) can have a very well-defined energy (small ΔE), but if it remains in a state for only a short time (small Δt), the uncertainty in energy must be correspondingly greater (large ΔE). Figure 39.8 illustrates this idea.

Example 39.3 The uncertainty principle: momentum and position

An electron is confined within a region of width 1.0×10^{-10} m. (a) Estimate the minimum uncertainty in the x-component of the electron's momentum. (b) If the electron has momentum with magnitude equal to the uncertainty found in part (a), what is its kinetic energy? Express the result in joules and in electron volts.

SOLUTION

IDENTIFY: This problem uses the Heisenberg uncertainty principle for position and momentum, as well as the relationship between a particle's momentum and its kinetic energy.

SET UP: We know that the electron is *somewhere* within the region to which it is confined. Since we don't know exactly where within this region the electron is, the width of the region is the position uncertainty: $\Delta x = 1.0 \times 10^{-10}$ m. (You could argue that the uncertainty should actually be half the width of the region. All we want is an estimate, however, so we won't worry about factors of 2.) We then find the momentum uncertainty Δp_x using Eq. (39.11), and we find the kinetic energy using $K = p^2/2m$.

EXECUTE: (a) For a given value of Δx, there is minimum uncertainty in momentum when the product $\Delta x \Delta p_x$ in Eq. (39.11) is equal to $\hbar$. Using the value of $\hbar$ from Eq. (39.12),

$$(\Delta p_x)_{\text{min}} = \frac{\hbar}{\Delta x} = \frac{1.055 \times 10^{-34}\ \text{J} \cdot \text{s}}{1.0 \times 10^{-10}\ \text{m}} = 1.1 \times 10^{-24}\ \text{kg} \cdot \text{m/s}$$

(b) An electron with this magnitude of momentum has kinetic energy

$$K = \frac{p^2}{2m} = \frac{(1.1 \times 10^{-24}\ \text{kg} \cdot \text{m/s})^2}{2(9.11 \times 10^{-31}\ \text{kg})}$$
$$= 6.1 \times 10^{-19}\ \text{J} = 3.8\ \text{eV}$$

EVALUATE: The region is roughly the same width as an atom, and the energy is of the same order of magnitude as typical electron energies in atoms. This is a very rough calculation, but it is reassuring that the energy has a reasonable order of magnitude.

In a type of radioactive decay called *beta-minus decay*, an electron is emitted from a nucleus. Although it seems reasonable to assume that the electron was confined within the nucleus before the decay, that would require the position of the electron to be known to within an uncertainty of $\Delta x = 10^{-14}$ m or so. But this would give the confined electron a value of Δp_x that is 10^4 times greater than for the electron in this example and an expected kinetic energy so large that we would need to use relativistic equations to calculate it. This high energy is one reason to believe that there are no electrons confined in nuclei. In beta-minus decay the electron is actually *produced* within the nucleus when a neutron changes into a proton.

Example 39.4 The uncertainty principle: energy and time

A sodium atom is in one of the states labelled 'Lowest excited levels' in Fig. 38.10 (Section 38.3). It remains in that state for an average time of 1.6×10^{-8} s before it makes a transition back to a ground state, emitting a photon with wavelength 589.0 nm and energy 2.105 eV. What is the uncertainty in energy of that excited state? What is the wavelength spread of the corresponding spectrum line?

SOLUTION

IDENTIFY: This problem uses the Heisenberg uncertainty principle for energy and time interval, as well as the relationship between the energy and wavelength of a photon.

SET UP: The average time that the atom spends in this excited state is equal to Δt in Eq. (39.13). We find the uncertainty in energy by replacing the $\geq$ sign in Eq. (39.13) with an equals sign and solving for ΔE.

EXECUTE: From Eq. (39.13),

$$\Delta E = \frac{\hbar}{\Delta t} = \frac{1.055 \times 10^{-34}\ \text{J} \cdot \text{s}}{1.6 \times 10^{-8}\ \text{s}}$$
$$= 6.6 \times 10^{-27}\ \text{J} = 4.1 \times 10^{-8}\ \text{eV}$$

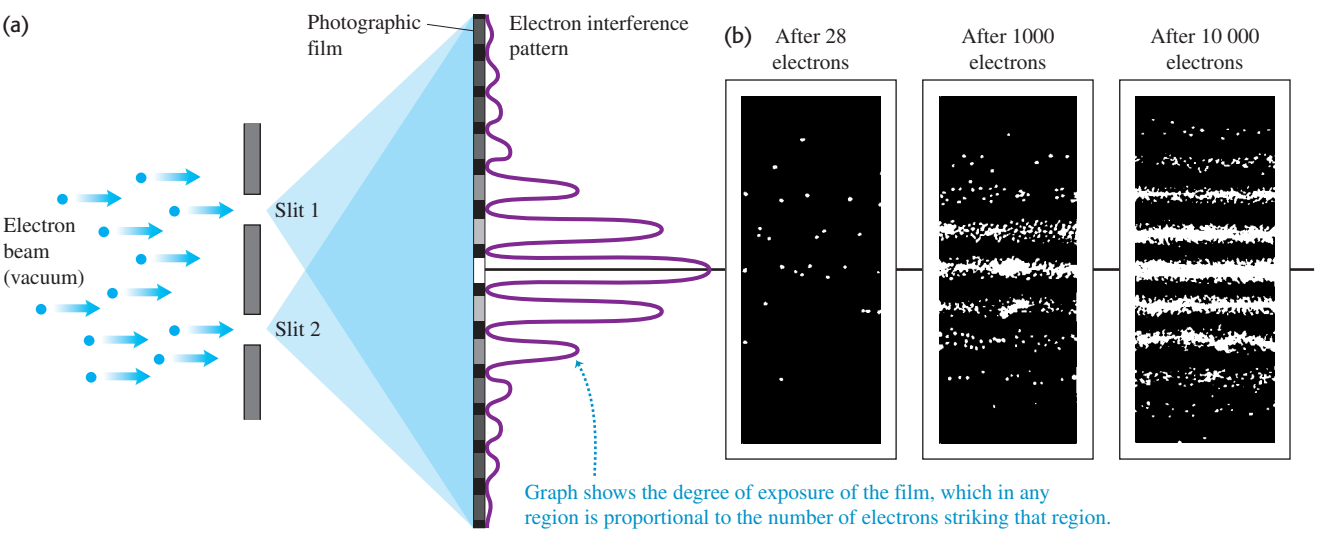
The atom remains an indefinitely long time in the ground state, so there is *no* fundamental uncertainty there. The fractional uncertainty of the photon energy is

$$\frac{4.1 \times 10^{-8}\ \text{eV}}{2.105\ \text{eV}} = 1.95 \times 10^{-8}$$

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

The corresponding spread in wavelength, or 'width', of the spectrum line is approximately

$$\Delta\lambda = (1.95 \times 10^{-8})(589.0\ \text{nm}) = 0.000011\ \text{nm}$$



EVALUATE: The irreducible uncertainty $\Delta\lambda$ that we have calculated is called the *natural line width* of this particular spectral line. Though very small, it is within the limits of resolution of present-day spectrometers. Ordinarily, the natural line width is much smaller than the line width from other causes such as the Doppler effect and collisions among the rapidly moving atoms.

Two-Slit Interference

Now let's take a brief look at a quantum interpretation of a *two-slit* optical interference pattern. We studied these patterns in detail for light in Sections 35.2 and 35.3, and in Section 38.9 we discussed their interpretation in terms of the probability that photons strike various regions of the screen where the pattern is formed.

It is natural to ask what happens when we do a two-slit interference experiment with electrons. The answer is exactly the same thing we saw in Section 38.9 with photons! We can again use photographic film (Fig. 39.9) or electronic detectors to trace out the interference pattern, as we did with photons. The principle of complementarity, introduced in Section 38.9, again tells us that we cannot simultaneously attempt to apply the wave model and the particle model to describe a single part of this experiment. Thus we *cannot* predict exactly where in the pattern (a wave phenomenon) any individual electron (a particle) will land. We can't even ask which slit an individual electron passed through in building up the two-slit interference pattern. If we do determine which slits that the electrons pass through by scattering photons off them, the electrons recoil and the two-slit interference pattern is not built up.

39.9 (a) Formation of an interference pattern for electrons incident on two slits, (b) after 28, 1000 and 10 000 electrons.

Test Your Understanding of Section 39.3 Rank the following situations according to the uncertainty in x-momentum, from largest to smallest. The mass of the proton is 1836 times the mass of the electron. (i) an electron whose x-coordinate is known to within 2×10^{-15} m; (ii) an electron whose x-coordinate is known to within 4×10^{-15} m; (iii) a proton whose x-coordinate is known to within 2×10^{-15} m; (iv) a proton whose x-coordinate is known to within 4×10^{-15} m.

39.4 The Electron Microscope

The **electron microscope** offers an important and interesting example of the interplay of wave and particle properties of electrons. An electron beam can be used to form an image of an object in much the same way as a light beam. A ray of light can be bent by reflection or refraction, and an electron trajectory can be bent by an electric or magnetic field. Rays of light diverging from a point on an object can be brought to convergence by a converging lens or concave mirror, and electrons diverging from a small region can be brought to convergence by electric and/or magnetic fields.

The analogy between light rays and electrons goes deeper. The *ray* model of geometric optics is an approximate representation of the more general *wave* model. Geometric optics (ray optics) is valid whenever interference and diffraction effects can be neglected. Similarly, the model of an electron as a point particle following a line trajectory is an approximate description of the actual behaviour of the electron; this model is useful when we can neglect effects associated with the wave nature of electrons.

How is an electron microscope superior to an optical microscope? The *resolution* of an optical microscope is limited by diffraction effects, as we discussed in Section 36.7. Using wavelengths around 500 nm, an optical microscope can't resolve objects smaller than a few hundred nanometres, no matter how carefully its lenses are made. The resolution of an electron microscope is similarly limited by the wavelengths of the electrons, but these wavelengths may be many thousands of times *smaller* than wavelengths of visible light. As a result, the useful magnification of an electron microscope can be thousands of times as great as that of an optical microscope.

Note that the ability of the electron microscope to form a magnified image *does not* depend on the wave properties of electrons. Within the limitations of the Heisenberg uncertainty principle, we can compute the electron trajectories by treating them as classical charged particles under the action of electric- and magnetic-field forces (in analogy to ray optics). Only when we talk about *resolution* do the wave properties become important.

Example 39.5 An electron microscope

The nonrelativistic electron beam in an electron microscope is formed by a setup similar to the electron gun used in the Davisson-Germer experiment (Fig. 39.3). What accelerating voltage is needed to produce electrons with wavelength 10 pm = 0.010 nm (roughly 50 000 times smaller than typical visible-light wavelengths)? The initial kinetic energy of the electrons is negligible.

SOLUTION

IDENTIFY: Since this situation is similar to the Davisson-Germer experiment, we can use all of the concepts that we developed to understand that experiment.

SET UP: The accelerating voltage (our target variable) is the quantity V_{ba} in Eq. (39.5). We are given the values of all the other quantities in that equation, so we can solve for V_{ba}.

EXECUTE: Solving Eq. (39.5) for V_{ba} and inserting the appropriate numbers, we find

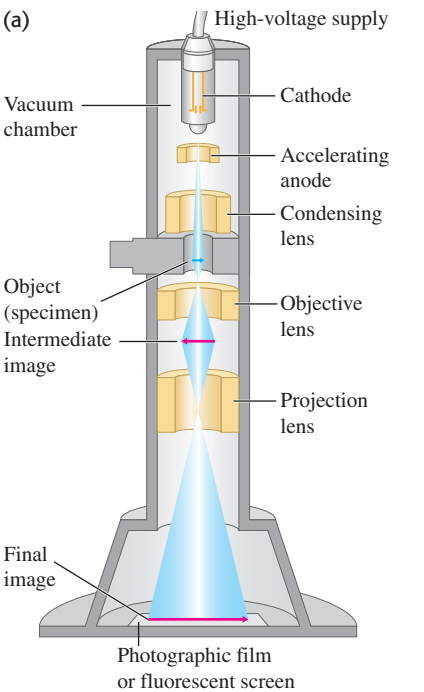
$$V_{ba} = \frac{h^2}{2me\lambda^2}$$

$$= \frac{(6.626 \times 10^{-34}\ \text{J}\cdot\text{s})^2}{2(9.109 \times 10^{-31}\ \text{kg})(1.602 \times 10^{-19}\ \text{C})(10 \times 10^{-12}\ \text{m})^2}$$

$$= 1.5 \times 10^4\ \text{V} = 15{,}000\ \text{V}$$

EVALUATE: This is approximately equal to the accelerating voltage for the electron beam in a TV picture tube. This example shows, incidentally, that the sharpness of a TV picture is *not* limited by electron diffraction effects. Also note that this 15 kV voltage will increase the kinetic energy of the electrons from a relatively small value to 15 keV. Since electrons have a rest energy of 0.511 MeV = 511 keV, we can accurately describe these 15 keV electrons as nonrelativistic.

The Transmission Electron Microscope



Except within their electron guns, most practical electron microscopes use magnetic fields rather than electric fields as 'lenses' for focusing the beam. A common setup for *transmission electron microscopes* includes three such lenses

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

in a compound-microscope arrangement, as shown in Fig. 39.10a. Electrons are emitted from a hot cathode and accelerated by a potential difference, typically 10 to 100 kV. The electrons pass through a condensing lens and are formed into a parallel beam before passing through the specimen or object to be viewed. The specimen to be viewed is very thin, typically 10 to 100 nm, so the electrons are not slowed appreciably as they pass through. The objective lens then forms an intermediate image of this object, and the projection lens produces a final real image of that image. The objective and projection lenses play the roles of the objective and eyepiece lenses, respectively, of a compound optical microscope (see Section 34.8). The final image is recorded on photographic film or projected onto a fluorescent screen for viewing or photographing. The entire apparatus, including the specimen, must be enclosed in a vacuum container, just as with the cathode-ray tube; otherwise, electrons would scatter off air molecules and muddle the image. Figure 39.10b shows an image made with a transmission electron microscope.

We might think that when the electron wavelength is 0.01 nm (as in Example 39.5), the resolution would also be about 0.01 nm. In fact, it is seldom better than 0.5 nm, in part because the focal length of a magnetic lens depends on the electron speed, which is never exactly the same for all electrons in the beam.

39.10 (a) Schematic diagram of a transmission electron microscope (TEM). (b) This TEM image shows a skin cell in the process of dividing into two daughter cells. False colour has been used to show the genetic material (dark green).

The Scanning Electron Microscope

An important variation is the *scanning electron microscope*. The electron beam is focused to a very fine line and is swept across the specimen, just as the electron beam in a TV picture tube traces out the picture. As the beam scans the specimen, electrons are knocked off and are collected by a collecting anode that is kept at a potential a few hundred volts positive with respect to the specimen. The current in the collecting anode is amplified and used to modulate the electron beam in a cathode-ray tube, which is swept in synchronisation with the microscope beam. Thus the cathode-ray tube traces out a greatly magnified image of the specimen. This scheme has several advantages. The specimen can be thick because the beam does not need to pass through it. Also, the knock-off electron production depends on the *angle* at which the beam strikes the surface. Thus scanning electron micrographs have an appearance that is much more three-dimensional than conventional visible-light micrographs. The resolution is typically of the order of 10 nm, still much finer than the best optical microscopes. The image that opens this chapter was made with a scanning electron microscope.

39.5 Wave Functions and the Schrödinger Equation

We have now seen persuasive evidence that on an atomic or subatomic scale, a particle such as an electron cannot be described simply as a point. Instead we use a *wave function* to describe the state of a particle. Let's describe more specifically the kinematic language we must use to replace the classical scheme of describing a particle by its coordinates and velocity components.

Our new scheme for describing the state of a particle has a lot in common with the language of classical wave motion. In Chapter 15, we described transverse waves on a string by specifying the position of each point in the string at each instant of time by means of a *wave function* (see Section 15.3). If y represents the displacement from equilibrium, at time t, of a point on the string at a distance x from the origin, then the function $y(x, t)$ represents the displacement of any point x at any time t. Once we know the wave function for a particular wave motion, we know everything there is to know about the motion. We can find the position and velocity of any point on the string at any time, and so on (Fig. 39.11). We worked out specific forms for these functions for *sinusoidal* waves, in which each particle undergoes simple harmonic motion.

39.11 These children are talking over a cup-and-string 'telephone'. The displacement of the string is completely described by a wave function $y(x, t)$. In an analogous way, a particle is completely described by a quantum-mechanical wave function $\Psi(x, y, z, t)$.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

We followed a similar pattern for sound waves in Chapter 16. The wave function $p(x, t)$ for a wave travelling along the x-direction represented the pressure variation at any point x at any time t. We used this language once more in Section 32.3, where we used *two* wave functions to describe the electric and magnetic fields of *electromagnetic* waves at any point in space at any time.

Thus it is natural to use a wave function as the central element of our new language. The symbol customarily used for this wave function is Ψ or ψ. In general, Ψ is a function of all the space coordinates and time, whereas ψ is a function of the space coordinates only—*not* of time. Just as the wave function $y(x, t)$ for mechanical waves on a string provides a complete description of the motion, so the wave function $\Psi(x, y, z, t)$ for a particle contains all the information that can be known about the particle. The mathematical theory of quantum mechanics describes how to use $\Psi(x, y, z, t)$ to determine the average values of the particle's position, velocity, momentum, energy and angular momentum. The required techniques are beyond the scope of this discussion, but they are well established and well supported by experimental results.

CAUTION **Particle waves vs. mechanical waves** Unlike for mechanical waves on a string or sound waves in air, the wave function for a particle is *not* a mechanical wave that needs some material medium in order to propagate. The wave function describes the particle, but we cannot define the function itself in terms of anything material. We can only describe how it is related to physically observable effects.

Interpretation of the Wave Function

The wave function describes the distribution of a particle in space, just as the wave functions for an electromagnetic wave describe the distribution of the electric and magnetic fields. When we worked out interference and diffraction patterns in Chapters 35 and 36, we found that the intensity I of the radiation at any point in a pattern is proportional to the square of the electric-field magnitude—that is, to E^2. In the photon interpretation of interference and diffraction (see Section 38.9), the intensity at each point is proportional to the number of photons striking around that point or, alternatively, to the *probability* that any individual photon will strike around the point. Thus the square of the electric-field magnitude at each point is proportional to the probability of finding a photon around that point.

In exactly the same way, the square of the wave function of a particle at each point tells us about the probability of finding the particle around that point. More precisely, we should say the square of the *absolute value* of the wave function, $|\Psi|^2$. This is necessary because, as we'll see later, Ψ may be a *complex* quantity with real and imaginary parts. (The imaginary part of the function is a real function multiplied by the imaginary number $i = \sqrt{-1}$.)

For a particle moving in three dimensions, the quantity $|\Psi(x, y, z, t)|^2\, dV$ is the probability that the particle will be found at time t within a volume dV around the point (x, y, z). The particle is most likely to be found in regions where $|\Psi|^2$ is large, and so on. This interpretation, first made by the German physicist Max Born (Fig. 39.12), requires that the wave function Ψ be *normalised*. That is, the integral of $|\Psi|^2\, dV$ over all space must equal exactly 1. In other words, the probability is exactly 1, or 100%, that the particle is *somewhere* in the universe.

39.12 In 1926, the German physicist Max Born (1882–1970) devised the interpretation that $|\Psi|^2\, dV$ is the probability of finding a particle within a given volume dV. He also coined the term 'quantum mechanics' (in the original German, *Quantenmechanik*). For his contributions, Born shared (with Walther Bothe) the 1954 Nobel Prize in physics.

CAUTION **Interpreting $|\Psi|^2$** Note that $|\Psi(x, y, z, t)|^2$ itself is *not* a probability. Rather, $|\Psi(x, y, z, t)|^2\, dV$ is the probability of finding the particle within a volume dV around the point (x, y, z) at time t. If the volume is made smaller, it becomes less likely that the particle will be found within that volume, so the probability decreases. A better name for $|\Psi(x, y, z, t)|^2$ is the **probability distribution function**, since it describes how the probability of finding the particle at different locations is distributed over space.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

Stationary States

In general, the value of $|\Psi(x, y, z, t)|^2$ at a particular point varies with time. This makes sense: As an electron in a television tube flies from the cathode towards the screen, the place it is most likely to be found changes with time. But if the particle is in a state of a definite energy, such as an atomic electron in an atom in a definite energy level, the value of $|\Psi|^2$ at each point is *independent* of time. Because the particle's probability distribution in such a state doesn't change with time, a state with a definite energy is called a **stationary state**. Such states are of tremendous importance in quantum mechanics. For example, for each definite-energy, stationary state in a hydrogen atom, there is a specific wave function. It is possible for an atom to be in a state that is not identical to any one of these stationary-state wave functions and that does not have a definite energy. Nevertheless, the wave function for any state can always be written as a combination of stationary-state wave functions. We saw something similar in Section 15.8: Any standing wave on a string, no matter how complex, can be expressed as a combination of the normal-mode vibrations of the string. We will devote most of Chapter 40 to finding the stationary-state wave functions for different physical situations.

Why *is* $|\Psi|^2$ independent of time if the particle is in a state of definite energy? That is, why are such states stationary? To answer this question, we first note the following result from quantum mechanics: For a particle in a state of definite energy E, the time-dependent wave function $\Psi(x, y, z, t)$ can be written as a product of a time-*independent* function $\psi(x, y, z)$ and a simple function of time:

$$\Psi(x, y, z, t) = \psi(x, y, z)e^{-iEt/\hbar} \qquad \text{(time-dependent wave function for a stationary state)} \qquad (39.14)$$

The exponential function in Eq. (39.14) is defined by *Euler's formula*, which states that for any angle θ,

$$e^{i\theta} = \cos\theta + i\sin\theta \quad \text{and} \quad e^{-i\theta} = \cos\theta - i\sin\theta \qquad (39.15)$$

Thus Eq. (39.14) shows that the wave function for any stationary state is a *complex* function.

Let's now look at the probability distribution function $|\Psi|^2$ obtained from Eq. (39.14). Note that $|\Psi|^2$ is the product of Ψ and its *complex conjugate* Ψ^*. To find the complex conjugate of a complex number, simply replace all i with $-i$. For example, the complex conjugate of $c = a + ib$, where a and b are real, is $c^* = a - ib$, so $|c|^2 = c^*c = (a + ib)(a - ib) = a^2 + b^2$ (recall that $i^2 = -1$). The complex conjugate of Eq. (39.14) is

$$\Psi^*(x, y, z, t) = \psi^*(x, y, z)e^{+iEt/\hbar} \qquad (39.16)$$

Hence

$$\begin{aligned} |\Psi(x, y, z, t)|^2 &= \Psi^*(x, y, z, t)\Psi(x, y, z, t) \\ &= \psi^*(x, y, z)\psi(x, y, z)e^{+iEt/\hbar}\, e^{-iEt/\hbar} \\ &= \psi^*(x, y, z)\psi(x, y, z)e^0 = |\psi(x, y, z)|^2 \end{aligned} \qquad (39.17)$$

Since $|\psi(x, y, z)|^2$ does not depend on time, Eq. (39.17) shows that the same must be true for the probability distribution function $|\Psi(x, y, z, t)|^2$. This justifies the term 'stationary state' for a state of definite energy.

The Schrödinger Equation

We have stressed the importance of stationary states in describing quantum-mechanical systems. As Eq. (39.14) shows, to describe a stationary state we must know its spatial wave function $\psi(x, y, z)$ and its energy E. To determine these

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

39.13 Erwin Schrödinger (1887–1961) developed the equation that bears his name in 1926, an accomplishment for which he shared (with the British physicist P. A. M. Dirac) the 1933 Nobel Prize in physics. In later life he did research into the philosophy and history of science.

values we use a tool developed in 1926 by the Austrian physicist Erwin Schrödinger (Fig. 39.13) and known as the *Schrödinger equation*. The Schrödinger equation plays the same central role in quantum mechanics as do Newton's laws in mechanics and Maxwell's equations in electromagnetism. Our understanding of every quantum-mechanical system, including atoms, molecules, atomic nuclei and electrons in solids, is based on the solutions to this equation for that system.

We can't *derive* the Schrödinger equation from other principles; it is a new principle of its own. But we can show how it is related to the de Broglie relationships, and we can make it seem plausible.

The simplest form of the Schrödinger equation is for a particle of mass m that moves in one dimension only, parallel to the x-axis, so that the spatial wave function ψ is a function only of x. We assume that the particle moves in the presence of a conservative force that has only an x-component, so there is a corresponding potential energy $U(x)$. The **Schrödinger equation** for such a particle with a definite energy E is

$$-\frac{\hbar^2}{2m}\frac{d^2\psi(x)}{dx^2} + U(x)\psi(x) = E\psi(x) \qquad \text{(one-dimensional Schrödinger equation)} \tag{39.18}$$

In this equation E is a constant. How do we know that this equation is correct? Because it works. Predictions made using this equation agree with experimental results. In Chapter 40 we'll apply Eq. (39.18) to several physical situations, each with a different form of the function $U(x)$.

Wave Equation for a Free Particle

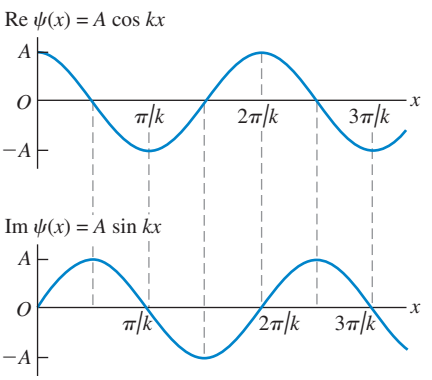
As an example, let's consider a *free* particle that experiences no force at all. If there is no force, $U(x)$ is independent of x; for simplicity we choose $U(x) = 0$. If such a free particle is moving in the $+x$-direction with momentum of magnitude p, its kinetic energy (and hence its total energy) is $E = p^2/2m$. Such a particle is in a state of definite energy (a stationary state).

From the de Broglie equations, the particle has a definite wavelength $\lambda = h/p$ and a definite frequency $f = E/h$. By analogy to the travelling mechanical waves we studied in Section 15.3, we write the wave function for the particle as

$$\Psi(x,t) = A\cos(kx - \omega t) + B\sin(kx - \omega t) \tag{39.19}$$

where A and B are constants. As we did for mechanical waves in Chapter 15 and electromagnetic waves in Chapter 32, we use the wave number $k = 2\pi/\lambda$ and the angular frequency $\omega = 2\pi f$ in Eq. (39.19). These are related to the momentum and energy by

$$k = \frac{2\pi}{\lambda} = \frac{2\pi}{h}\frac{h}{\lambda} = \frac{p}{\hbar} \qquad \omega = 2\pi f = \frac{2\pi}{h}hf = \frac{E}{\hbar} \tag{39.20}$$



The wave function in Eq. (39.19) doesn't seem to be of the stationary-state form given in Eq. (39.14). We can cast it into this form, however, if we let $B = iA$. Then

$$\begin{aligned}\Psi(x,t) &= A\cos(kx - \omega t) + iA\sin(kx - \omega t)\\ &= A[\cos(kx - \omega t) + i\sin(kx - \omega t)]\\ &= Ae^{i(kx-\omega t)} = Ae^{ikx}e^{-i\omega t}\end{aligned} \tag{39.21}$$

In Eq. (39.21) we have again used Euler's formula, which states that for any angle θ,

$$e^{i\theta} = \cos\theta + i\sin\theta \quad \text{and} \quad e^{-i\theta} = \cos\theta - i\sin\theta \tag{39.22}$$

Comparing Eq. (39.21) and Eq. (39.14), we see that our wave function does indeed represent a stationary state with energy $E = \hbar\omega$ and spatial wave function $\psi(x) = Ae^{ikx}$. Figure 39.14 graphs the real and imaginary parts of this function.

39.14 The spatial wave function $\psi(x) = Ae^{ikx}$ for a free particle of definite momentum $p = \hbar k$ is a *complex* function: It has both a real part and an imaginary part.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

If we substitute $\psi(x)$ into the left-hand side of the Schrödinger equation, Eq. (39.18), we obtain

$$-\frac{\hbar^2}{2m}\frac{d^2(Ae^{ikx})}{dx^2} + (0)(Ae^{ikx}) = -\frac{\hbar^2}{2m}(ik)^2 Ae^{ikx} = \frac{\hbar^2k^2}{2m}Ae^{ikx} = \frac{p^2}{2m}\psi(x) \tag{39.23}$$

(We used the result that the second derivative of e^{ax}, where a is a constant, is a^2e^{ax}.) The right-hand side of Eq. (39.18) is $E\psi(x)$. Since $E = p^2/2m$ from Eq. (39.18), we see from Eq. (39.23) that the free-particle wave function in Eq. (39.21) satisfies the Schrödinger equation.

If k is positive in Eq. (39.21), the wave function represents a free particle moving in the positive x-direction. If k is negative, the momentum and hence the motion are in the negative x-direction. (With a negative value of k, the wavelength is $\lambda = 2\pi/|k|$.)

For a free particle, there is no restriction on the value of p and hence no restriction on the value of the energy $E = p^2/2m$. We will find in Chapter 40 that if $U(x)$ is not a constant, then solutions of the Schrödinger equation are possible only for certain values of E. These values represent the allowed *energy levels* of the system described by $U(x)$. This discovery is of the utmost importance. Before the development of the Schrödinger equation, there was no way to predict energy levels from any fundamental theory except the Bohr model, which had very limited success.

There is also a version of the Schrödinger equation that includes time dependence. It is needed to study states that are *not* stationary and for which the probability distribution function $|\Psi(x, y, z, t)|^2$ depends on time. However, we don't need that version to calculate the energy levels and wave functions of stationary states. If we do need a time-dependent wave function for a stationary state of energy E, we simply use Eq. (39.14). The time-dependent Schrödinger equation is essential for studying the details of *transitions* between states. In more advanced courses you may study the quantum mechanics of time-dependent phenomena such as photon emission and absorption and the lifetimes of states.

Example 39.6 The Schrödinger equation

Consider the wave function $\psi(x) = A_1e^{ikx} + A_2e^{-ikx}$, where k is positive. Is this a valid stationary-state wave function for a free particle? What is the energy?

SOLUTION

IDENTIFY: A valid stationary-state wave function for a free particle must satisfy the Schrödinger equation, Eq. (39.18), with $U(x) = 0$.

SET UP: To test the given function $\psi(x)$, we simply substitute it into the left-hand side of the equation. If the result is a constant times $\psi(x)$, then the wave function is indeed a solution and the constant is equal to the energy E.

EXECUTE: Substituting $\psi(x) = A_1e^{ikx} + A_2e^{-ikx}$ and $U(x) = 0$ into Eq. (39.18), we obtain

$$\begin{aligned}-\frac{\hbar^2}{2m}\frac{d^2\psi(x)}{dx^2} &= -\frac{\hbar^2}{2m}\frac{d^2(A_1e^{ikx} + A_2e^{-ikx})}{dx^2}\\ &= -\frac{\hbar^2}{2m}[(ik)^2A_1e^{ikx} + (-ik)^2A_2e^{ikx}]\\ &= \frac{\hbar^2k^2}{2m}(A_1e^{ikx} + A_2e^{-ikx}) = \frac{\hbar^2k^2}{2m}\psi(x)\end{aligned}$$

We see that the left-hand side of the Schrödinger equation is equal to a constant times $\psi(x)$, so this $\psi(x)$ is indeed a valid stationary-state wave function for a free particle. The constant is just equal to the energy: $E = \hbar^2k^2/2m$.

EVALUATE: Note that $\psi(x)$ is a *superposition* of two different wave functions: one for a particle with a given magnitude of momentum $p = \hbar k$ moving in the positive x-direction and one for a particle with the same magnitude of momentum moving in the negative x-direction. While the combined wave function represents a stationary state with a definite energy, this state does *not* have a definite momentum. We will see in Chapter 40 that such a wave function can represent a *standing wave*, and we will explore the situations in which such standing matter waves can arise.

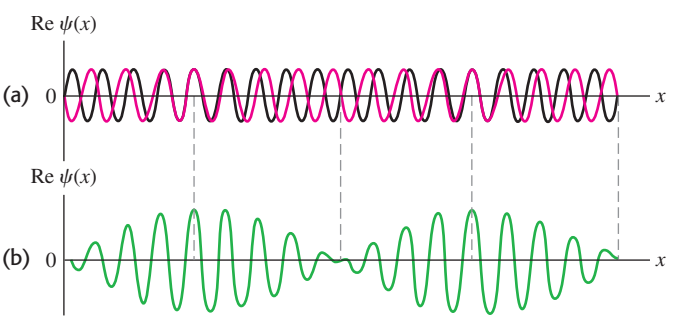
17.7 Wave Packets

Wave Packets

The wave function for a free particle given by Eq. (39.21) has a definite momentum p in the x-direction. For such a state, there is *no* uncertainty in momentum: $\Delta p_x = 0$. The Heisenberg uncertainty principle, Eq. (39.11), says that $\Delta x \Delta p_x \geq \hbar$. If Δp_x is zero, then Δx must be infinite. The price we pay for knowing the particle's momentum precisely is that we have no idea *where* the particle is! We can show this by calculating the probability distribution function $|\Psi(x,t)|^2$:

$$\begin{aligned}|\Psi(x,t)|^2 &= \Psi^*(x,t)\Psi(x,t) = (A^* e^{-ikx} e^{+i\omega t})(A e^{ikx} e^{-i\omega t}) \\ &= A^* A e^0 = |A|^2\end{aligned}$$

The probability distribution function doesn't depend on time, as we would expect because this is a stationary state (a state of definite energy). It also doesn't depend on position, which says that we are equally likely to find the particle *anywhere* in space! Mathematically, this situation occurs because the spatial wave function $\psi(x) = Ae^{ikx} = A\cos kx + iA\sin kx$ is a sinusoidal function that extends all the way from $x = -\infty$ to $x = +\infty$ with the same amplitude A. (This also means that the wave function can't be normalised: The integral of $|\Psi(x,t)|^2$ over all space would be infinite for any value of A.)



In practical situations, we always have *some* idea where a particle is. To describe this situation, we need a wave function that is more localised in space. We can create one by superimposing two or more sinusoidal functions, as we did in Example 39.6. In that example we added two wave functions with opposite wave numbers k and $-k$; to make a localised wave function, we must make a different choice.

To keep things simple, we'll imagine wave functions that depend on only one spatial coordinate (x), and we'll consider them at one instant of time (say, $t = 0$). Our wave functions are then functions only of x, so we'll denote them as ψ. For example, let's add together two different stationary-state wave functions for a free particle as given by Eq. (39.21), but with slightly different values k_1 and k_2 of the wave number. At $t = 0$ the time factors $e^{-i\omega_1 t}$ and $e^{-i\omega_2 t}$ are both equal to $e^0 = 1$, so the wave function at $t = 0$ is

$$\begin{aligned}\psi(x) &= A_1 e^{ik_1 x} + A_2 e^{ik_2 x} \\ &= [A_1\cos(k_1 x) + iA_1\sin(k_1 x)] + [A_2\cos(k_2 x) + iA_2\sin(k_2 x)] \\ &= [A_1\cos(k_1 x) + A_2\cos(k_2 x)] + i[A_1\sin(k_1 x) + A_2\sin(k_2 x)]\end{aligned} \quad (39.24)$$

We have used Euler's formula, Eq. (39.22), to separate the real and imaginary parts of $\psi(x)$.

Figure 39.15a is a graph of the real parts of the individual wave functions for the case $A_2 = -A_1$; Fig. 39.15b graphs the real part of the combined wave function $\psi(x)$ given by Eq. (39.24). We saw something very similar to Fig. 39.15b in our discussion of beats in Section 16.7: When we superimposed two sinusoidal waves with slightly different frequencies (Fig. 16.24), the result was a wave with

39.15 (a) The real parts of two sinusoidal waves with slightly different wave numbers, shown at one instant of time. (b) The superposition of these waves has a wave number equal to the average of the two individual wave numbers. The amplitude varies, giving the total wave a lumpy character not possessed by either individual wave.

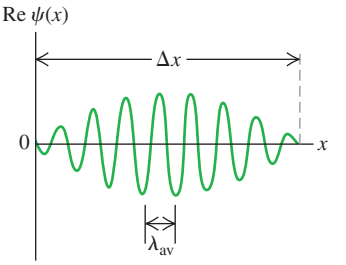
Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

a lumpy character that the individual waves did not possess. In the same way, a particle represented by the lumpy wave function given in Eq. (39.24) is more likely to be found in some regions than in others; that is, it is *localised*. However, the particle's momentum no longer has a definite value because we began with two different wave numbers. This agrees with the Heisenberg uncertainty principle: By decreasing the uncertainty in the particle's position, we have increased the uncertainty in its momentum.

It's not hard to imagine superposing two additional sinusoidal waves with different wave numbers and amplitudes so as to reinforce alternate lumps in Fig. 39.15b and cancel out the in-between ones. Finally, if we superpose waves with a very large number of different wave numbers, we can construct a wave with only one lump (Fig. 39.16). Then, finally, we have something that begins to look like both a particle and a wave. It is a particle in the sense that it is localised in space; if we look from a distance, it may look like a point. But it also has a periodic structure that is characteristic of a wave.

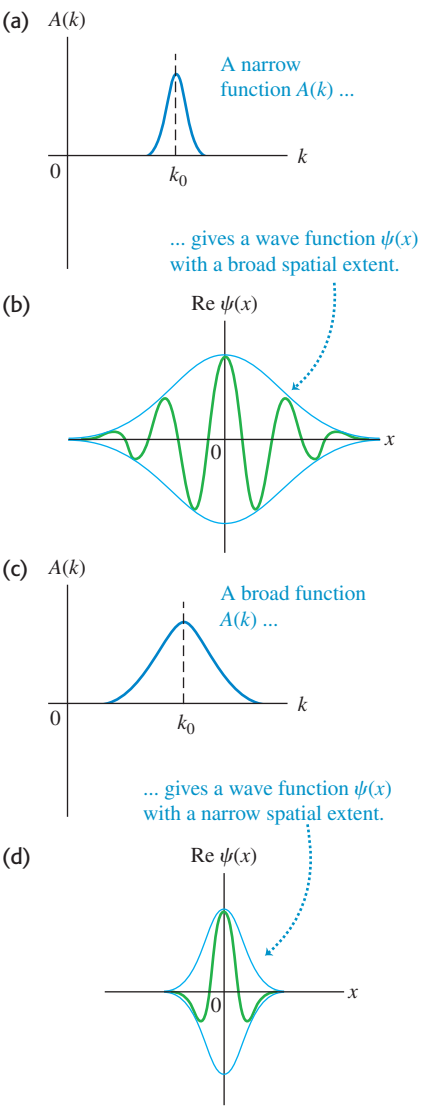
Such a wave pulse is called a **wave packet**. We can represent such a superposition by an expression such as

$$\psi(x) = \int_{-\infty}^{\infty} A(k)e^{ikx}\,dk \tag{39.25}$$



This integral represents a superposition of a very large number of waves, each with a different wave number and each with an amplitude $A(k)$ that depends on k.

There is an important relationship between the two functions $\psi(x)$ and $A(k)$. This relationship is shown qualitatively in Fig. 39.17. If the function $A(k)$ is sharply peaked, as in Fig. 39.17a, we are superposing only a narrow range of wave numbers. The resulting wave pulse is then relatively broad (Fig. 39.17b). But if we use a wider range of wave numbers, so that the function $A(k)$ is broader (Fig. 39.17c), then the wave pulse is more narrowly localised (Fig. 39.17d).



What we are seeing is the uncertainty principle in action. A narrow range of k means a narrow range of $p_x = \hbar k$ and thus a small Δp_x; the result is a relatively large Δx. A broad range of k corresponds to a large Δp_x, and the resulting Δx is smaller. Thus we see that the uncertainty principle $\Delta x \Delta p_x \geq \hbar$ is an inevitable consequence of the de Broglie relationship and the properties of integrals such as Eq. (39.25). These integrals are called *Fourier integrals*; they are a generalisation of the concept of Fourier series, which we mentioned in Section 15.8. In both cases we are representing a complex wave form as a superposition of sinusoidal functions. With Fourier series we use a sequence of frequencies (or values of k) that are integer multiples of some basic value, while with Fourier integrals we superpose functions with a *continuous* distribution of values of k.

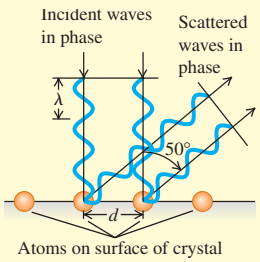
Test Your Understanding of Section 39.5 Does a wave packet given by Eq. (39.25) represent a stationary state?

39.16 Superimposing a large number of sinusoidal waves with different wave numbers and appropriate amplitudes can produce a wave pulse with a wavelength $\lambda_{av} = 2\pi/k_{av}$ that is localised in a region of space of length Δx. This localised pulse has aspects of both particle and wave.

39.17 How varying the function $A(k)$ in the wave-packet expression, Eq. (39.25), changes the character of the wave function $\psi(x)$.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

CHAPTER 39 SUMMARY

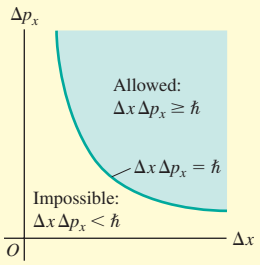


de Broglie waves: Electrons and other particles have wave properties. The wavelength of the wave depends on the particle's momentum in the same way as for photons. The state of a particle is described not by its coordinates and velocity components but rather by a wave function, which in general is a function of the three space coordinates and time. (See Example 39.1.)

$$\lambda = \frac{h}{p} = \frac{h}{mv} \tag{39.1}$$

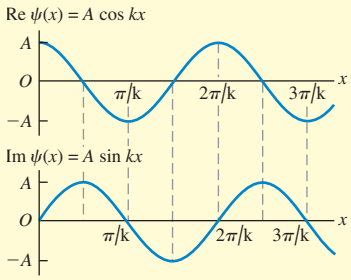
$$E = hf \tag{39.2}$$

Electron diffraction and electron microscopes: Diffraction of an electron beam from the surface of a metallic crystal provided the first direct confirmation of the wave nature of particles. If a nonrelativistic electron has been accelerated from rest through a potential difference V_{ba}, its wavelength is given by Eq. (39.5). Electron microscopes use the very small wavelengths of fast-moving electrons to make images with resolution thousands of times finer than is possible with visible-light microscopes. (See Examples 39.2 and 39.5.)



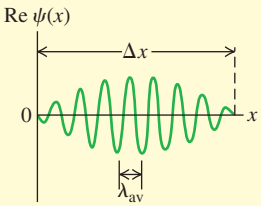
$$\lambda = \frac{h}{p} = \frac{h}{\sqrt{2meV_{ba}}} \tag{39.5}$$

The Heisenberg uncertainty principle: It is impossible to make precise determinations of a coordinate of a particle and of the corresponding momentum component at the same time. The precision of such measurements for the x-components is limited by the Heisenberg uncertainty principle, Eq. (39.11); there are corresponding relationships for the y- and z-components. The uncertainty ΔE in the energy of a state that is occupied for a time Δt is given by Eq. (39.13). In these expressions, $\hbar = h/2\pi$. (See Examples 39.3 and 39.4.)



$$\Delta x \Delta p_x \geq \hbar \tag{39.11}$$
(Heisenberg uncertainty principle for position and momentum)

$$\Delta E \Delta t \geq \hbar \tag{39.13}$$
(Heisenberg uncertainty principle for energy and time)



Wave functions: The wave function $\Psi(x, y, z, t)$ for a particle contains all of the information about that particle. The quantity $|\Psi(x, y, z, t)|^2$, called the probability distribution function, determines the relative probability of finding a particle near a given position at a given time. If the particle is in a state of definite energy, called a stationary state, $\Psi(x, y, z, t)$ is a product of a function ψ that depends only on spatial coordinates and a function $e^{-iEt/\hbar}$ that depends only on time. For a stationary state, the probability distribution function is independent of time.

$$\Psi(x, y, z, t) = \psi(x, y, z)\, e^{-iEt/\hbar} \tag{39.14}$$
(stationary state)

The Schrödinger equation: For a particle that moves in one dimension in the presence of a potential-energy function $U(x)$, the wave function for a stationary state of energy E satisfies the Schrödinger equation. More complex wave functions can be made by superposing stationary-state wave functions. These can represent particles that are localised in a certain region and still have wave properties, giving them both particle and wave aspects. (See Example 39.6.)

$$-\frac{\hbar^2}{2m}\frac{d^2\psi(x)}{dx^2} + U(x)\psi(x) = E\psi(x)$$
(one-dimensional Schrödinger equation) (39.18)

Answer to Chapter Opening Question ?

The smallest detail visible in an image is comparable to the wavelength used to make the image. Electrons can easily be given a large momentum p and hence a short wavelength $\lambda = h/p$, and so can be used to resolve extremely fine details. (See Section 39.4.)

Answers to Test Your Understanding Questions

39.1 Answer: (i) From Example 39.1, the speed of a particle is $v = h/\lambda m$ and the kinetic energy is $K = \frac{1}{2}mv^2 = (m/2)(h/\lambda m)^2 = h^2/2\lambda^2 m$. This shows that for a given wavelength, the kinetic energy is inversely proportional to the mass. Hence the proton, with a smaller mass, has more kinetic energy than the neutron.

39.2 Answer: no The energy of a photon is $E = hf$, and the frequency of a photon is $f = c/\lambda$. Hence $E = hc/\lambda$ and $\lambda = hc/E = (4.136 \times 10^{-15}\ \text{eV} \cdot \text{s}) \times (2.998 \times 10^8\ \text{m/s})/(54\ \text{eV}) = 2.3 \times 10^{-8}$ m. This is more than 100 times greater than the wavelength of an electron of the same energy. While both photons and electrons have wavelike properties, they have different relationships between their energy and momentum and hence between their frequency and wavelength.

39.3 Answer: (i) and (iii) (tie), (ii) and (iv) (tie) According to the Heisenberg uncertainty principle, the smaller the uncertainty Δx in the x-coordinate, the greater the uncertainty Δp_x in the x-momentum. The relationship between Δx and Δp_x does not depend on the mass of the particle, and so is the same for a proton as for an electron.

39.5 Answer: no Equation (39.25) represents a superposition of wave functions with different values of wave number k and hence different values of energy $E = \hbar^2 k^2/2m$. The state that this combined wave function represents is not a state of definite energy, and therefore not a stationary state. Another way to see this is to note that the time-dependent wave function $\Psi(x, t)$ would include a factor $e^{-iEt/\hbar}$ inside the integral in Eq. (39.25), with a different value of E for each value of k. This wave function therefore has a very complicated time dependence, and the probability distribution function $|\Psi(x, t)|^2$ does depend on time.

PROBLEMS

For instructor-assigned homework, go to **www.pearson.com.au/masteringphysics** MP

Exercises

Section 39.1 de Broglie Waves

39.1. (a) An electron moves with a speed of 4.70×10^6 m/s. What is its de Broglie wavelength? (b) A proton moves with the same speed. Determine its de Broglie wavelength.

39.2. For crystal diffraction experiments (discussed in Section 39.2), wavelengths on the order of 0.20 nm are often appropriate. Find the energy in electron volts for a particle with this wavelength if the particle is (a) a photon; (b) an electron; (c) an alpha particle $(m = 6.64 \times 10^{-27}\ \text{kg})$.

39.3. An electron has a de Broglie wavelength of 2.80×10^{-10} m. Determine (a) the magnitude of its momentum and (b) its kinetic energy (in joules and in electron volts).

39.4. An alpha particle $(m = 6.64 \times 10^{-27}\ \text{kg})$ emitted in the radioactive decay of uranium-238 has an energy of 4.20 MeV. What is its de Broglie wavelength?

39.5. In the Bohr model of the hydrogen atom, what is the de Broglie wavelength for the electron when it is in (a) the $n = 1$ level and (b) the $n = 4$ level? In each case, compare the de Broglie wavelength to the circumference $2\pi r_n$ of the orbit.

39.6. (a) A nonrelativistic free particle with mass m has kinetic energy K. Derive an expression for the de Broglie wavelength of the particle in terms of m and K. (b) What is the de Broglie wavelength of an 800 eV electron?

39.7. (a) Calculate the de Broglie wavelength of a typical person walking through a doorway. Make reasonable approximations for the necessary quantities. (b) Will the person in part (a) exhibit wave-like behaviour when walking through the 'single slit' of a doorway? Why?

39.8. What is the de Broglie wavelength for an electron with speed (a) $v = 0.480c$ and (b) $v = 0.960c$? (*Hint:* Use the correct relativistic expression for linear momentum if necessary.)

39.9. (a) If a photon and an electron each have the same energy of 20.0 eV, find the wavelength of each. (b) If a photon and an electron each have the same wavelength of 250 nm, find the energy of each. (c) You want to study an organic molecule that is about 250 nm long using either a photon or an electron microscope. Approximately what wavelength should you use, and which probe, the electron or the photon, is likely to damage the molecule the least?

39.10. Hydrogen gas (H_2) is at 0°C. The mass of a hydrogen *atom* is 1.67×10^{-27} kg. (a) What is the average de Broglie wavelength of the hydrogen molecules? (b) How fast would an electron have to move to have the same de Broglie wavelength as the hydrogen? Do we need to consider relativity for this electron? (c) What would be the energy of a photon having the same wavelength as the H_2 molecules and the electrons? Compare it to the kinetic energy of the hydrogen molecule in part (a) and the electron in part (b).

39.11. Calculate the de Broglie wavelength of a 5.00 g bullet that is moving at 340 m/s. Will the bullet exhibit wavelike properties?

Section 39.2 Electron Diffraction

39.12. Through what potential difference must electrons be accelerated so they will have (a) the same wavelength as an x-ray of wavelength 0.150 nm and (b) the same energy as the x-ray in part (a)?

39.13. (a) Approximately how fast should an electron move so it has a wavelength that makes it useful to measure the distance

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

between adjacent atoms in typical crystals (about 0.10 nm)? (b) What is the kinetic energy of the electron in part (a)? (c) What would be the energy of a photon of the same wavelength as the electron in part (b)? (d) Which would make a more effective probe of small-scale structures, electrons or photons? Why?

39.14. A beam of electrons is accelerated from rest through a potential difference of 0.100 kV and then passes through a thin slit. The diffracted beam shows its first diffraction minima at $\pm 11.5°$ from the original direction of the beam when viewed far from the slit. (a) Do we need to use relativity formulas? How do you know? (b) How wide is the slit?

39.15. A beam of neutrons that all have the same energy scatters from the atoms that have a spacing of 0.0910 nm in the surface plane of a crystal. The $m = 1$ intensity maximum occurs when the angle θ in Fig. 39.3 is 28.6°. What is the kinetic energy (in electron volts) of each neutron in the beam?

39.16. A beam of 188 eV electrons is directed at normal incidence onto a crystal surface as shown in Fig. 39.4b. The $m = 2$ intensity maximum occurs at an angle $\theta = 60.6°$. (a) What is the spacing between adjacent atoms on the surface? (b) At what other angle or angles is there an intensity maximum? (c) For what electron energy (in electron volts) would the $m = 1$ intensity maximum occur at $\theta = 60.6°$? For this energy, is there an $m = 2$ intensity maximum? Explain.

39.17. A CD-ROM is used instead of a crystal in an electron-diffraction experiment like that shown in Fig. 39.3. The surface of the CD-ROM has tracks of tiny pits with a uniform spacing of 1.60 μm. (a) If the speed of the electrons is 1.26×10^4/s, at which values of θ will the $m = 1$ and $m = 2$ intensity maxima appear? (b) The scattered electrons in these maxima strike at normal incidence a piece of photographic film that is 50.0 cm from the CD-ROM. What is the spacing on the film between these maxima?

Section 39.3 Probability and Uncertainty

39.18. A pesky 1.5 mg mosquito is annoying you as you attempt to study physics in your room, which is 5.0 m wide and 2.5 m high. You decide to swat the bothersome insect as it flies towards you, but you need to estimate its speed to make a successful hit. (a) What is the maximum uncertainty in the horizontal position of the mosquito? (b) What limit does the Heisenberg uncertainty principle place on your ability to know the horizontal velocity of this mosquito? Is this limitation a serious impediment to your attempt to swat it?

39.19. By extremely careful measurement, you determine the x-coordinate of a car's centre of mass with an uncertainty of only 1.00 μm. The car has a mass of 1200 kg. (a) What is the minimum uncertainty in the x-component of the velocity of the car's centre of mass as prescribed by the Heisenberg uncertainty principle? (b) Does the uncertainty principle impose a practical limit on our ability to make simultaneous measurements of the positions and velocities of ordinary objects like cars, books and people? Explain.

39.20. A 10.0 g marble is gently placed on a horizontal tabletop that is 1.75 m wide. (a) What is the maximum uncertainty in the horizontal position of the marble? (b) According to the Heisenberg uncertainty principle, what is the minimum uncertainty in the horizontal velocity of the marble? (c) In light of your answer to part (b), what is the longest time the marble could remain on the table? Compare this time to the age of the universe, which is approximately 14 billion years. (*Hint:* Can you know that the horizontal velocity of the marble is *exactly* zero?)

39.21. A scientist has devised a new method of isolating individual particles. He claims that this method enables him to detect simultaneously the position of a particle along an axis with a standard deviation of 0.12 nm and its momentum component along this axis with a standard deviation of 3.0×10^{-25} kg · m/s. Use the Heisenberg uncertainty principle to evaluate the validity of this claim.

39.22. (a) The x-coordinate of an electron is measured with an uncertainty of 0.20 mm. What is the x-component of the electron's velocity, v_x, if the minimum percentage uncertainty in a simultaneous measurement of v_x is 1.0%? (b) Repeat part (a) for a proton.

39.23. An atom in a metastable state has a lifetime of 5.2 ms. What is the uncertainty in energy of the metastable state?

39.24. (a) The uncertainty in the y-component of a proton's position is 2.0×10^{-12} m. What is the minimum uncertainty in a simultaneous measurement of the y-component of the proton's velocity? (b) The uncertainty in the z-component of an electron's velocity is 0.250 m/s. What is the minimum uncertainty in a simultaneous measurement of the z-coordinate of the electron?

39.25. The ψ ('psi') particle has a rest energy of 3097 MeV $(1\text{ MeV} = 10^6\text{ eV})$. The ψ particle is unstable with a lifetime of 7.6×10^{-21} s. Estimate the uncertainty in rest energy of the ψ particle. Express your answer in MeV and as a fraction of the rest energy of the particle.

39.26. The unstable W^+ particle has a rest energy of 80.41 GeV $(1\text{ GeV} = 10^9\text{ eV})$ and an uncertainty in rest energy of 2.06 GeV. Estimate the lifetime of the W^+ particle.

Section 39.4 The Electron Microscope

39.27. You want to study a biological specimen by means of a wavelength of 10.0 nm, and you have a choice of using electromagnetic waves or an electron microscope. (a) Calculate the ratio of the energy of a 10.0 nm wavelength photon to the kinetic energy of a 10.0 nm wavelength electron. (b) In view of your answer to part (a), which would be less damaging to the specimen you are studying: photons or electrons?

39.28. (a) In an electron microscope, what accelerating voltage is needed to produce electrons with wavelength 0.0600 nm? (b) If protons are used instead of electrons, what accelerating voltage is needed to produce protons with wavelength 0.0600 nm? (*Hint:* In each case the initial kinetic energy is negligible.)

Section 39.5 Wave Functions and the Schrödinger Equation

39.29. Consider a wave function given by $\psi(x) = A\sin kx$, where $k = 2\pi/\lambda$ and A is a real constant. (a) For what values of x is there the highest probability of finding the particle described by this wave function? Explain. (b) For which values of x is the probability *zero?* Explain.

39.30. Compute $|\Psi|^2$ for $\Psi = \psi\sin\omega t$, where ψ is time independent and ω is a real constant. Is this a wave function for a stationary state? Why or why not?

39.31. Consider a particle moving in one dimension, which we shall call the x-axis. (a) What does it mean for the wave function of this particle to be *normalised?* (b) Is the wave function $\psi(x) = e^{ax}$, where a is a positive real number, normalised? Could this be a valid wave function? (c) If the particle described by the wave function $\psi(x) = Ae^{-bx}$, where A and b are positive real numbers, is confined to the range $x \geq 0$, determine A (including its units) so that the wave function is normalised.

39.32. A particle is described by a wave function $\psi(x) = Ae^{-\alpha x^2}$, where A and α are real, positive constants. If the value of α is increased, what effect does this have on (a) the particle's uncertainty in position and (b) the particle's uncertainty in momentum? Explain your answers.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

39.33. Consider the complex-valued function $f(x, y) = (x - iy)/(x + iy)$. Calculate $|f|^2$.

39.34. Particle A is described by the wave function $\psi(x, y, z)$. Particle B is described by the wave function $\psi(x, y, z)e^{i\phi}$, where ϕ is a real constant. How does the probability of finding particle A within a volume dV around a certain point in space compare with the probability of finding particle B within this same volume?

39.35. A particle moving in one dimension (the x-axis) is described by the wave function

$$\psi(x) = \begin{cases} Ae^{-bx}, & \text{for } x \geq 0 \\ Ae^{bx}, & \text{for } x < 0 \end{cases}$$

where $b = 2.00\ \text{m}^{-1}$, $A > 0$, and the $+x$-axis points towards the right. (a) Determine A so that the wave function is normalised. (b) Sketch the graph of the wave function. (c) Find the probability of finding this particle in each of the following regions: (i) within 50.0 cm of the origin, (ii) on the left side of the origin (can you first guess the answer by looking at the graph of the wave function?), (iii) between $x = 0.500$ m and $x = 1.00$ m.

39.36. Let ψ_1 and ψ_2 be two solutions of Eq. (39.18) with the same energy E. Show that $\psi = B\psi_1 + C\psi_2$ is also a solution with energy E, for any values of the constants B and C.

39.37. Let ψ_1 and ψ_2 be two solutions of Eq. (39.18) with energies E_1 and E_2, respectively, where $E_1 \neq E_2$. Is $\psi = A\psi_1 + B\psi_2$, where A and B are nonzero constants, a solution to Eq. (39.18)? Explain your answer.

Problems

39.38. A beam of 40 eV electrons travelling in the $+x$-direction passes through a slit that is parallel to the y-axis and 5.0 μm wide. The diffraction pattern is recorded on a screen 2.5 m from the slit. (a) What is the de Broglie wavelength of the electrons? (b) How much time does it take the electrons to travel from the slit to the screen? (c) Use the width of the central diffraction pattern to calculate the uncertainty in the y-component of momentum of an electron just after it has passed through the slit. (d) Use the result of part (c) and the Heisenberg uncertainty principle (Eq. 39.11 for y) to estimate the minimum uncertainty in the y-coordinate of an electron just after it has passed through the slit. Compare your result to the width of the slit.

39.39. (a) What is the energy of a photon that has wavelength 0.10 μm? (b) Through approximately what potential difference must electrons be accelerated so that they will exhibit wave nature in passing through a pinhole 0.10 μm in diameter? What is the speed of these electrons? (c) If protons rather than electrons were used, through what potential difference would protons have to be accelerated so they would exhibit wave nature in passing through this pinhole? What would be the speed of these protons?

39.40. Electrons go through a single slit 150 nm wide and strike a screen 24.0 cm away. You find that at angles of $\pm 20.0°$ from the centre of the diffraction pattern, no electrons hit the screen but electrons hit at all points closer to the centre. (a) How fast were these electrons moving when they went through the slit? (b) What will be the next larger angles at which no electrons hit the screen?

39.41. A beam of electrons is accelerated from rest and then passes through a pair of identical thin slits that are 1.25 nm apart. You observe that the first double-slit interference dark fringe occurs at $\pm 18.0°$ from the original direction of the beam when viewed on a distant screen. (a) Are these electrons relativistic? How do you know? (b) Through what potential difference were the electrons accelerated?

39.42. A beam of protons and a beam of alpha particles (of mass 6.64×10^{-27} kg and charge $+2e$) are accelerated from rest through the same potential difference and pass through identical circular holes in a very thin, opaque film. When viewed far from the hole, the diffracted proton beam forms its first dark ring at 15° with respect to its original direction. When viewed similarly, at what angle will the alpha particle form its first dark ring?

39.43. An electron beam and a photon beam pass through identical slits. On a distant screen, the first dark fringe occurs at the same angle for both of the beams. The electron speeds are much slower than that of light. (a) Express the energy of a photon in terms of the kinetic energy K of one of the electrons. (b) Which is greater, the energy of a photon or the kinetic energy of an electron?

39.44. Coherent light is passed through two narrow slits whose separation is 40.0 μm. The second-order bright fringe in the interference pattern is located at an angle of 0.0300 rad. If electrons are used instead of light, what must the kinetic energy (in electron volts) of the electrons be if they are to produce an interference pattern for which the second-order maximum is also at 0.0300 rad?

39.45. What is the de Broglie wavelength of a red blood cell, with mass 1.00×10^{-11} g, that is moving with a speed of 0.400 cm/s? Do we need to be concerned with the wave nature of the blood cells when we describe the flow of blood in the body?

39.46. High-speed electrons are used to probe the interior structure of the atomic nucleus. For such electrons the expression $\lambda = h/p$ still holds, but we must use the relativistic expression for momentum, $p = mv/\sqrt{1 - v^2/c^2}$. (a) Show that the speed of an electron that has de Broglie wavelength λ is

$$v = \frac{c}{\sqrt{1 + (mc\lambda/h)^2}}$$

(b) The quantity h/mc equals 2.426×10^{-12} m. (As we saw in Section 38.7, this same quantity appears in Eq. (38.23), the expression for Compton scattering of photons by electrons.) If λ is small compared to h/mc, the denominator in the expression found in part (a) is close to unity and the speed v is very close to c. In this case it is convenient to write $v = (1 - \Delta)c$ and express the speed of the electron in terms of Δ rather than v. Find an expression for Δ valid when $\lambda \ll h/mc$. [*Hint:* Use the binomial expansion $(1 + z)^n = 1 + nz + n(n - 1)z^2/2 + \cdots$, valid for the case $|z| < 1$. (c) How fast must an electron move for its de Broglie wavelength to be 1.00×10^{-15} m, comparable to the size of a proton? Express your answer in the form $v = (1 - \Delta)c$, and state the value of Δ.

39.47. (a) What is the de Broglie wavelength of an electron accelerated from rest through a potential increase of 125 V? (b) What is the de Broglie wavelength of an alpha particle $(q = +2e, m = 6.64 \times 10^{-27}\ \text{kg})$ accelerated from rest through a potential drop of 125 V?

39.48. Suppose that the uncertainty of position of an electron is equal to the radius of the $n = 1$ Bohr orbit for hydrogen. Calculate the simultaneous minimum uncertainty of the corresponding momentum component, and compare this with the magnitude of the momentum of the electron in the $n = 1$ Bohr orbit. Discuss your results.

39.49. (a) A particle with mass m has kinetic energy equal to three times its rest energy. What is the de Broglie wavelength of this particle? (*Hint:* You must use the relativistic expressions for momentum and kinetic energy: $E^2 = (pc)^2 + (mc^2)^2$ and $K = E - mc^2$.) (b) Determine the numerical value of the kinetic energy (in

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

MeV) and the wavelength (in metres) if the particle in part (a) is (i) an electron and (ii) a proton.

39.50. The radii of atomic nuclei are of the order of 5.0×10^{-15} m. (a) Estimate the minimum uncertainty in the momentum of a proton if it is confined within a nucleus. (b) Take this uncertainty in momentum to be an estimate of the magnitude of the momentum. Use the relativistic relationship between energy and momentum, Eq. (37.39), to obtain an estimate of the kinetic energy of a proton confined within a nucleus. (c) For a proton to remain bound within a nucleus, what must the magnitude of the (negative) potential energy for a proton be within the nucleus? Give your answer in eV and in MeV. Compare to the potential energy for an electron in a hydrogen atom, which has a magnitude of a few tens of eV. (This shows why the interaction that binds the nucleus together is called the 'strong nuclear force.')

39.51. The radii of atomic nuclei are of the order of 5.0×10^{-15} m. (a) Estimate the minimum uncertainty in the momentum of an electron if it is confined within a nucleus. (b) Take this uncertainty in momentum to be an estimate of the magnitude of the momentum. Use the relativistic relationship between energy and momentum, Eq. (37.39), to obtain an estimate of the kinetic energy of an electron confined within a nucleus. (c) Compare the energy calculated in part (b) to the magnitude of the Coulomb potential energy of a proton and an electron separated by 5.0×10^{-15} m. On the basis of your result, could there be electrons within the nucleus? (*Note:* It is interesting to compare this result to that of Problem 39.50.)

39.52. In a TV picture tube the accelerating voltage is 15.0 kV, and the electron beam passes through an aperture 0.50 mm in diameter to a screen 0.300 m away. (a) Calculate the uncertainty in the component of the electron's velocity perpendicular to the line between aperture and screen. (b) What is the uncertainty in position of the point where the electrons strike the screen? (c) Does this uncertainty affect the clarity of the picture significantly? (Use nonrelativistic expressions for the motion of the electrons. This is fairly accurate and is certainly adequate for obtaining an estimate of uncertainty effects.)

39.53. The neutral pion (π^0) is an unstable particle produced in high-energy particle collisions. Its mass is about 264 times that of the electron, and it exists for an average lifetime of 8.4×10^{-17} s before decaying into two gamma-ray photons. Using the relationship $E = mc^2$ between rest mass and energy, find the uncertainty in the mass of the particle and express it as a fraction of the mass.

39.54. A 1.25 mg insect flies through a 4.00 mm diameter hole in an ordinary window screen. The thickness of the screen is 0.500 mm. (a) What should be the approximate wavelength and speed of the insect for her to show wave behaviour as she goes through the hole? (b) At the speed found in part (a), how long would it take the insect to pass through the 0.500 mm thickness of the hole in the screen? Compare this time to the age of the universe (about 14 billion years). Would you expect to see 'insect diffraction' in daily life?

39.55. If your wavelength were 1.0 m, you would undergo considerable diffraction in moving through a doorway. (a) What must your speed be for you to have this wavelength? (Assume that your mass is 60.0 kg.) (b) At the speed calculated in part (a), how many years would it take you to move 0.80 m (one step)? Will you notice diffraction effects as you walk through doorways?

39.56. A certain atom has an energy level 2.58 eV above the ground level. Once excited to this level, the atom remains in this level for 1.64×10^{-7} s (on average) before emitting a photon and returning to the ground level. (a) What is the energy of the photon (in electron volts)? What is its wavelength (in nanometres)? (b) What is the smallest possible uncertainty in energy of the photon? Give your answer in electron volts. (c) Show that $|\Delta E/E| = |\Delta\lambda/\lambda|$ if $|\Delta\lambda/\lambda| \ll 1$. Use this to calculate the magnitude of the smallest possible uncertainty in the wavelength of the photon. Give your answer in nanometres.

39.57. You intend to use an electron microscope to study the structure of some crystals. For accurate resolution, you want the electron wavelength to be 1.00 nm. (a) Are these electrons relativistic? How do you know? (b) What accelerating potential is needed? (c) What is the kinetic energy of the electrons you are using? To see if it is great enough to damage the crystals you are studying, compare it to the potential energy of a typical NaCl molecule, which is about 6.0 eV. (d) If you decided to use electromagnetic waves as you probe, what energy should their photons have to provide the same resolution as the electrons? Would this energy damage the crystal?

39.58. For x-rays with wavelength 0.0300 nm, the $m = 1$ intensity maximum for a crystal occurs when the angle θ in Fig. 39.3 is 35.8°. At what angle θ does the $m = 1$ maximum occur when a beam of 4.50 keV electrons is used instead? Assume that the electrons also scatter from the atoms in the surface plane of this same crystal.

39.59. Electron diffraction can also take place when there is interference between electron waves that scatter from atoms on the surface of a crystal and waves that scatter from atoms in the next plane below the surface, a distance d from the surface (see Fig. 36.23c). (a) Find an equation for the angles θ at which there is an intensity maximum for electron waves of wavelength λ. (b) The spacing between crystal planes in a certain metal is 0.091 nm. If 71.0 eV electrons are used, find the angle at which there is an intensity maximum due to interference between scattered waves from adjacent crystal planes. The angle is measured as shown in Fig. 36.23c. (c) The actual angle of the intensity maximum is slightly different from your result in part (b). The reason is the work function ϕ of the metal (see Section 38.2), which changes the electron potential energy by $-e\phi$ when it moves from vacuum into the metal. If the effect of the work function is taken into account, is the angle of the intensity maximum larger or smaller than the value found in part (b)? Explain.

39.60. Consider a particle with mass m moving in a potential $U = \frac{1}{2}kx^2$, as in a mass-spring system. The total energy of the particle is $E = p^2/2m + \frac{1}{2}kx^2$. Assume that p and x are approximately related by the Heisenberg uncertainty principle, $px \approx h$. (a) Calculate the minimum possible value of the energy E, and the value of x that gives this minimum E. This lowest possible energy, which is not zero, is called the *zero-point energy*. (b) For the x calculated in part (a), what is the ratio of the kinetic to the potential energy of the particle?

39.61. A particle with mass m moves in a potential $U(x) = A|x|$, where A is a positive constant. In a simplified picture, quarks (the constituents of protons, neutrons and other particles, as will be described in Chapter 44) have a potential energy of interaction of approximately this form, where x represents the separation between a pair of quarks. Because $U(x) \to \infty$ as $x \to \infty$, it's not possible to separate quarks from each other (a phenomenon called *quark confinement*). (a) Classically, what is the force acting on this particle as a function of x? (b) Using the uncertainty principle as in Problem 39.60, determine approximately the zero-point energy of the particle.

39.62. The discussion in Section 39.5 shows that the wave function $\Psi = \psi e^{-i\omega t}$ is a stationary state, where ψ is time independent

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

and ω is a real (not complex) constant. Consider the wave function $\Psi = \psi_1 e^{-i\omega_1 t} + \psi_2 e^{-i\omega_2 t}$, where ψ_1 and ψ_2 are different time-independent functions and ω_1 and ω_2 are different real constants. Assume that ψ_1 and ψ_2 are real-valued functions, so that $\psi_1^* = \psi_1$ and $\psi_2^* = \psi_2$. Is this Ψ a wave function for a stationary state? Why or why not?

39.63. Equation (39.18) is the time-independent Schrödinger equation in one dimension. The time-dependent Schrödinger equation is

$$-\frac{\hbar^2}{2m}\frac{\partial^2\Psi(x,t)}{\partial x^2} + U(x)\Psi(x,t) = i\hbar\frac{\partial\Psi(x,t)}{\partial t}$$

If $\psi(x)$ is a solution to Eq. (39.18) with energy E, show that the time-dependent function $\Psi(x,t) = \psi(x)e^{-i\omega t}$ is a solution to the time-dependent Schrödinger equation if ω is chosen appropriately. What is the value of ω that makes Ψ a solution?

39.64. One example of a time-dependent wave function is that of a free particle [one for which $U(x) = 0$ for all x] of energy E and x-component of momentum p. From the de Broglie relationships (see Section 39.1), such a particle has associated with it a frequency $f = E/h$ and a wavelength $\lambda = h/p$. A reasonable first guess for the time-dependent wave function for such a particle is $\Psi(x,t) = A\cos(kx - \omega t)$, where A is a constant, $\omega = 2\pi f$ is the angular frequency, and $k = 2\pi/\lambda$ is the wave number. This is the same function we used to describe a mechanical wave [see Eq. (15.7)] or an electromagnetic wave propagating in the x-direction [see Eq. (32.16)]. (a) Show that $\omega = E\hbar, k = p/\hbar$, and $\omega = \hbar k^2/2m$. (*Hint:* The energy is purely kinetic, so $E = p^2/2m$.) (b) To check this guess for the time-dependent wave function, substitute $\Psi(x,t) = A\cos(kx - \omega t)$ into the time-dependent Schrödinger equation (see Problem 39.63) with $U(x) = 0$ (so the particle is free). Show that this guess for $\Psi(x,t)$ does *not* satisfy this equation and so is not a suitable wave function for a free particle. (c) Use the procedure described in part (b) to show that a second guess, $\Psi(x,t) = A\sin(kx - \omega t)$, is also not a suitable wave function for a free particle. (d) Consider a combination of the functions proposed in parts (b) and (c):

$$\Psi(x,t) = A\cos(kx - \omega t) + B\sin(kx - \omega t)$$

By using the procedure described in part (b), show that this wave function is a solution to the time-dependent Schrödinger equation with $U(x) = 0$, but only if $B = iA$. (*Hint:* To satisfy the time-dependent Schrödinger equation for all x and t, the coefficients of $\cos(kx - \omega t)$ on both sides of the equation must be equal. The same is true for the coefficients of $\sin(kx - \omega t)$ on both sides of the equation.) This is an example of the general result that time-dependent wave functions always have both a real part and an imaginary part.

39.65. Imagine another universe in which the value of Planck's constant is 0.0663 J · s, but in which the physical laws and all other physical constants are the same as in our universe. In this universe, two physics students are playing catch. They are 12 m apart, and one throws a 0.25 kg ball directly towards the other with a speed of 6.0 m/s. (a) What is the uncertainty in the ball's horizontal momentum, in a direction perpendicular to that in which it is being thrown, if the student throwing the ball knows that it is located within a cube with volume 125 cm^3 at the time she throws it? (b) By what horizontal distance could the ball miss the second student?

39.66. A particle is described by the normalised wave function $\psi(x,y,z) = Axe^{-\alpha x^2}e^{-\beta y^2}e^{-\gamma z^2}$, where A, α, β, and γ are all real, positive constants. The probability that the particle will be found in the infinitesimal volume $dx\,dy\,dz$ centred at the point (x_0, y_0, z_0) is $|\psi(x_0, y_0, z_0)|^2\,dx\,dy\,dz$. (a) At what value of x_0 is the particle most likely to be found? (b) Are there values of x_0 for which the probability of the particle being found is zero? If so, at what x_0?

39.67. A particle is described by the normalised wave function $\psi(x,y,z) = Ae^{-\alpha(x^2+y^2+z^2)}$, where A and α are real, positive constants. (a) Determine the probability of finding the particle at a distance between r and $r + dr$ from the origin. (*Hint:* See Problem 39.66. Consider a spherical shell centred on the origin with inner radius r and thickness dr.) (b) For what value of r does the probability in part (a) have its maximum value? Is this the same value of r for which $|\psi(x,y,z)|^2$ is a maximum? Explain any differences.

39.68. Consider the wave packet defined by

$$\psi(x) = \int_0^\infty B(k)\cos kx\,dk$$

Let $B(k) = e^{-\alpha^2 k^2}$. (a) The function $B(k)$ has its maximum value at $k = 0$. Let k_h be the value of k at which $B(k)$ has fallen to half its maximum value, and define the width of $B(k)$ as $w_k = k_h$. In terms of α, what is w_k? (b) Use integral tables to evaluate the integral that gives $\psi(x)$. For what value of x is $\psi(x)$ maximum? (c) Define the width of $\psi(x)$ as $w_x = x_h$, where x_h is the positive value of x where $\psi(x)$ has fallen to half its maximum value. Calculate w_x in terms of α. (d) The momentum p is equal to $hk/2\pi$, so the width of B in momentum is $w_p = hw_k/2\pi$. Calculate the product $w_p w_x$ and compare to the Heisenberg uncertainty principle.

39.69. (a) Using the integral in Problem 39.68, determine the wave function $\psi(x)$ for a function $B(k)$ given by

$$B(k) = \begin{cases} 0 & k < 0 \\ 1/k_0, & 0 \le k \le k_0 \\ 0, & k > k_0 \end{cases}$$

This represents an equal combination of all wave numbers between 0 and k_0. Thus $\psi(x)$ represents a particle with average wave number $k_0/2$, with a total spread or uncertainty in wave number of k_0. We will call this spread the *width* w_k of $B(k)$, so $w_k = k_0$. (b) Graph $B(k)$ versus k and $\psi(x)$ versus x for the case $k_0 = 2\pi/L$, where L is a length. Locate the point where $\psi(x)$ has its maximum value and label this point on your graph. Locate the two points closest to this maximum (one on each side of it) where $\psi(x) = 0$, and define the distance along the x-axis between these two points as w_x, the width of $\psi(x)$. Indicate the distance w_x on your graph. What is the value of w_x if $k_0 = 2\pi/L$? (c) Repeat part (b) for the case $k_0 = \pi/L$. (d) The momentum p is equal to $hk/2\pi$, so the width of B in momentum is $w_p = hw_k/2\pi$. Calculate the product $w_p w_x$ for each of the cases $k_0 = 2\pi/L$ and $k_0 = \pi/L$. Discuss your results in light of the Heisenberg uncertainty principle.

Challenge Problems

39.70. The wave nature of particles results in the quantum-mechanical situation that a particle confined in a box can assume only wavelengths that result in standing waves in the box, with nodes at the box walls. (a) Show that an electron confined in a one-dimensional box of length L will have energy levels given by

$$E_n = \frac{n^2h^2}{8mL^2}$$

(*Hint:* Recall that the relationship between the de Broglie wavelength and the speed of a nonrelativistic particle is $mv = h/\lambda$. The

energy of the particle is $\frac{1}{2}mv^2$.) (b) If a hydrogen atom is modelled as a one-dimensional box with length equal to the Bohr radius, what is the energy (in electron volts) of the lowest energy level of the electron?

39.71. You have entered a contest in which the contestants drop a marble with mass 20.0 g from the roof of a building onto a small target 25.0 m below. From uncertainty considerations, what is the typical distance by which you will miss the target, given that you aim with the highest possible precision? (*Hint:* The uncertainty Δx_f in the x-coordinate of the marble when it reaches the ground comes in part from the uncertainty Δx_i in the x-coordinate initially and in part from the initial uncertainty in v_x. The latter gives rise to an uncertainty Δv_x in the horizontal motion of the marble as it falls. The values of Δx_i and Δv_x are related by the uncertainty principle. A small Δx_i gives rise to a large Δv_x, and vice versa. Find the value of Δx_i that gives the smallest total uncertainty in x at the ground. Ignore any effects of air resistance.)

QUANTUM MECHANICS 40

?Each of these containers holds a solution of microscopic semiconductor particles, each of which acts like a nanometer-sized 'atom'. The particles glow when exposed to ultraviolet light. Why do the smallest particles (on the left) glow blue, while the largest particles (on the right) glow red?

LEARNING GOALS

By studying this chapter, you will be able to explain:

- How to calculate the wave functions and energy levels for a particle confined to a box.
- How to analyse the quantum-mechanical behaviour of a particle in a potential well.
- How quantum mechanics makes it possible for particles to go where Newtonian mechanics says they cannot.
- How to use quantum mechanics to analyse a harmonic oscillator.
- How to extend quantum-mechanical calculations to three-dimensional problems.

In Chapter 39 we found that particles sometimes behave like waves and that they can be described by wave functions. Now we're ready for a systematic analysis of particles that are trapped in *bound states* (such as electrons in atoms), including finding their possible wave functions and energy levels.

Our analysis involves finding solutions of the Schrödinger equation, which we introduced in Chapter 39. For any quantum-mechanical system, the wave functions for any state of definite energy must be solutions of the Schrödinger equation for that system. As we will see, solving the Schrödinger equation automatically gives the possible energy levels for the system. We'll discuss several simple one-dimensional applications of the Schrödinger equation.

Besides energies, solving the Schrödinger equation gives us the probabilities of finding a particle in various regions. One surprising result is that there is a nonzero probability that microscopic particles will pass through thin barriers, even though such a process is forbidden by Newtonian mechanics.

Finally, we'll generalise the Schrödinger equation to three dimensions. This will pave the way for describing the wave functions for the hydrogen atom in Chapter 41. The hydrogen-atom wave functions in turn form the foundation for our analysis of more complex atoms, of the periodic table of the elements, of x-ray energy levels and of other properties of atoms.

40.1 Particle in a Box

In this chapter we want to learn how to use the Schrödinger equation to determine the possible energy levels and the corresponding wave functions for various systems. As in Chapter 39, we refer to the states of definite energy as *stationary states*. For simplicity, we begin with problems in which the particle can move

Activ ONLINE Physics
20.2 Particle in a Box

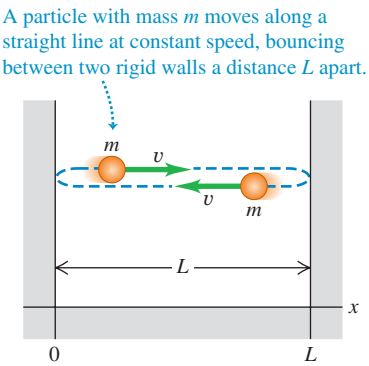
only along the x-axis. From Section 39.5, the Schrödinger equation for such one-dimensional problems is

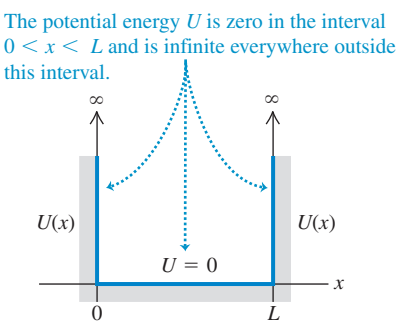
$$-\frac{\hbar^2}{2m}\frac{d^2\psi(x)}{dx^2} + U(x)\psi(x) = E\psi(x) \qquad \text{(one-dimensional Schrödinger equation)} \tag{40.1}$$

This equation is really a statement that the kinetic energy [represented by the term $-(\hbar^2/2m)d^2\psi(x)/dx^2$] plus the potential energy [represented by the term $U(x)\psi(x)$] is equal to the total energy [represented by the term $E\psi(x)$]. The fundamental problem is then the following: For a given potential energy function $U(x)$, what are the possible stationary-state wave functions $\psi(x)$, and what are the corresponding energies E?



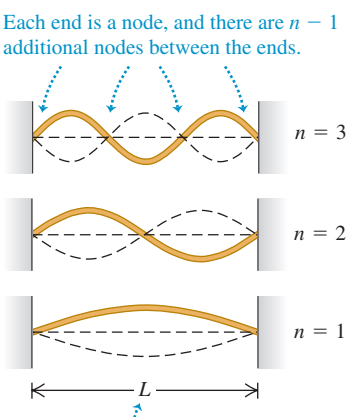
In Section 39.5 we solved this problem for the case $U(x) = 0$, corresponding to a *free* particle. The allowed wave functions and corresponding energies are

$$\psi(x) = Ae^{ikx} \qquad E = \frac{\hbar^2 k^2}{2m} \qquad \text{(free particle)} \tag{40.2}$$



The wave number k is equal to $2\pi/\lambda$, where λ is the wavelength. We found that k can have any real value, so the energy E of a free particle can have any value from zero to infinity. Furthermore, the particle can be found with equal probability at any value of x from $-\infty$ to $+\infty$.

Now let's look at a simple model in which a particle is *bound* so that it cannot escape to infinity, but rather is confined to a restricted region of space. Our system consists of a particle confined between two rigid walls separated by a distance L (Fig. 40.1). The motion is purely one dimensional, with the particle moving along the x-axis only and the walls at $x = 0$ and $x = L$. The potential energy corresponding to the rigid walls is infinite, so the particle cannot escape; between the walls, the potential energy is zero. This situation is often described as a '**particle in a box**'. This model might represent an electron that is free to move within a long, straight molecule or along a very thin wire. The potential-energy function is graphed in Fig. 40.2.



40.1 The Newtonian view of a particle in a box.

40.2 The potential-energy function for a particle in a box.

40.3 Normal modes of vibration for a string with length L, held at both ends.

Wave Function for a Particle in a Box

To solve the Schrödinger equation for this system, we begin with some restrictions on the particle's wave function $\psi(x)$. Because the particle is confined to the region $0 \le x \le L$, we expect $\psi(x)$ to be zero outside that region. This agrees with the Schrödinger equation: If the term $U(x)\psi(x)$ in Eq. (40.1) is to be finite, then $\psi(x)$ must be zero where $U(x)$ is infinite.

Furthermore, $\psi(x)$ must be a *continuous* function to be a mathematically well-behaved solution to the Schrödinger equation. If it is, then $\psi(x)$ must be zero at the region's boundary, $x = 0$ and $x = L$. These two conditions serve as *boundary conditions* for the problem. They should look familiar, because they are the same conditions that we used to find the normal modes of a vibrating string in Section 15.8 (Fig. 40.3); you should review that discussion.

An additional condition is that to calculate the second derivative $d^2\psi(x)/dx^2$ in Eq. (40.1), the *first* derivative $d\psi(x)/dx$ must also be continuous except at points where the potential energy becomes infinite (as it does at the walls of the box). This is analogous to the requirement that a vibrating string, like those shown in Fig. 40.3, cannot have a kink in it (which would correspond to a discontinuity in the first derivative of the wave function) except at the ends of the string.

We now solve for the wave functions in the region $0 \le x \le L$ subject to the above conditions. In this region $U(x) = 0$, so the wave function in this region must satisfy

$$-\frac{\hbar^2}{2m}\frac{d^2\psi(x)}{dx^2} = E\psi(x) \qquad \text{(particle in a box)} \tag{40.3}$$

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

Equation (40.3) is the *same* Schrödinger equation as for a free particle, so it is tempting to conclude that the wave functions and energies are given by Eq. (40.2). It is true that $\psi(x) = Ae^{ikx}$ satisfies the Schrödinger equation with $U(x) = 0$, is continuous and has a continuous first derivative $d\psi(x)/dx = ikAe^{ikx}$. However, this wave function does *not* satisfy the boundary conditions that $\psi(x)$ must be zero at $x = 0$ and $x = L$: At $x = 0$ the wave function in Eq. (40.2) is equal to $Ae^0 = A$, and at $x = L$ it is equal to Ae^{ikL}. (These would be equal to zero if $A = 0$, but then the wave function would be zero and there would be no particle at all!)

The way out of this dilemma is to recall Example 39.6 (Section 39.5), in which we found that a more general stationary-state solution to the Schrödinger equation with $U(x) = 0$ is

$$\psi(x) = A_1 e^{ikx} + A_2 e^{-ikx} \tag{40.4}$$

This wave function is a superposition of two waves: one travelling in the $+x$-direction of amplitude A_1, and one travelling in the $-x$-direction with the same wave number but amplitude A_2. This is analogous to the situation for standing waves on a string (Fig. 40.3), which we can regard as the superposition of two sinusoidal waves propagating in opposite directions (see Section 15.7). The energy that corresponds to Eq. (40.4) is $E = \hbar^2 k^2/2m$, just as for a single wave.

University of Queensland

A Federation Fellow, Professor Gerard Milburn is the Deputy Director of the Australian Research Council Centre of Excellence for Quantum Computer Technology at the University of Queensland. He is a Fellow of the Australian Academy of Science and was recognised by the Academy for his pioneering work of squeezed states of light and optical quantum measurements. His work on the quantum stochastic treatment of quantum control theory provided one of the first solvable examples of decoherence in non-linear dynamics and his work on optical quantum computing opened a new path to physical implementation. He is developing design principles based on quantum theory for new nano-scale devices, particularly quantum electromechanical systems (QEMS) with applications to electronics, nano-optics, metrology and biology

FRONTIERS OF RESEARCH

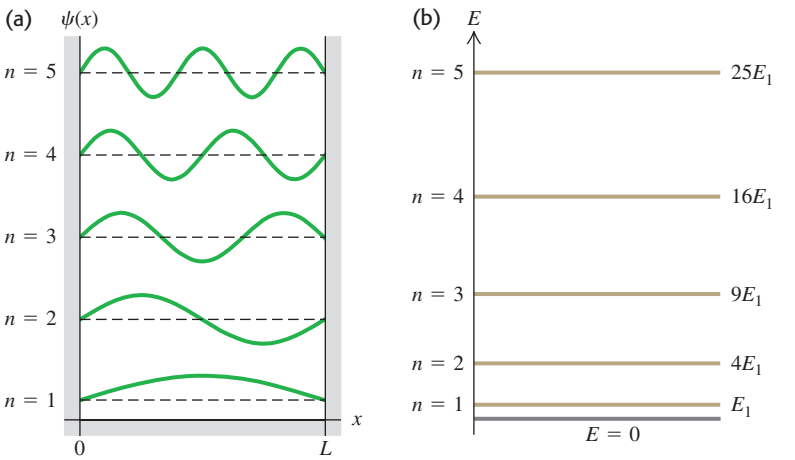
To see whether the wave function given by Eq. (40.4) can satisfy the boundary conditions, let's first rewrite it in terms of sines and cosines using Euler's formula, Eq. (39.15):

$$\begin{aligned}\psi(x) &= A_1(\cos kx + i\sin kx) + A_2[\cos(-kx) + i\sin(-kx)] \\ &= A_1(\cos kx + i\sin kx) + A_2(\cos kx - i\sin kx) \\ &= (A_1 + A_2)\cos kx + i(A_1 - A_2)\sin kx\end{aligned} \tag{40.5}$$

At $x = 0$ this is equal to $\psi(0) = A_1 + A_2$, which must equal zero if we are to satisfy the boundary condition at that point. Hence $A_2 = -A_1$, and Eq. (40.5) becomes

$$\psi(x) = 2iA_1 \sin kx = C\sin kx \tag{40.6}$$

We have simplified the expression by introducing the constant $C = 2iA_1$. (We'll come back to this constant later.) We can also satisfy the second boundary condition that $\psi = 0$ at $x = L$ by choosing values of k such that $kL = n\pi$ $(n = 1, 2, 3, \ldots)$. Hence Eq. (40.6) does give the stationary-state wave functions for a particle in a box in the region $0 \le x \le L$. (Outside this region, $\psi(x) = 0$.) The possible values of k and the wavelength $\lambda = 2\pi/k$ are



$$k = \frac{n\pi}{L} \quad \text{and} \quad \lambda = \frac{2\pi}{k} = \frac{2L}{n} \qquad (n = 1, 2, 3, \ldots) \tag{40.7}$$

Just as for the string in Fig. 40.3, the length L of the region is an integral number of half-wavelengths.

Energy Levels For a Particle in a Box

The possible energy levels are given by $E = \hbar^2 k^2/2m = p^2/2m$, where $p = \hbar k = (h/2\pi)(2\pi/\lambda) = h/\lambda$ is the magnitude of momentum of a free particle with wave number k and wavelength λ. This makes sense, since inside the region

40.4 (a) Wave functions for a particle in a box, with $n = 1, 2, 3, 4$ and 5. Each of the horizontal dashed lines represents $\psi = 0$ for the respective wave function. The five graphs have been displaced vertically for clarity, as in Fig. 40.3. (b) Energy-level diagram for a particle in a box. Each energy is n^2E_1, where E_1 is the ground-level energy.

$0 \le x \le L$ the potential energy is zero and the energy is all kinetic. For each value of n there are corresponding values of p, λ, and E; let's call them p_n, λ_n, and E_n. Putting the pieces together, we get

$$p_n = \frac{h}{\lambda_n} = \frac{nh}{2L} \tag{40.8}$$

and

$$E_n = \frac{p_n^2}{2m} = \frac{n^2h^2}{8mL^2} = \frac{n^2\pi^2\hbar^2}{2mL^2} \qquad (n = 1, 2, 3 \ldots) \qquad \text{(energy levels, particle in a box)} \tag{40.9}$$

These are the possible energy levels for a particle in a box. Each energy level has its own value of the quantum number n and a corresponding wave function, which we denote by ψ_n. When we replace k in Eq. (40.6) by $n\pi/L$ from Eq. (40.7), we find

$$\psi_n(x) = C\sin\frac{n\pi x}{L} \qquad (n = 1, 2, 3 \ldots) \tag{40.10}$$

Figure 40.4a shows graphs of the wave functions $\psi_n(x)$ for $n = 1$, 2, 3, 4, and 5. Note that these functions look identical to those for a standing wave on a string (Fig. 40.3). Figure 40.4b shows the energy-level diagram for this system. The levels of successively higher energies, proportional to n^2, are spaced farther and farther apart. There are an infinite number of levels because the walls are perfectly rigid; even a particle of infinitely great kinetic energy is confined within the box.

Example 40.1 Electron in an atom-size box

Find the lowest energy level for a particle in a box if the particle is an electron in a box 5.0×10^{-10} m across, or a little bigger than an atom.

SOLUTION

IDENTIFY: This problem uses what we have learned in this section about a particle in a box.

SET UP: The lowest energy level (that is, the ground level) corresponds to $n = 1$ in Eq. (40.9).

EXECUTE: From Eq. (40.9),

$$E_1 = \frac{h^2}{8mL^2} = \frac{(6.626 \times 10^{-34}\ \text{J}\cdot\text{s})^2}{8(9.109 \times 10^{-31}\ \text{kg})(5.0 \times 10^{-10}\ \text{m})^2}$$
$$= 2.4 \times 10^{-19}\ \text{J} = 1.5\ \text{eV}$$

EVALUATE: A particle trapped in a box is rather different from an electron bound in an atom, but it is reassuring that this energy is of the same order of magnitude as actual atomic energy levels.

You should be able to show that replacing the electron with a proton or a neutron $(m = 1.67 \times 10^{-27}\ \text{kg})$ in a box the width of a medium-sized nucleus $(L = 1.1 \times 10^{-14}\ \text{m})$ gives $E_1 = 1.7$ MeV. This shows us that the energies for particles in the nucleus are about a million times greater than the energies of electrons in atoms, giving us a clue as to why each nuclear fission and fusion reaction provides so much more energy than each chemical reaction.

If you repeat this calculation for a billiard ball $(m = 0.2\ \text{kg})$ bouncing back and forth between the cushions of a frictionless, perfectly elastic billiard table $(L = 1.5\ \text{m})$, you'll find the separation between energy levels to be as small as 4×10^{-67} J (See Exercise 40.1). This negligible value shows that quantum effects won't have much effect on your billiard game.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

CAUTION **Zero energy is not permitted** Note that the energy of a particle in a box *cannot* be zero. Equation (40.9) shows that $E = 0$ would require $n = 0$, but substituting $n = 0$ into Eq. (40.10) gives a zero wave function. Since a particle is described by a nonzero wave function, this means that there cannot be a particle with $E = 0$.

Probability and Normalisation

Let's look a bit more closely at the wave functions for a particle in a box, keeping in mind the *probability* interpretation of the wave function ψ that we discussed in Section 39.5. In our one-dimensional situation the quantity $|\psi(x)|^2\,dx$ is proportional to the probability that the particle will be found within a small interval dx about x. For a particle in a box,

$$|\psi(x)|^2\,dx = C^2\sin^2\frac{n\pi x}{L}\,dx$$

Both $\psi(x)$ and $|\psi(x)|^2$ are plotted in Fig. 40.5 for $n = 1$, 2 and 3. We note that not all positions are equally likely. This is in contrast to the situation in classical mechanics, in which all positions between $x = 0$ and $x = L$ are equally likely. We see in Fig. 40.5b that $|\psi(x)|^2 = 0$ at some points, so the probability is zero of finding the particle exactly at these points. Don't let that bother you; the uncertainty principle has already shown us that we can't measure position exactly. The particle is localised only to be somewhere between $x = 0$ and $x = L$, not to be exactly at some particular value of x.

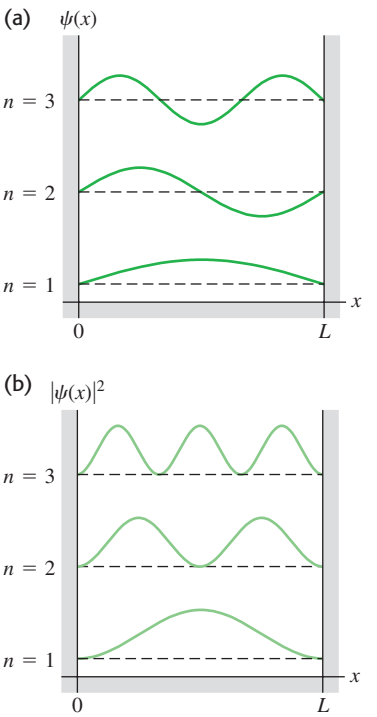
We know that the particle must be *somewhere* in the universe—that is, between $x = -\infty$ and $x = +\infty$. So the *sum* of the probabilities for all the dx's everywhere (the *total* probability of finding the particle) must equal 1. That is,

$$\int_{-\infty}^{\infty}|\psi(x)|^2\,dx = 1 \qquad \text{(normalisation condition)} \qquad (40.11)$$

A wave function is said to be *normalised* if it has a constant such as C in Eq. (40.10) that is calculated to make the total probability equal 1 in Eq. (40.11). The process of determining the constant is called **normalisation**, as we mentioned in Section 39.5. Why bother with normalisation? Because for a normalised wave function, $|\psi(x)|^2\,dx$ is not merely proportional to, but *equals*, the probability of finding the particle in dx. Recall from Section 39.5 that we call $|\psi(x)|^2$ the *probability distribution function*.

Now let's normalise the wave function $\psi(x)$ given by Eq. (40.10) for the particle in a box. Since $\psi(x)$ is zero except between $x = 0$ and $x = L$, Eq. (40.11) becomes

$$\int_0^L C^2\sin^2\frac{n\pi x}{L}\,dx = 1 \qquad (40.12)$$



You can evaluate this integral using the trigonometric identity $\sin^2\theta = \frac{1}{2}(1 - \cos 2\theta)$; the result is $C^2L/2$. Thus our probability interpretation of the wave function demands that $C^2L/2 = 1$, or $C = (2/L)^{1/2}$; the constant C is *not* arbitrary. (This is in contrast to the classical vibrating string problem, in which C represents an amplitude that depends on initial conditions.) Thus the normalised stationary-state wave functions for a particle in a box are

$$\psi_n(x) = \sqrt{\frac{2}{L}}\sin\frac{n\pi x}{L} \qquad (n = 1, 2, 3, \ldots) \qquad \text{(particle in a box)} \qquad (40.13)$$

Next, let's check whether our results for the particle in a box are consistent with the uncertainty principle. We can write the position of the particle as $x = L/2 \pm L/2$, so we can estimate the uncertainty in position as $\Delta x \approx L/2$. From Eq. (40.8) the magnitude of momentum in state n is $p_n = nh/2L$. A reasonable estimate of the momentum uncertainty is the difference in momentum of two levels that differ by 1 in their n values, that is, $\Delta p_x \approx h/2L$. Then the product $\Delta x\,\Delta p_x$ is

$$\Delta x\,\Delta p_x = \frac{h}{4}$$

40.5 Graphs of (a) $\psi(x)$ and (b) $|\psi(x)|^2$ for the first three wave functions $(n = 1, 2, 3)$ for a particle in a box. The horizontal dashed lines represent $\psi(x) = 0$ and $|\psi(x)|^2 = 0$ for each of the three levels. The value of $|\psi(x)|^2\,dx$ at each point is the probability of finding the particle in a small interval dx about the point.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

This is consistent with the uncertainty principle, Eq. (39.11), $\Delta x\,\Delta p_x \geq \hbar = h/2\pi$, in which the uncertainties were more precisely defined as standard deviations.

Example 40.2 A nonsinusoidal wave function?

(a) Show that $\psi(x) = Ax + B$, where A and B are constants, is a solution of the Schrödinger equation for an $E = 0$ energy level of a particle in a box. (b) What constraints do the boundary conditions at $x = 0$ and $x = L$ place on the constants A and B?

SOLUTION

IDENTIFY: This problem uses the idea that any physically reasonable wave function must satisfy both the Schrödinger equation and the appropriate boundary conditions.

SET UP: In part (a) we substitute $\psi(x)$ into the Schrödinger equation for a particle in a box, Eq. (40.3), to determine whether it is a solution. In part (b) we demand that $\psi(x)$ be equal to zero at $x = 0$ and at $x = L$.

EXECUTE: (a) From Eq. (40.3), the Schrödinger equation for this situation is $-(\hbar^2/2m)\,d^2\psi(x)/dx^2 = E\psi(x)$. Differentiating $\psi(x) = Ax + B$ twice with respect to x gives $d^2\psi(x)/dx^2 = 0$, so the left side of the equation is zero. Since we assume $E = 0$, the right side of the equation is also zero. Since $0 = 0$, $\psi(x) = Ax + B$ is a solution of this Schrödinger equation for $E = 0$. Note that both $\psi(x)$ and its derivative $d\psi(x)/dx = A$ are continuous functions, as they must be.

(b) Applying the boundary condition at $x = 0$ gives $\psi(0) = B$, so the constant B must be zero and $\psi(x) = Ax$. Applying the boundary condition at $x = L$ gives $\psi(L) = AL = 0$, so the constant A must also be zero. Thus the wave function equals zero inside the box as well as outside the box, and there is *zero* probability of finding the particle anywhere with this wave function. Hence $\psi(x) = Ax + B$ is not a physically valid wave function.

EVALUATE: The moral of this story is that there are many functions that satisfy the Schrödinger equation for a given physical situation, but most of these—including the function considered here—have to be rejected because they don't satisfy the boundary conditions.

Time Dependence

Finally, we note that the wave functions $\psi_n(x)$ in Eq. (40.13) depend only on the *spatial* coordinate x. From Section 39.5, the full wave function also depends on *time*. Equation (39.14) shows that if $\psi(x)$ is the wave function for a state of definite energy E, the full time-dependent wave function $\Psi(x, t)$ is

$$\Psi(x, t) = \psi(x)\, e^{-iEt/\hbar} \qquad \text{(time-dependent wave function for a stationary state)} \tag{40.14}$$

From Eq. (40.13), it follows that the time-dependent wave functions for a particle in a box are

$$\Psi(x, t) = \sqrt{\frac{2}{L}}\sin\left(\frac{n\pi x}{L}\right)e^{-iE_n t/\hbar} \qquad (n = 1, 2, 3, \ldots) \tag{40.15}$$

In this expression the energies E_n are given by Eq. (40.9).

The absolute value of $e^{-iEt/\hbar}$ is unity: $|e^{-iEt/\hbar}|^2 = e^{+iEt/\hbar}e^{-iEt/\hbar} = e^0 = 1$. Hence $|\Psi(x, t)|^2$ is equal to $|\psi(x)|^2$, and the probability distribution function does not depend on time. We saw in Section 39.5 that this is the origin of the term *stationary state* for a state of definite energy. So in calculations with states that have definite energy, we are justified in omitting the time factor. We'll be concerned mostly with stationary states in our applications of quantum mechanics.

Test Your Understanding of Section 40.1 If a particle in a box is in the nth energy level, what is the average value of its x-component of momentum p_x? (i) $nh/2L$; (ii) $(\sqrt{2}/2)nh/L$; (iii) $(1/\sqrt{2})nh/L$; (iv) $(1/2\sqrt{2})nh/L$; (v) zero.

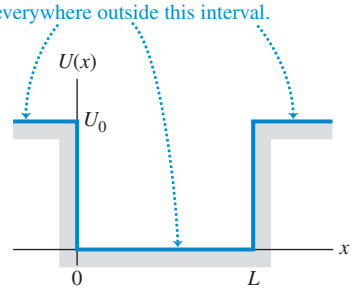
20.1 Potential Energy Diagrams
20.2 Potential Wells

40.2 Potential Wells

A **potential well** is a potential-energy function $U(x)$ that has a minimum. We introduced this term in Section 7.5, and we also used it in our discussion of periodic motion in Chapter 13. In Newtonian mechanics a particle trapped in a



Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

potential well can vibrate back and forth with periodic motion. Our first application of the Schrödinger equation, the particle in a box, involved a rudimentary potential well with a function $U(x)$ that is zero within a certain interval and infinite everywhere else. This function corresponds to a few situations found in nature, as mentioned in Section 40.1, but the correspondence is only approximate.

A potential well that serves as a better approximation to several actual physical situations is a well with straight sides but *finite* height. Figure 40.6 shows a potential-energy function that is zero in the interval $0 \le x \le L$ and has the value U_0 outside this interval. This function is often called a **square-well potential**. It could serve as a simple model of an electron within a metallic sheet with thickness L, moving perpendicular to the surfaces of the sheet. The electron can move freely inside the metal but has to climb a potential-energy barrier with height U_0 to escape from either surface of the metal. The energy U_0 is related to the *work function* that we discussed in Section 38.2 in connection with the photoelectric effect. In a three-dimensional application a spherical version of a potential well can be used to approximately describe the motions of protons and neutrons within a nucleus.

40.6 A square-well potential.

The potential energy U is zero in the interval $0 \le x \le L$ and has the constant value U_0 everywhere outside this interval.

Bound States of a Square-Well Potential

In Newtonian mechanics, the particle is trapped (localised) in a well if the total energy E is less than U_0. In quantum mechanics, such a trapped state is often called a **bound state**. All states are bound for an infinitely deep well, but if E is greater than U_0 for a finite well, the particle is *not* bound.

For a finite square well, let's consider bound-state solutions of the Schrödinger equation, corresponding to $E < U_0$. The easiest approach is to consider separately the regions where $U = 0$ and where $U = U_0$. Where $U = 0$, the Schrödinger equation reduces to Eq. (40.3). Rearranging this equation, we find

$$\frac{d^2\psi(x)}{dx^2} = -\frac{2mE}{\hbar^2}\psi(x) \tag{40.16}$$

From Eq. (40.5), we can express the solutions of this equation as combinations of $\cos kx$ and $\sin kx$, where $E = \hbar^2k^2/2m$ and so $k = \sqrt{2mE}/\hbar$. Hence inside the square well $(0 \le x \le L)$ we have

$$\psi(x) = A\cos\frac{\sqrt{2mE}}{\hbar}x + B\sin\frac{\sqrt{2mE}}{\hbar}x \qquad \text{(inside the well)} \tag{40.17}$$

where A and B are constants. So far, this looks a lot like the particle-in-a-box analysis in Section 40.1.

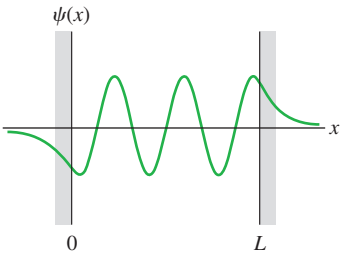
In the regions $x < 0$ and $x > L$ we use Eq. (40.1)with $U = U_0$. Rearranging, we get

$$\frac{d^2\psi(x)}{dx^2} = \frac{2m(U_0 - E)}{\hbar^2}\psi(x) \tag{40.18}$$

The quantity $U_0 - E$ is positive, so the solutions of this equation are exponential. Using κ (the Greek letter kappa) as positive in the abbreviation $\kappa = [2m(U_0 - E)]^{1/2}/\hbar$, we can write the solutions as

$$\psi(x) = Ce^{\kappa x} + De^{-\kappa x} \qquad \text{(outside the well)} \tag{40.19}$$

where C and D are constants with different values in the $x < 0$ and $x > L$ regions.



We see that the bound-state wave functions for this system are sinusoidal inside the well and exponential outside it. We have to use the positive exponent in the $x < 0$ region and the negative exponent in the $x > L$ region. That is, $D = 0$ for $x < 0$ and $C = 0$ for $x > L$. Without this choice of constants, ψ would approach infinity as $|x|$ approached infinity, and the normalisation condition, Eq. (40.11), could not be satisfied. We also have to match the wave functions so

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

that they satisfy the boundary conditions that we mentioned in Section 40.1: $\psi(x)$ and $d\psi(x)/dx$ must be continuous at the boundary points ($x = 0$ and $x = L$). If the wave function $\psi(x)$ or the slope $d\psi(x)/dx$ were to change discontinuously at a point, the second derivative $d^2\psi(x)/dx^2$ would be *infinite* at that point. But that would violate the Schrödinger equation, which says that at every point, $d^2\psi(x)/dx^2$ is proportional to $U - E$. In our situation, $U - E$ is finite everywhere, so $d^2\psi(x)/dx^2$ must also be finite everywhere.

Matching the sinusoidal and exponential functions at the boundary points so that they join smoothly is possible only for certain specific values of the total energy E, so this requirement determines the possible energy levels of the finite square well. There is no simple formula for the energy levels as there was for the infinitely deep well. Finding the levels is a fairly complex mathematical problem that requires solving a transcendental equation by numerical approximation; we won't go into the details. Figure 40.7 shows the general shape of a possible wave function. The most striking features of this wave function are the 'exponential tails' that extend outside the well into regions that are forbidden by Newtonian mechanics (because in those regions the particle would have negative kinetic energy). We see that there is some probability for finding the particle *outside* the potential well, despite the fact that in classical mechanics this is impossible. This penetration into classically forbidden regions is a quantum effect that has no classical analog for particles. We will discuss an amazing result of this effect in Section 40.3.

40.7 A possible wave function for a particle in a finite potential well. The function is sinusoidal inside the well ($0 \le x \le L$) and exponential outside it. It approaches zero asymptotically at large $|x|$. The functions must join smoothly at $x = 0$ and $x = L$; the wave function and its derivative must be continuous.

Example 40.3 Well versus box

Show that Eq. (40.19), $\psi(x) = Ce^{\kappa x} + De^{-\kappa x}$, is consistent with the corresponding particle-in-a-box wave function.

SOLUTION

IDENTIFY: Equation (40.19) gives the possible wave functions outside the potential well. Since the wave function outside the box (an infinite potential well) equals zero, we must show that $\psi(x) = Ce^{\kappa x} + De^{-\kappa x}$ approaches zero for both $x < 0$ and $x > L$ as the depth of the potential well (U_0) approaches infinity.

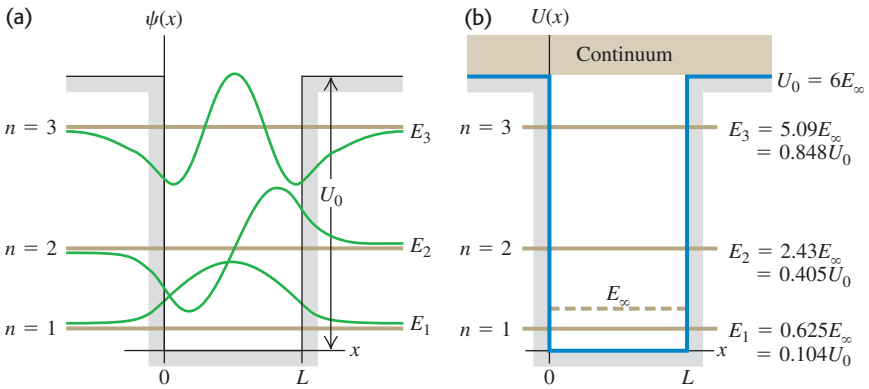
SET UP: We use our knowledge of the exponential function and the definition of the quantity κ in Eq. (40.19): $\kappa = [2m(U_0 - E)]^{1/2}/\hbar$.

EXECUTE: As U_0 approaches infinity, κ also approaches infinity. In the region $x < 0$, the wave function is $\psi(x) = Ce^{\kappa x}$; as $\kappa \to \infty$, $\kappa x \to -\infty$ and $e^{\kappa x} \to 0$, so the wave function approaches zero for all $x < 0$. In the region $x > L$, the wave function is $\psi(x) = De^{-\kappa x}$; as $\kappa \to \infty$, $-\kappa x \to -\infty$ and $e^{-\kappa x} \to 0$, so the wave function also approaches zero for all $x > L$.

EVALUATE: In Section 40.1 we *assumed* $\psi(x) = 0$ outside the box. This analysis validates our assumption.

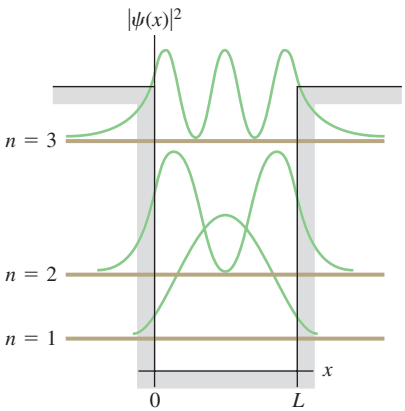
In our study of mechanics, we often considered limiting cases to check our results (see Examples 5.11 and 5.13 in Section 5.2). This example shows that this technique is also useful for problems in quantum mechanics, as it is for problems in all branches of physics.

Comparing Finite and Infinite Square Wells



Let's continue the comparison of the finite-depth potential well with the infinitely deep well that we began in Example 40.3. First, because the wave functions for the finite well aren't zero at $x = 0$ and $x = L$, the wavelength of the sinusoidal part of each wave function is *longer* than it would be with an infinite well. From $p = h/\lambda$ this increase in λ corresponds to a reduced magnitude of momentum and therefore a reduced energy. Thus each energy level, including the ground level, is *lower* for a finite well than for an infinitely deep well with the same width.

Second, a well with finite depth U_0 has only a *finite* number of bound states and corresponding energy levels, compared to the *infinite* number for an infinitely deep well. How many levels there are depends on the magnitude of U_0 in comparison with the ground-level energy for the infinite well, which we call E_∞. From Eq. (40.9),



$$E_\infty = \frac{\pi^2\hbar^2}{2mL^2} \tag{40.20}$$

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

40.8 (a) Wave functions for the three bound states for a particle in a finite potential well with depth U_0, for the case $U_0 = 6E_\infty$. The horizontal brown line for each wave function corresponds to $\psi = 0$; the vertical placement of these lines indicates the energy of each bound state. (b) Energy-level diagram for this system. The energies are expressed both as multiples of E_∞ and as fractions of U_0. All energies greater than U_0 are possible; states with $E > U_0$ form a continuum.

40.9 Probability distribution functions $|\psi(x)|^2$ for the square-well wave functions shown in Fig. 40.8. The horizontal brown line for each wave function corresponds to $|\psi|^2 = 0$.

When U_0 is *much larger* than E_∞ (a very deep well), there are many bound states, and the energies of the lowest few are nearly the same as the energies for the infinitely deep well. When U_0 is only a few times as large as E_∞, there are only a few bound states. (But there is always at least one bound state, no matter how shallow the well.) As with the infinitely deep well, there is *no* state with $E = 0$; such a state would violate the uncertainty principle.

Figure 40.8 shows the particular case in which $U_0 = 6E_\infty$; for this case there are three bound states. The energy levels are expressed both as fractions of the well depth U_0 and as multiples of E_∞. Note that if the well were infinitely deep, the lowest three levels, as given by Eq. (40.9), would be E_∞, $4E_\infty$ and $9E_\infty$. The wave functions for the three bound states are also shown.

It turns out that when U_0 is less than E_∞, there is only one bound state. In the limit when U_0 is *much smaller* than E_∞ (a very shallow or very narrow well), the energy of this single state is approximately $E = 0.68U_0$.

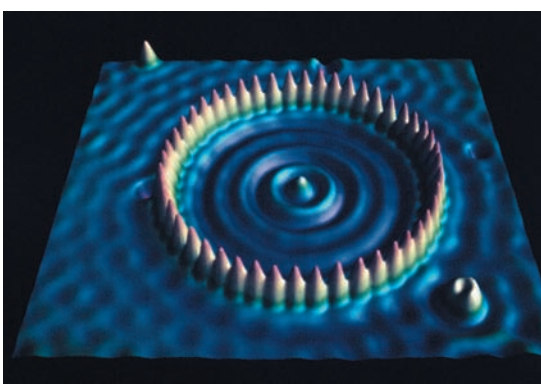


Figure 40.9 shows graphs of the probability distributions—that is, the values of $|\psi|^2$,—for the wave functions shown in Fig. 40.8a. As with the infinite well, not all positions are equally likely. We have already commented on the possibility of finding the particle outside the well, in the classically forbidden regions.

There are also states for which E is *greater than* U_0. In this case the particle is not bound but is free to move through all values of x. Thus *any* energy E greater than U_0 is possible. These free-particle states thus form a *continuum* rather than a discrete set of states with definite energy levels. The free-particle wave functions are sinusoidal both inside and outside the well. The wavelength is shorter inside the well than outside, corresponding to greater kinetic energy in the well than outside it.

The square-well potential described in this section has a number of practical applications. We mentioned earlier the example of an electron inside a metallic sheet. A three-dimensional version, in which U is zero inside a spherical region with radius R and has the value U_0 outside, provides a simple model to represent the interaction of a neutron with a nucleus in neutron-scattering experiments. In this context the model is called the *crystal-ball model* of the nucleus, because neutrons interacting with such a potential are scattered in a way that's analogous to scattering of light by a crystal ball.

Figure 40.10 shows a graphic demonstration of particles in a *two*-dimensional finite potential well, and Example 40.4 describes another application of the square-well potential.

40.10 To make this image, 48 iron atoms (shown as yellow peaks) were placed in a circle on a copper surface. The 'elevation' at each point inside the circle indicates the electron density within the circle. The standing-wave pattern is very similar to the probability distribution function for a particle in a one-dimensional finite potential well. (This image was made with a scanning tunnelling microscope, to be discussed in Section 40.3.)

Example 40.4 Electron in a square well

An electron is trapped in a square well with a width of 0.50 nm (comparable to a few atomic diameters). (a) Find the ground-level energy if the well is infinitely deep. (b) If the actual well depth is six times the ground-level energy found in part (a), find the energy levels. (c) If the atom makes a transition from a state with energy E_2 to a state with energy E_1 by emitting a photon, find the wavelength of the photon. In what region of the electromagnetic spectrum does the photon lie? (d) If the electron is initially in its ground level and absorbs a photon, what is the minimum energy the photon must have to liberate the electron from the well? In what region of the spectrum does the photon lie?

SOLUTION

IDENTIFY: We use the ideas of a particle in a box and a square well. The energy of the photon emitted or absorbed in a transition is equal to the difference in energy between two levels involved in the transition.

SET UP: We use Eq. (40.20) to find the ground-level energy E_∞ for an infinitely deep well. The energies for a square well with $U_0 = 6E_\infty$. are shown in Fig. 40.8b. The photon wavelength is given by the relationship $E = hf = hc/\lambda$ [Eq. (38.8)].

EXECUTE: (a) From Eq. (40.20),

$$E_\infty = \frac{\pi^2\hbar^2}{2mL^2} = \frac{\pi^2(1.055 \times 10^{-34}\ \text{J}\cdot\text{s})^2}{2(9.11 \times 10^{-31}\ \text{kg})(0.50 \times 10^{-9}\ \text{m})^2}$$
$$= 2.4 \times 10^{-19}\ \text{J} = 1.5\ \text{eV}$$

(b) We are given $U_0 = 6E_\infty$, so $U_0 = 6(1.5\ \text{eV}) = 9.0\ \text{eV}$. We can simply read off the energy levels from Fig. 40.8b. Our answers are

$$E_1 = 0.104U_0 = 0.104(9.0\ \text{eV}) = 0.94\ \text{eV}$$
$$E_2 = 0.405U_0 = 0.405(9.0\ \text{eV}) = 3.6\ \text{eV}$$
$$E_3 = 0.848U_0 = 0.848(9.0\ \text{eV}) = 7.6\ \text{eV}$$

Alternatively,

$$E_1 = 0.625E_\infty = 0.625(1.5\ \text{eV}) = 0.94\ \text{eV}$$
$$E_2 = 2.43E_\infty = 2.43(1.5\ \text{eV}) = 3.6\ \text{eV}$$
$$E_3 = 5.09E_\infty = 5.09(1.5\ \text{eV}) = 7.6\ \text{eV}$$

(c) The photon energy is

$$E_2 - E_1 = 3.6\ \text{eV} - 0.94\ \text{eV} = 2.7\ \text{eV}$$

We determine the wavelength from $E = hf = hc/\lambda$:

$$\lambda = \frac{hc}{E} = \frac{(4.136 \times 10^{-15}\ \text{eV}\cdot\text{s})(3.00 \times 10^8\ \text{m/s})}{2.7\ \text{eV}} = 460\ \text{nm}$$

This photon is in the blue region of the visible spectrum.

(d) We see from Fig. 40.8b that the minimum energy needed to lift the electron out of the well from its $n = 1$ ground level is the well depth $(U_0 = 9.0\ \text{eV})$ minus the electron's initial energy $(E_1 = 0.94\ \text{eV})$, or 8.1 eV. Since 8.1 eV is three times the 2.7 eV photon energy of part (c), the corresponding photon wavelength is one-third of 460 nm, or 150 nm, which is in the ultraviolet region of the spectrum.

EVALUATE: To check our results for the energies of the three bound states, note that if the well had been infinitely deep, the energies would have been

$$E_1 = E_\infty = 1.5\ \text{eV}$$
$$E_2 = 4E_\infty = 6.0\ \text{eV}$$
$$E_3 = 9E_\infty = 13.5\ \text{eV}$$

The energies we found in part (b) are less than these values. This makes sense: As we mentioned earlier, the finite depth of the well lowers the energy levels compared to the levels for an infinitely deep well.

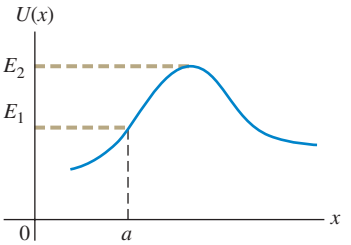
One application of these ideas is to *quantum dots*, which are nanometer-sized particles of a semiconductor such as cadmium selenide (CdSe). An electron within a quantum dot behaves much like a particle in a finite potential well with a width L equal to the size of the dot. When quantum dots are illuminated with ultraviolet light, the electrons absorb the ultraviolet photons and are excited into high energy levels like the $n = 3$ level described in this example. If the electron returns to the ground level $(n = 1)$ in two or more steps (for example, from $n = 3$ to $n = 2$ and from $n = 2$ to $n = 1$), one of the steps will involve emitting a visible-light photon as we have calculated here. (We described this process of *fluorescence* in Section 38.3.) Increasing the value of L decreases the energies of the levels and hence the spacing between them, and hence decreases the energy and increases the wavelength of the emitted photons. The photograph that opens this chapter shows quantum dots of different sizes in solution, each of which emits a characteristic wavelength depending on the dot size. Quantum dots can be injected into living tissue and their fluorescent glow used as a tracer for biological research and for medicine. They may also be the key to a new generation of lasers and ultrafast computers.

Test Your Understanding of Section 40.2 Suppose that the width of the finite potential well shown in Fig. 40.8 is reduced by one-half. How must the value of U_0 change so that there are still just three bound energy levels whose energies are the fractions of U_0 shown in Fig. 40.8b? (i) U_0 must increase by a factor of 4; (ii) U_0 must increase by a factor of 2; (iii) U_0 must remain the same; (iv) U_0 must decrease by a factor of $\frac{1}{2}$; (v) U_0 must decrease by a factor of $\frac{1}{4}$.

40.3 Potential Barriers and Tunnelling

A **potential barrier** is the opposite of a potential well; it is a potential-energy function with a *maximum*. Figure 40.11 shows an example. In Newtonian mechanics, if the total energy is E_1, a particle that is initially to the left of the barrier

ActivPhysics ONLINE
20.4 Potential Barriers

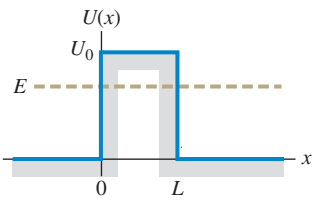


Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

must remain to the left of the point $x = a$. If it were to move to the right of this point, the potential energy U would be greater than the total energy E. Because $K = E - U$, the kinetic energy would be negative, and this is impossible since a negative value of $K = \frac{1}{2}mv^2$ would require negative mass or imaginary speed.

If the total energy is greater than E_2, the particle can get past the barrier. A roller-coaster car can surmount a hill if it has enough kinetic energy at the bottom. If it doesn't, it stops partway up and then rolls back down.

Quantum mechanics supplies us with a peculiar and very interesting phenomenon in connection with potential barriers. A particle that encounters such a barrier is not necessarily turned back; there is some probability for it to emerge on the other side, even when it doesn't have enough kinetic energy to surmount the barrier according to Newtonian mechanics. This penetration of a barrier is called **tunnelling**. It's a natural name; if you dig a tunnel through a hill, you don't have to go over the top. However, in quantum-mechanical tunnelling, the particle does not actually bore a hole through the barrier and it loses no energy in the tunnelling process.

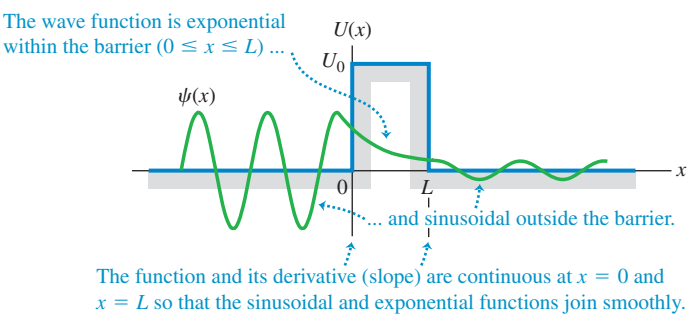


40.11 A potential-energy barrier. According to Newtonian mechanics, if the total energy is E_1, a particle that is on the left side of the barrier can go no farther than $x = a$. If the total energy is greater than E_2, the particle can pass the barrier.

Tunnelling Through a Rectangular Barrier

To understand how tunnelling can occur, let's look at the potential-energy function $U(x)$ shown in Fig. 40.12. It's like Fig. 40.6 turned upside-down; the potential energy is zero everywhere except in the range $0 \le x \le L$, where it has the value U_0. This might represent a simple model for an electron and two slabs of metal separated by an air gap of thickness L. We let the potential energy be zero within either slab but equal to U_0 in the gap between them.

40.12 A rectangular potential-energy barrier with width L and height U_0. According to Newtonian mechanics, if the total energy E is less than U_0, a particle cannot pass over this barrier but is confined to the side where it starts.



Let's consider solutions of the Schrödinger equation for this potential-energy function for the case in which E is less than U_0. We can use our results from Section 40.2. In the regions $x < 0$ and $x > L$ the solution is sinusoidal and given by Eq. (40.17). Within the barrier $(0 \le x \le L)$ the solution is exponential, as in Eq. (40.19). Just as with the finite potential well, the functions have to join smoothly at the boundary points $x = 0$ and $x = L$. That is, the function and its derivative have to be continuous at these points.

These requirements lead to a wave function like the one shown in Fig. 40.13. The function is *not* zero inside the barrier (the region forbidden by Newtonian mechanics). Even more remarkable, a particle that is initially to the *left* of the barrier has some probability of being found to the *right* of the barrier. How great a probability? That depends on the width L of the barrier and the particle's energy E (all kinetic) in comparison with the barrier height U_0. The probability T that the particle gets through the barrier is proportional to the square of the ratio of the amplitudes of sinusoidal wave functions on the two sides of the barrier. These amplitudes are determined by matching wave functions and their derivatives at the boundary points, a fairly involved mathematical problem. When T is much smaller than unity, it is given approximately by

$$T = Ge^{-2\kappa L} \quad \text{where} \quad G = 16\frac{E}{U_0}\left(1 - \frac{E}{U_0}\right) \quad \text{and} \quad \kappa = \frac{\sqrt{2m(U_0 - E)}}{\hbar} \tag{40.21}$$

(probability of tunnelling)

40.13 A possible wave function for a particle tunnelling through the potential-energy barrier shown in Fig. 40.12.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

The probability decreases rapidly with increasing barrier width L. It also depends critically on the energy difference $U_0 - E$, representing the additional kinetic energy the particle would need to be able to climb over the barrier in a Newtonian analysis.

Example 40.5 Tunnelling through a barrier

A 2.0 eV electron encounters a barrier with height 5.0 eV. What is the probability that it will tunnel through the barrier if the barrier width is (a) 1.00 nm; and (b) 0.50 nm (roughly ten and five atomic diameters, respectively)?

SOLUTION

IDENTIFY: This problem uses the ideas of tunnelling through a rectangular barrier like that shown in Figs. 40.12 and 40.13.

SET UP: Our target variable is the tunnelling probability T in Eq. (40.21), which we evaluate for the given values $E = 2.0$ eV (electron energy), $U = 5.0$ eV (barrier height), $m = 9.11 \times 10^{-31}$ kg (mass of the electron), and $L = 1.00$ nm or 0.50 nm (barrier width).

EXECUTE: First we evaluate G and κ in Eq. (40.21), using $E = K = 2.0$ eV:

$$G = 16\frac{2.0\text{ eV}}{5.0\text{ eV}}\left(1 - \frac{2.0\text{ eV}}{5.0\text{ eV}}\right) = 3.8$$

$$U_0 - E = 5.0\text{ eV} - 2.0\text{ eV} = 3.0\text{ eV} = 4.8 \times 10^{-19}\text{ J}$$

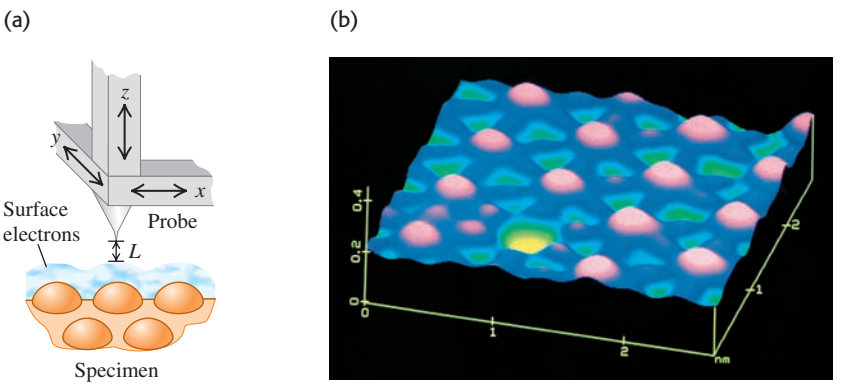
$$\kappa = \frac{\sqrt{2(9.11 \times 10^{-31}\text{ kg})(4.8 \times 10^{-19}\text{ J})}}{1.055 \times 10^{-34}\text{ J}\cdot\text{s}} = 8.9 \times 10^{9}\text{ m}^{-1}$$

(Note that the eV energy units cancelled in calculating G, but we had to convert eV to J $= \text{kg}\cdot\text{m}^2/\text{s}^2$ to find κ in m^{-1}.)

(a) When $L = 1.00\text{ nm} = 1.00 \times 10^{-9}$ m, $2\kappa L = 2(8.9 \times 10^{9}\text{ m}^{-1}) \times (1.00 \times 10^{-9}\text{ m}) = 17.8$, and

$$T = Ge^{-2\kappa L} = 3.8e^{-17.8} = 7.1 \times 10^{-8}$$

(b) When $L = 0.50$ nm, half of 1.00 nm, $2\kappa L$ is half of 17.8, or 8.9, and



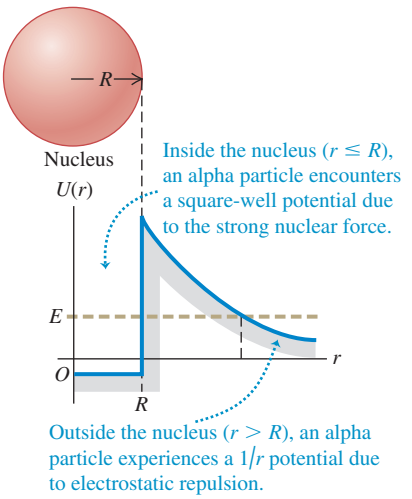
$$T = 3.8e^{-8.9} = 5.2 \times 10^{-4}$$

EVALUATE: Halving the width of this barrier increases the tunnelling probability by a factor of nearly ten thousand.

Applications of Tunnelling

Tunnelling is significant in many areas of physics, including some with considerable practical importance. For example, when you twist two copper wires together or close the contacts of a switch, current passes from one conductor to the other despite a thin layer of nonconducting copper oxide between them. The electrons tunnel through this thin insulating layer. The *tunnel diode* is a semiconductor device in which electrons tunnel through a potential barrier. The current can be switched on and off very quickly (within a few picoseconds) by varying the height of the barrier. The *Josephson junction* consists of two superconductors separated by an oxide layer a few atoms (1 to 2 nm) thick. Electron pairs in the superconductors can tunnel through the barrier layer, giving such a device unusual circuit properties. Josephson junctions are useful for establishing precise voltage standards and measuring tiny magnetic fields.

The *scanning tunnelling microscope* (STM) uses electron tunnelling to create images of surfaces down to the scale of individual atoms. An extremely sharp conducting needle is brought very close to the surface, within 1 nm or so (Fig. 40.14a).



40.14 (a) Schematic diagram of the probe of a scanning tunnelling microscope (STM). As the sharp conducting probe is scanned across the surface in the x- and y-directions, it is also moved in the z-direction to maintain a constant tunnelling current. The changing position of the probe is recorded and used to construct an image of the surface. (b) This coloured STM image shows sodium atoms (pink) adsorbed on a platinum surface. The yellow spot indicates a missing atom.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

When the needle is at a positive potential with respect to the surface, electrons can tunnel through the surface potential-energy barrier and reach the needle. As Example 40.5 shows, the tunnelling probability and hence the tunnelling current depend strongly on the width L of the barrier (the distance between the surface and the needle tip). In one mode of operation the needle is scanned across the surface and at the same time is moved perpendicular to the surface to maintain a constant tunnelling current. The needle motion is recorded, and after many parallel scans, an image of the surface can be reconstructed. Extremely precise control of needle motion, including isolation from vibration, is essential. Figure 40.14b shows an image of sodium atoms on the surface of a platinum crystal. (Figure 40.10 is also an STM image.)

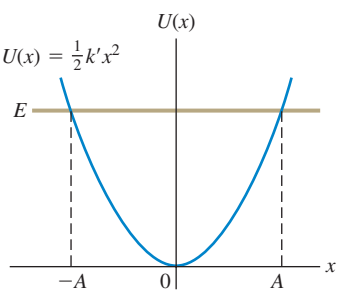
Tunnelling is of great importance in nuclear physics. A fusion reaction can occur when two nuclei tunnel through the barrier caused by their electrical repulsion and approach each other closely enough for the attractive nuclear force to cause them to fuse. Fusion reactions occur in the cores of stars, including the sun; without tunnelling, the sun wouldn't shine. The emission of alpha particles from unstable nuclei also involves tunnelling. An alpha particle at the surface of a nucleus encounters a potential barrier that results from the combined effect of the attractive nuclear force and the electrical repulsion of the remaining part of the nucleus (Fig. 40.15). The alpha particle tunnels through this barrier. Because the tunnelling probability depends so critically on the barrier height and width, the lifetimes of alpha-emitting nuclei vary over an extremely wide range. We'll return to alpha decay in Chapter 43.

40.15 Approximate potential-energy function for an alpha particle interacting with a nucleus of radius R. If an alpha particle inside the nucleus has energy E greater than zero, it can tunnel through the barrier and escape from the nucleus.

Test Your Understanding of Section 40.3 Is it possible for a particle undergoing tunnelling to be found *within* the barrier rather than on either side of it?

40.4 The Harmonic Oscillator

In Newtonian mechanics a **harmonic oscillator** is a particle with mass m acted on by a conservative force component $F_x = -k'x$. (In this discussion we will use k' for the *force constant* to minimise confusion with the wave number $k = 2\pi/\lambda$.) This force component is proportional to the particle's displacement x from its equilibrium position, $x = 0$. The corresponding potential-energy function is $U = \frac{1}{2}k'x^2$ (Fig. 40.16). When the particle is displaced from equilibrium, it undergoes sinusoidal motion with angular frequency $\omega = (k'/m)^{1/2}$. We studied this system in detail in Chapter 13; you should review that discussion.



A quantum-mechanical analysis of the harmonic oscillator using the Schrödinger equation is an interesting and useful study. The solutions provide insight into vibrations of molecules, the quantum theory of heat capacities, atomic vibrations in crystalline solids, and many other situations.

Before we get into the details, let's make an enlightened guess about the energy levels. The energy E of a *photon* is related to its angular frequency ω by $E = hf = (h/2\pi)(\omega/2\pi) = \hbar\omega$. The harmonic oscillator has a characteristic angular frequency ω, at least in Newtonian mechanics. So a reasonable guess would be that in the quantum-mechanical analysis the energy levels of a harmonic oscillator would be multiples of the quantity

$$\hbar\omega = \hbar\sqrt{\frac{k'}{m}}$$

These are the energy levels that Planck assumed in deriving his radiation law (see Section 38.8). It was a good assumption; the energy levels are in fact half-integer $\left(\frac{1}{2}, \frac{3}{2}, \frac{5}{2}, \ldots\right)$ multiples of $\hbar\omega$.

40.16 Potential-energy function for the harmonic oscillator. In Newtonian mechanics the amplitude A is related to the total energy E by $E = \frac{1}{2}k'A^2$, and the particle is restricted to the range from $x = -A$ to $x = A$.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

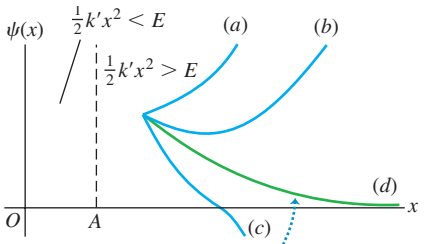
For the harmonic oscillator we write $\frac{1}{2}k'x^2$ in place of U in the one-dimensional Schrödinger equation, Eq. (40.1):

$$-\frac{\hbar^2}{2m}\frac{d^2\psi}{dx^2}+\frac{1}{2}k'x^2\psi = E\psi \qquad \text{(Schrödinger equation for the harmonic oscillator)} \tag{40.22}$$

The solutions of this equation are wave functions for the physically possible states of the system.

Wave Functions, Boundary Conditions and Energy Levels

In the discussion of square-well potentials in Section 40.2 we found that the energy levels are determined by boundary conditions at the walls of the well. However, the harmonic-oscillator potential has no walls as such; what, then, are the appropriate boundary conditions? Classically, $|x|$ cannot be greater than the amplitude A, which is the maximum displacement from equilibrium. Quantum mechanics does allow some penetration into classically forbidden regions, but the probability decreases as that penetration increases. Thus the wave functions must approach zero as $|x|$ grows large.



Satisfying the requirement that $\psi(x) \to 0$ as $|x| \to \infty$ is not as trivial as it may seem. Suppose we compute solutions of Eq. (40.22) *numerically*. We start at some point x, choosing values of $\psi(x)$ and $d\psi(x)/dx$ at that point. Using the Schrödinger equation to evaluate $d^2\psi(x)/dx^2$ at the point, we can compute $\psi(x)$ and $d\psi(x)/dx$ at a neighbouring point $x + \Delta x$, and so on. By using a computer to iterate this process many times with sufficiently small steps Δx, we can compute the wave function with great precision. There is no guarantee, however, that a function obtained in this way will approach zero at large x. To see what kinds of trouble we can get into, let's rewrite Eq. (40.22) in the form

$$\frac{d^2\psi(x)}{dx^2} = \frac{2m}{\hbar^2}\left(\frac{1}{2}k'x^2 - E\right)\psi(x) \tag{40.23}$$

In this form, the equation shows that when x is large enough (either positive or negative) to make the quantity $(\frac{1}{2}k'x^2 - E)$ positive, the function $\psi(x)$ and its second derivative $d^2\psi(x)/dx^2$ have the same sign.

The second derivative of $\psi(x)$ is the rate of change of the *slope* of $\psi(x)$. Consider a point with $x > A$ for which $\frac{1}{2}k'x^2 - E > 0$. If $\psi(x)$ is positive, so is $d^2\psi(x)/dx^2$ and the function is *concave upward*. Figure 40.17 shows four possible kinds of behaviour beginning at a point $x > A$. If the slope is initially positive, the function curves upward more and more steeply (curve a) and goes to infinity. If the slope is initially negative at the point, there are three possibilities. If the slope changes too quickly (curve b), the curve bends up and again goes to infinity. If the slope doesn't change quickly enough, the curve bends down and crosses the x-axis. After it has crossed, $\psi(x)$ and $d^2\psi(x)/dx^2$ are both negative (curve c) and the concave-downward curve heads for *negative* infinity. Between these infinities is the chance that the curve may bend just enough to glide in asymptotically to the x-axis (curve d). In this case, $\psi(x)$, $d\psi(x)/dx$, and $d^2\psi(x)/dx^2$ all approach zero at large x; in this possibility lies the only hope of satisfying the boundary condition that $\psi(x) \to 0$ as $|x| \to \infty$, and it occurs only for certain very special values of the constant E.

40.17 Possible behaviours of harmonic-oscillator wave functions in the region $\frac{1}{2}k'x^2 > E$. In this region, $\psi(x)$ and $d^2\psi(x)/dx^2$ have the same sign. The curve is concave upward when $d^2\psi(x)/dx^2$ is positive and concave downward when $d^2\psi(x)/dx^2$ is negative.

Only curve d, which approaches the x-axis asymptotically for large x, is an acceptable wave function for this system.

This qualitative discussion offers some insight into how the boundary conditions for this problem determine the possible energy levels. Equation (40.22) can also be solved exactly. The solutions, although not encountered in elementary calculus courses, are well known to mathematicians; they are called *Hermite functions*. Each one is an exponential function multiplied by a polynomial in x. The state with lowest energy (the ground level) has the wave function

$$\psi(x) = Ce^{-\sqrt{mk'}x^2/2\hbar} \tag{40.24}$$

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

The constant C is chosen to normalise the function—that is, to make $\int_{-\infty}^{\infty}|\psi|^2\,dx = 1$. You can find C using, from integral tables,

$$\int_{-\infty}^{\infty} e^{-a^2x^2}\,dx = \frac{\sqrt{\pi}}{a}$$

The corresponding energy, which we'll call E_0, is the ground-state energy; it is

$$E_0 = \frac{1}{2}\hbar\omega = \frac{1}{2}\hbar\sqrt{\frac{k'}{m}} \tag{40.25}$$

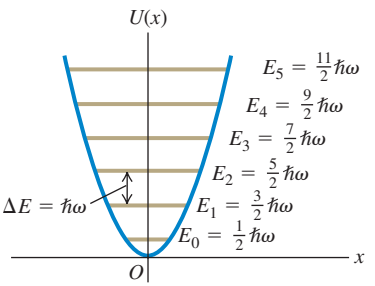
You may not believe that Eq. (40.24) really *is* a solution of Eq. (40.22) (the Schrödinger equation for the harmonic oscillator) with the energy given by Eq. (40.25). We invite you to calculate the second derivative of Eq. (40.24), substitute it into Eq. (40.22), and verify that it really is a solution if Eq. (40.25) gives E_0 (see exercise 40.28). It's a little messy, but the result is satisfying and worth the effort.

Further analysis of the Schrödinger equation for the harmonic oscillator shows that it can be written in the form

$$\frac{d^2\psi(x)}{dx^2} = \frac{2m}{\hbar^2}\left[\frac{1}{2}k'x^2 - \left(n + \frac{1}{2}\right)\hbar\sqrt{\frac{k'}{m}}\right]\psi(x)$$

Comparing this complicated expression to Eq. (40.23) gives us a pleasant surprise: The energy levels, which we'll call E_n, are given by the simple formula

$$E_n = \left(n + \frac{1}{2}\right)\hbar\sqrt{\frac{k'}{m}} = \left(n + \frac{1}{2}\right)\hbar\omega \qquad (n = 0, 1, 2, \ldots)$$



(energy levels, harmonic oscillator) (40.26)

where n is the quantum number identifying each state and energy level. Note that the ground level of energy $E_0 = \frac{1}{2}\hbar\omega$ is denoted by $n = 0$, *not* $n = 1$.

Equation (40.26) confirms our guess that the energy levels are multiples of $\hbar\omega$. Adjacent energy levels are separated by a constant interval of $\hbar\omega = hf$, as Planck assumed in 1900. There are infinitely many levels; this shouldn't be surprising because we are dealing with an infinitely deep potential well. As $|x|$ increases, $U = \frac{1}{2}k'x^2$ increases without bound.

Figure 40.18 shows the lowest six energy levels and the potential-energy function $U(x)$. For each level n, the value of $|x|$ at which the horizontal line representing the total energy E_n intersects $U(x)$ gives the amplitude A_n of the corresponding Newtonian oscillator.

40.18 Energy levels for the harmonic oscillator. The spacing between any two adjacent levels is $\Delta E = \hbar\omega$. The energy of the ground level is $E_0 = \frac{1}{2}\hbar\omega$.

Example 40.6 Vibration in a sodium crystal

A sodium atom of mass 3.82×10^{-26} kg vibrates with simple harmonic motion in a crystal. The potential energy increases by 0.0075 eV when the atom is displaced 0.014 nm from its equilibrium position. (a) Find the angular frequency, according to Newtonian mechanics. (b) Find the spacing of adjacent energy levels in electron volts. (c) If an atom emits a photon during a transition from one vibrational level to the next lower level, what is the wavelength of the emitted photon? In what region of the electromagnetic spectrum does it lie?

SOLUTION

IDENTIFY: This problem uses both the Newtonian and quantum-mechanical descriptions of a harmonic oscillator.

SET UP: To find the angular frequency $\omega = (k'/m)^{1/2}$, we use the information given and the expression $U(x) = \frac{1}{2}k'x^2$ for the potential energy. The spacing between adjacent energy levels is given by Eq. (40.26). We calculate the wavelength of the emitted photon using the same ideas as in Example 40.4 (Section 40.2).

Continued

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

EXECUTE: We don't know k', but we can find it from the fact that $U = 0.0075\ \text{eV} = 1.2 \times 10^{-21}\ \text{J}$ when $x = 0.014 \times 10^{-9}\ \text{m}$. We have

$$U = \frac{1}{2}k'x^2$$

$$k' = \frac{2U}{x^2} = \frac{2(1.2 \times 10^{-21}\ \text{J})}{(0.014 \times 10^{-9}\ \text{m})^2} = 12.2\ \text{N/m}$$

(a) The angular frequency is

$$\omega = \sqrt{\frac{k'}{m}} = \sqrt{\frac{12.2\ \text{N/m}}{3.82 \times 10^{-26}\ \text{kg}}} = 1.79 \times 10^{13}\ \text{rad/s}$$

(b) From Eq. (40.26) and Fig. 40.18 the spacing between adjacent energy levels is

$$\hbar\omega = (1.054 \times 10^{-34}\ \text{J} \cdot \text{s})(1.79 \times 10^{13}\ \text{s}^{-1}) = 1.88 \times 10^{-21}\ \text{J} = 0.0118\ \text{eV}$$

(c) From $E = hc/\lambda$ the corresponding wavelength is

$$\lambda = \frac{hc}{E} = \frac{(4.136 \times 10^{-15}\ \text{eV} \cdot \text{s})(3.00 \times 10^{8}\ \text{m/s})}{0.0118\ \text{eV}} = 1.05 \times 10^{-4}\ \text{m} = 105\ \mu\text{m}$$

This photon is in the infrared region of the spectrum.

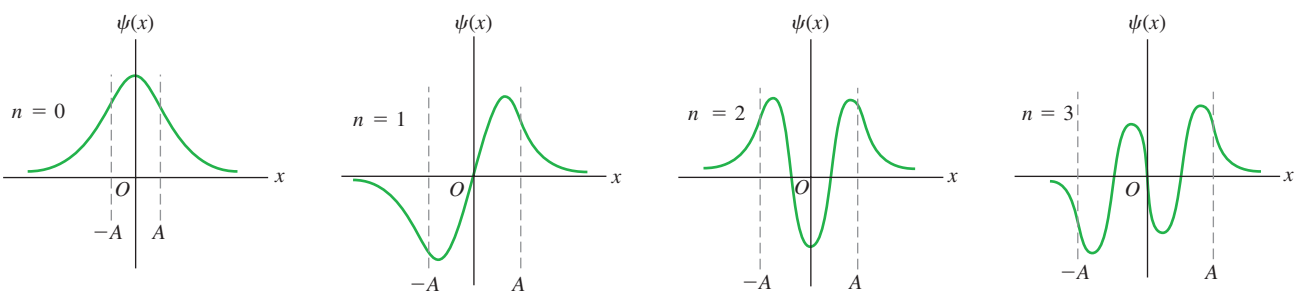
EVALUATE: This example shows us that the force constants for interatomic forces are on the order of a few N/m, not very different from the values for household springs or spring-based toys such as a Slinky.™ It also suggests that physicists can learn about the vibrations of atoms by measuring the radiation that they emit as they transition from one vibrational state to a lower state. We will explore this idea further in Chapter 42.

Comparing Quantum and Newtonian Oscillators

Activ Online Physics

20.1.6 Potential Energy Diagrams, Question 6

Figure 40.19 shows the first four harmonic-oscillator wave functions. Each graph also shows the amplitude A of a Newtonian harmonic oscillator with the same energy—that is, the value of A determined from



$$\frac{1}{2}k'A^2 = \left(n + \frac{1}{2}\right)\hbar\omega \qquad (40.27)$$

In each case there is some penetration of the wave function into the regions $|x| > A$ that are forbidden by Newtonian mechanics. This is similar to the effect that we noted with the particle in a finite square well.

CAUTION **Be very careful with your algebraic symbols** This Newtonian amplitude A (in units of m) is *not* the same as the quantum-mechanical normalising constant A (in $\text{m}^{-1/2}$) that is used in several wave functions in this chapter. Also the angular frequency ω (in rad/s) of the harmonic oscillator is *not* the same as the angular frequency ω (also in rad/s) obtained from the de Broglie relationship $E = \hbar\omega$ (which is why we expressed Eq. (40.14) in terms of $2\pi E/h = E/\hbar$ rather than in terms of ω). Finally, we have distinguished the force constant k' (in N/m or kg/s^2) from the wave number k (in rad/m). Neither of these is the same as κ (in m^{-1}) used in Eqs. (40.19) and (40.21) or the kinetic energy K (in J or eV). ▮

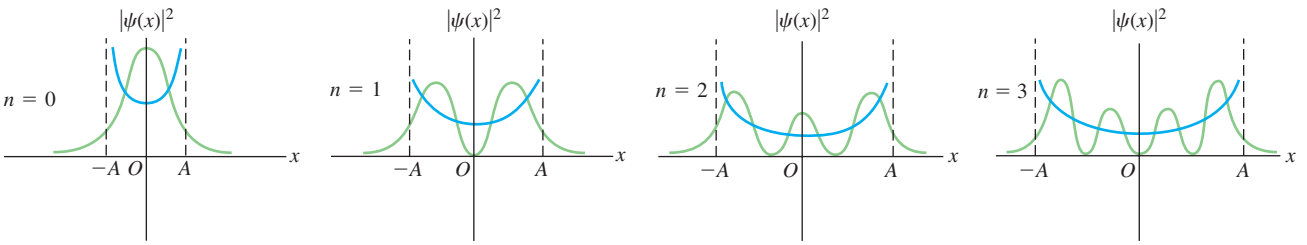


Figure 40.20 shows the probability distributions $|\psi(x)|^2$ for these same states. Each graph also shows the probability distribution determined from Newtonian analysis, in which the probability of finding the particle near a randomly

40.19 The first four wave functions for the harmonic oscillator. The amplitude A of a Newtonian oscillator with the same total energy is shown for each. Each wave function penetrates somewhat into the classically forbidden regions $|x| > A$. The total number of finite maxima and minima for each function is $n + 1$, one more than the quantum number.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

40.20 Probability distribution functions $|\psi|^2$ for the harmonic-oscillator wave functions shown in Fig. 40.19. The amplitude A of the Newtonian motion with the same energy is shown for each. The blue lines show the corresponding probability distributions for the Newtonian motion. As n increases, the averaged-out quantum-mechanical functions resemble the Newtonian curves more and more.

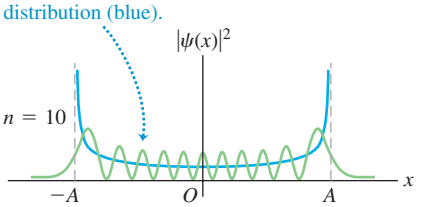
chosen point is inversely proportional to its speed at that point. If we average out the wiggles in the quantum-mechanical probability curves, the results for $n > 0$ resemble the Newtonian predictions. This agreement improves with increasing n; Fig. 40.21 shows the classical and quantum-mechanical probability functions for $n = 10$. Notice that the spacing between zeros of $|\psi(x)|^2$ in Fig. 40.21 increases with increasing distance from $x = 0$. This makes sense from the Newtonian perspective: As a particle moves away from $x = 0$, its kinetic energy K and the magnitude p of its momentum both decrease. Thinking quantum-mechanically, this means that the wavelength $\lambda = h/p$ increases, so the spacing between zeros of $\psi(x)$ (and hence of $|\psi(x)|^2$) also increases.

In the Newtonian analysis of the harmonic oscillator the minimum energy is zero, with the particle at rest at its equilibrium position. This is not possible in quantum mechanics; no solution of the Schrödinger equation has $E = 0$ and satisfies the boundary conditions. Furthermore, if there were such a state, it would violate the uncertainty principle because there would be no uncertainty in either position or momentum. Indeed, the energy must be at least $\frac{1}{2}\hbar\omega$ for the system to conform to the uncertainty principle. To see qualitatively why this is so, consider a Newtonian oscillator with total energy $\frac{1}{2}\hbar\omega$. We can find the amplitude A and the maximum velocity just as we did in Section 13.3. The appropriate relationships are Eqs. (13.21) for the total energy and (13.23) for the maximum speed. Setting $E = \frac{1}{2}\hbar\omega$, we find

$$E = \frac{1}{2}k'A^2 = \frac{1}{2}\hbar\omega = \frac{1}{2}\hbar\sqrt{\frac{k'}{m}} \qquad A = \sqrt{\frac{\hbar}{\sqrt{k'm}}}$$

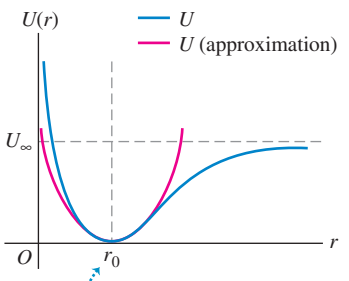
$$p_{\max} = mv_{\max} = m\sqrt{\frac{k'}{m}}A = m\sqrt{\frac{k'}{m}}\sqrt{\frac{\hbar}{\sqrt{k'm}}} = \sqrt{\hbar\sqrt{k'm}}$$

Finally, if we assume that A represents the uncertainty Δx in position and $p_{\max}$ is the corresponding uncertainty Δp_x in momentum, then the product of the two uncertainties is



$$\Delta x\,\Delta p_x = \sqrt{\frac{\hbar}{\sqrt{k'm}}}\sqrt{\hbar\sqrt{k'm}} = \hbar$$

So the product equals the minimum value allowed by Eq. (39.11), $\Delta x\,\Delta p_x \geq \hbar$, and thus satisfies the uncertainty principle. If the energy had been less than $\frac{1}{2}\hbar\omega$, the product $\Delta x\,\Delta p_x$ would have been less than $\hbar$, and the uncertainty principle would have been violated.



Even when a potential-energy function isn't precisely parabolic in shape, we may be able to approximate it by the harmonic-oscillator potential for sufficiently small displacements from equilibrium. Figure 40.22 shows a typical potential-energy function for an interatomic force in a molecule. At large separations it levels off, corresponding to the absence of force at great distances. But it is approximately parabolic near the minimum point (the equilibrium position of the

40.21 Newtonian and quantum-mechanical probability distribution functions for a harmonic oscillator for the state $n = 10$. The Newtonian amplitude A is also shown.

The larger the value of n, the more closely the quantum-mechanical probability distribution (green) matches the Newtonian probability distribution (blue).

40.22 A potential-energy function describing the interaction of two atoms in a diatomic molecule. The equilibrium position is at $r = r_0$. The potential energy needed to dissociate the molecule is U_∞.

When r is near r_0, the potential-energy curve is approximately parabolic (as shown by the red curve) and the motion is approximately simple harmonic.

He is also recognised world-wide for his contributions to the study of Bose-Einstein condensation, quantum information theory and quantum fundamental phenomena

FRONTIERS OF RESEARCH

atoms). Near equilibrium the molecular vibration is approximately simple harmonic with energy levels given by Eq. (40.26), as we assumed in Example 40.6.

Test Your Understanding of Section 40.4 A quantum-mechanical system initially in its ground level absorbs a photon and ends up in the first excited state. The system then absorbs a second photon and ends up in the second excited state. For which of the following systems does the second photon have a longer wavelength than the first one? (i) a harmonic oscillator; (ii) a hydrogen atom; (iii) a particle in a box.

40.5 Three-Dimensional Problems

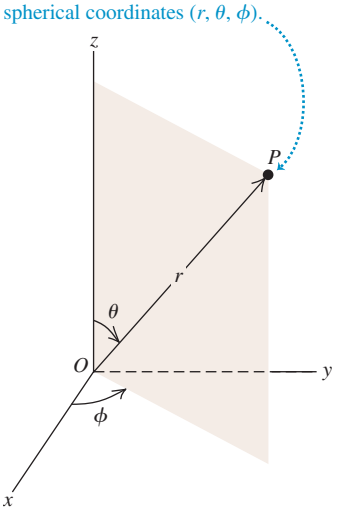
We have discussed the Schrödinger equation and its applications only for *one-dimensional* problems, the analog of a Newtonian particle moving along a straight line. The straight-line model is adequate for some applications, but to understand atomic structure, we need a three-dimensional generalisation.

It's not difficult to guess what the three-dimensional Schrödinger equation should look like. First, the wave function ψ is a function of all three space coordinates (x, y, z). In general, the potential-energy function also depends on all three coordinates and can be written as $U(x, y, z)$. Next, note that the term $-(\hbar^2/2m)d^2\psi/dx^2$ in the one-dimensional Schrödinger equation, Eq. (40.1), is related to the kinetic energy of the particle in the state described by the wave function ψ. For example, if we insert into this term the wave function $\psi(x) = Ae^{ikx}$ for a free particle with magnitude of momentum $p = \hbar k$ and kinetic energy $K = p^2/2m$, we obtain $-(\hbar^2/2m)(ik)^2Ae^{ikx} = (\hbar^2k^2/2m)Ae^{ikx} = (p^2/2m)\psi(x) = K\psi(x)$. If the particle's momentum has three components (p_x, p_y, p_z), then the kinetic energy is

$$K = \frac{p_x^2}{2m} + \frac{p_y^2}{2m} + \frac{p_z^2}{2m} \tag{40.28}$$

These observations, taken together, suggest that the correct generalisation of the Schrödinger equation to three dimensions is

$$-\frac{\hbar^2}{2m}\left(\frac{\partial^2\psi(x,y,z)}{\partial x^2} + \frac{\partial^2\psi(x,y,z)}{\partial y^2} + \frac{\partial^2\psi(x,y,z)}{\partial z^2}\right) + U(x,y,z)\psi(x,y,z) = E\psi(x,y,z) \tag{40.29}$$



(three-dimensional Schrödinger equation)

We use partial derivatives, since ψ is a function of x, y and z. As in one dimension, E is constant for a state of particular energy.

We won't pretend that we have *derived* Eq. (40.29). Like the one-dimensional version, this equation has to be tested by comparison of its predictions with experimental results. As we will see in later chapters, Eq. (40.29) passes this test with flying colours, so we are confident that it *is* the correct equation.

In many practical problems, in atomic structure and elsewhere, the potential-energy function is *spherically symmetric*; it depends only on the distance $r = (x^2 + y^2 + z^2)^{1/2}$ from the origin of coordinates. To take advantage of this symmetry, we use *spherical coordinates* (r, θ, ϕ) (Fig. 40.23) instead of Cartesian coordinates (x, y, z). Then a spherically symmetric potential-energy func-

40.23 In quantum mechanics, spherical coordinates are particularly useful in problems in which the potential energy depends only on r, the distance from the origin.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

tion is a function only of r, not of θ or ϕ, so $U = U(r)$. This fact turns out to simplify greatly the problem of finding solutions of the Schrödinger equation, even though the derivatives in Eq. (40.29) are considerably more complex when expressed in terms of spherical coordinates. Be careful; many maths texts exchange the angles θ and ϕ shown in Fig. 40.23.

For the hydrogen atom the potential-energy function $U(r)$ is the familiar Coulomb's-law function:

$$U(r) = -\frac{1}{4\pi\epsilon_0}\frac{e^2}{r} \tag{40.30}$$

We will find that for *all* spherically symmetric potential-energy functions $U(r)$, each possible wave function can be expressed as a product of three functions: one a function only of r, one only of θ, and one only of ϕ. Furthermore, the functions of θ and ϕ are *the same* for *every* spherically symmetric potential-energy function. This result is directly related to the problem of finding the possible values of *angular momentum* for the various states. We'll discuss these matters more in the next chapter.

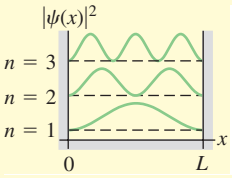
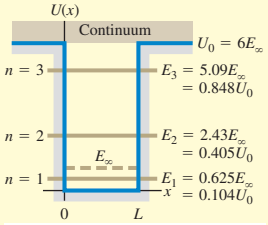
CHAPTER 40 SUMMARY

Particle in a box: The energy levels for a particle of mass m in a box (an infinitely deep square potential well) with width L are given by Eq. (40.9). The corresponding normalised wave functions of the particle are given by Eq. (40.13). (See Examples 40.1 and 40.2.)

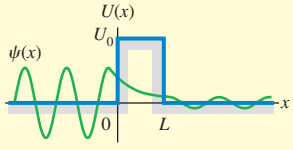


$$E_n = \frac{p_n^2}{2m} = \frac{n^2h^2}{8mL^2} = \frac{n^2\pi^2\hbar^2}{2mL^2} \quad (n = 1, 2, 3, \ldots) \tag{40.9}$$

$$\psi_n(x) = \sqrt{\frac{2}{L}}\sin\frac{n\pi x}{L} \quad (n = 1, 2, 3, \ldots) \tag{40.13}$$

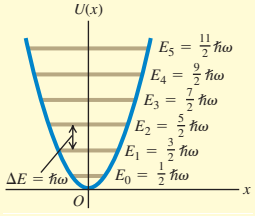


Wave functions and normalisation: To be a solution of the Schrödinger equation, the wave function $\psi(x)$ and its derivative $d\psi(x)/dx$ must be continuous everywhere, except where the potential-energy function $U(x)$ has an infinite discontinuity. Wave functions are usually normalised so that the total probability for finding the particle somewhere is unity.



$$\int_{-\infty}^{\infty} |\psi(x)|^2\,dx = 1 \quad \text{(normalisation condition)} \tag{40.11}$$

Finite potential well: In a potential well with finite depth U_0, the energy levels are lower than those for an infinitely deep well with the same width, and the number of energy levels corresponding to bound states is finite. The levels are obtained by matching wave functions at the well walls to satisfy the continuity of $\psi(x)$ and $d\psi(x)/dx$. (See Examples 40.3 and 40.4.)



Potential barriers and tunnelling: There is a certain probability that a particle will penetrate a potential-energy barrier even though its initial kinetic energy is less than the barrier height. This process is called tunnelling. (See Example 40.5.)

Quantum harmonic oscillator: The energy levels for the harmonic oscillator, for which $U(x) = \frac{1}{2}k'x^2$, are given by Eq. (40.26). The spacing between any two adjacent levels is $\hbar\omega$, where $\omega = \sqrt{k'/m}$ is the oscillation angular frequency of the corresponding Newtonian harmonic oscillator. (See Example 40.6.)

$$E_n = \left(n + \frac{1}{2}\right)\hbar\omega = \left(n + \frac{1}{2}\right)\hbar\sqrt{\frac{k'}{m}} \quad (n = 0, 1, 2, 3, \ldots) \tag{40.26}$$

Three-dimensional problems: The Schrödinger equation for three-dimensional problems is given by Eq. (40.29).

$$-\frac{\hbar^2}{2m}\left(\frac{\partial^2\psi(x,y,z)}{\partial x^2} + \frac{\partial^2\psi(x,y,z)}{\partial y^2} + \frac{\partial^2\psi(x,y,z)}{\partial z^2}\right) + U(x,y,z)\psi(x,y,z) = E\psi(x,y,z) \tag{40.29}$$

Answer to Chapter Opening Question ?

When an electron in one of these particles—called *quantum dots*—makes a transition from an excited level to a lower level, it emits a photon whose energy is equal to the difference in energy between the levels. The smaller the quantum dot, the larger the energy spacing between levels and hence the shorter (bluer) the wavelength of the emitted photons. See Example 40.4 (Section 40.2) for more details.

Answers to Test Your Understanding Questions

40.1 Answer: (v) Our derivation of the stationary-state wave functions for a particle in a box shows that they are superpositions of waves propagating in opposite directions, just like a standing wave on a string. One wave has momentum in the positive x-direction, while the other wave has an equal magnitude of momentum in the negative x-direction. The *total* x-component of momentum is zero.

40.2 Answer (i) The energy levels are arranged as shown in Fig. 40.8b if $U_0 = 6E_\infty$, where $E_\infty = \pi^2\hbar^2/2mL^2$ is the ground-level energy of an infinite well. If the well width L is reduced to $\frac{1}{2}$ of its initial value, E_∞ increases by a factor of 4 and so U_0 must also increase by a factor of 4. The energies E_1, E_2, and E_3 shown in Fig. 40.8b are all specific fractions of U_0, so they will also increase by a factor of 4.

40.3 Answer: yes Figure 40.13 shows a possible wave function $\psi(x)$ for tunnelling; since $\psi(x)$ is not zero within the barrier $(0 \le x \le L)$, there is some probability that the particle can be found there.

40.4 Answer: (ii) If the second photon has a longer wavelength and hence lower energy than the first photon, the difference in energy between the first and second excited levels must be less than the difference between the ground level and the first excited level. This is the case for the hydrogen atom, for which the energy difference between levels decreases as the energy increases (see Fig. 38.9). By contrast, the energy difference between successive levels increases for a particle in a box (see Fig. 40.4b) and is constant for a harmonic oscillator (see Fig. 40.18).

PROBLEMS

Exercises

Section 40.1 Particle in a Box

40.1. (a) Find the lowest energy level for a particle in a box if the particle is a billiard ball $(m = 0.20\text{kg})$ and the box has a width of 1.5 m, the size of a billiard table. (Assume that the billiard ball slides without friction rather than rolls. That is, ignore the *rotational* kinetic energy.) (b) Since the energy in part (a) is all kinetic, to what speed does this correspond? How much time would it take at this speed for the ball to move from one side of the table to the other? (c) What is the difference in energy between the $n = 2$ and $n = 1$ levels? (d) Are quantum-mechanical effects important for the game of billiards?

40.2. A proton is in a box of width L. What must the width of the box be for the ground-level energy to be 5.0 MeV, a typical value for the energy with which the particles in a nucleus are bound? Compare your result to the size of a nucleus—that is, on the order of 10^{-14} m.

40.3. Find the width L of a one-dimensional box for which the ground state energy of an electron in the box equals the absolute value of the ground state of a hydrogen atom.

40.4. When a hydrogen atom undergoes a transition from the $n = 2$ to the $n = 1$ level, a photon with $\lambda = 122$ nm is emitted. (a) If the atom is modelled as an electron in a one-dimensional box, what is the width of the box in order for the $n = 2$ to $n = 1$ transition to correspond to emission of a photon of this energy? (b) For a box with the width calculated in part (a), what is the ground-state energy? How does this correspond to the ground-state energy of a hydrogen atom? (c) Do you think a one-dimensional box is a good model for a hydrogen atom? Explain. (*Hint:* Compare the spacing between adjacent energy levels as a function of n.)

40.5. A certain atom requires 3.0 eV of energy to excite an electron from the ground level to the first excited level. Model the atom as an electron in a box and find the width L of the box.

40.6. Recall that $|\psi|^2\,dx$ is the probability of finding the particle that has normalised wave function $\psi(x)$ in the interval x to $x + dx$. Consider a particle in a box with rigid walls at $x = 0$ and $x = L$. Let the particle be in the ground level and use ψ_n as given in Eq. (40.13). (a) For which values of x, if any, in the range from 0 to L is the probability of finding the particle zero? (b) For which values of x is the probability highest? (c) In parts (a) and (b) are your answers consistent with Fig. 40.8? Explain.

40.7. Repeat Exercise 40.6 for the particle in the first excited level.

40.8. (a) Show that $\psi = A\sin kx$ is a solution to Eq. (40.3) if $k = \sqrt{2mE}/\hbar$. (b) Explain why this is an acceptable wave function for a particle in a box with rigid walls at $x = 0$ and $x = L$ only if k is an integer multiple of π/L.

40.9. (a) Repeat Exercise 40.8 for $\psi = A\cos kx$. (b) Explain why this cannot be an acceptable wave function for a particle in a box with rigid walls at $x = 0$ and $x = L$ no matter what the value of k.

40.10. (a) Find the excitation energy from the ground level to the third excited level for an electron confined to a box that has a width of 0.125 nm. (b) The electron makes a transition from the $n = 1$ to $n = 4$ level by absorbing a photon. Calculate the wavelength of this photon.

40.11. An electron is in a box of width 3.0×10^{-10} m. What are the de Broglie wavelength and the magnitude of the momentum of the electron if it is in (a) the $n = 1$ level; (b) the $n = 2$ level; (c) the $n = 3$ level? In each case how does the wavelength compare to the width of the box?

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

40.12. Show that the time-dependent wave function given by Eq. (40.15) is a solution to the one-dimensional Schrödinger equation, Eq. (40.1).

Section 40.2 Potential Wells

40.13. (a) Show that $\psi = A\sin kx$, where k is a (not complex) constant, is *not* a solution of Eq. (40.1) for $U = U_0$ and $E < U_0$. 9 (b) Is this ψ a solution for $E > U_0$?

40.14. An electron is moving past the square well shown in Fig. 40.6. The electron has energy $E = 3U_0$. What is the ratio of the de Broglie wavelength of the electron in the region $x > L$ to the wavelength for $0 < x < L$?

40.15. An electron is bound in a square well of depth $U_0 = 6E_\infty$. What is the width of the well if its ground-state energy is 2.00 eV?

40.16. An electron is bound in a square well of width 1.50 nm and depth $U_0 = 6E_\infty$. If the electron is initially in the ground level and absorbs a photon, what maximum wavelength can the photon have and still liberate the electron from the well?

40.17. Calculate $d^2\psi/dx^2$ for the wave function of Eq. (40.17), and show that the function is a solution of Eq. (40.16).

40.18. Calculate $d^2\psi/dx^2$ for the wave function of Eq. (40.19), and show that for any values of C and D it is a solution of Eq. (40.1) for $x \le 0$ and $x \ge L$ when $U = U_0$ and $E < U_0$.

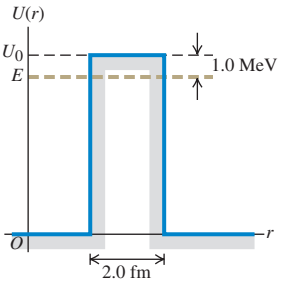
40.19. A proton is bound in a square well of width 4.0 fm $= 4.0 \times 10^{-15}$ m. The depth of the well is six times the ground-level energy E_∞ of the corresponding infinite well. If the proton makes a transition from the level with energy E_1 to the level with energy E_3 by absorbing a photon, find the wavelength of the photon.

40.20. An electron is bound in a square well with a depth equal to six times the ground-level energy E_∞ of an infinite well of the same width. The longest-wavelength photon that is absorbed by the electron has a wavelength of 400.0 nm. Determine the width of the well.

Section 40.3 Potential Barriers and Tunnelling

40.21. An electron with initial kinetic energy 6.0 eV encounters a barrier with height 11.0 eV. What is the probability of tunnelling if the width of the barrier is (a) 0.80 nm and (b) 0.40 nm?

40.22. An electron with initial kinetic energy 5.0 eV encounters a barrier with height U_0 and width .060 nm. What is the transmission coefficient if (a) $U_0 = 7.0$ eV; (b) $U_0 = 9.0$ eV; (c) $U_0 = 13.0$ eV?



40.23. An electron is moving past the square barrier shown in Fig. 40.12, but the energy of the electron is *greater* than the barrier height. If $E = 2U_0$, what is the ratio of the de Broglie wavelength of the electron in the region $x > L$ to the wavelength for $0 < x < L$?

40.24. A proton with initial kinetic energy 50.0 eV encounters a barrier of height 70.0 eV. What is the width of the barrier if the probability of tunnelling is 3.0×10^{-3}? How does this compare with the barrier width for an electron with the same energy tunnelling through a barrier of the same height with the same probability?

40.25. (a) An electron with initial kinetic energy 32 eV encounters a square barrier with height 41 eV and width 0.25 nm. What is the probability that the electron will tunnel through the barrier? (b) A proton with the same kinetic energy encounters the same barrier. What is the probability that the proton will tunnel through the barrier?

40.26. In a simple model for a radioactive nucleus, an alpha particle $(m = 6.64 \times 10^{-27}\ \text{kg})$ is trapped by a square barrier that has width 2.0 fm and height 30.0 MeV. (a) What is the tunnelling probability when the alpha particle encounters the barrier if its kinetic energy is 1.0 MeV below the top of the barrier (Fig. 40.24)? (b) What is the tunnelling probability if the energy of the alpha particle is 10.0 MeV below the top of the barrier?

Figure 40.24 Exercise 40.26.

Section 40.4 The Harmonic Oscillator

40.27. A wooden block with mass 0.250 kg is oscillating on the end of a spring that has force constant 110 N/m. Calculate the ground-level energy and the energy separation between adjacent levels. Express your results in joules and in electron volts. Are quantum effects important?

40.28. Show that $\psi(x)$ given by Eq. (40.24) is a solution to Eq. (40.22) with energy $E_0 = \hbar\omega/2$.

40.29. Chemists use infrared absorption spectra to identify chemicals in a sample. In one sample, a chemist finds that light of wavelength 5.8 μm is absorbed. (a) Find the energy of this transition. (b) If the molecule has mass 5.6×10^{-26} kg, find the force constant.

40.30. The ground-state energy of a harmonic oscillator is 5.60 eV. If the oscillator undergoes a transition from its $n = 3$ to $n = 2$ level by emitting a photon, what is the wavelength of the photon?

40.31. In Section 40.4 it is shown that for the ground level of a harmonic oscillator, $\Delta x \Delta p_x = \hbar$. Do a similar analysis for an excited level that has quantum number n. How does the uncertainty product $\Delta x \Delta p_x$ depend on n?

40.32. For the ground-level harmonic oscillator wave function $\psi(x)$ given in Eq. (40.24), $|\psi|^2$ has a maximum at $x = 0$. (a) Compute the ratio of $|\psi|^2$ at $x = +A$ to $|\psi|^2$ at $x = 0$, where A is given by Eq. (40.27) with $n = 0$ for the ground level. (b) Compute the ratio of $|\psi|^2$ at $x = +2A$ to $|\psi|^2$ at $x = 0$. In each case is your result consistent with what is shown in Fig. 40.20?

40.33. For the sodium atom of Example 40.6, find (a) the ground-state energy, (b) the wavelength of a photon emitted when the $n = 4$ to $n = 3$ transition occurs; (c) the energy difference for any $\Delta n = 1$ transition.

Problems

40.34. Show that the wave function $\psi(x) = Ae^{ikx}$ is a solution of Eq. 40.1 for a particle of mass m, in a region where the potential energy is a constant $U_0 < E$. Find an expression for k, and relate it to the particle's momentum and to its de Broglie wavelength.

40.35. Wave functions like the one in Problem 40.34 can represent free particles moving with velocity $v = p/m$ in the x-direction. Consider a beam of such particles incident on a potential-energy step $U(x) = 0$, for $x < 0$, and $U(x) = U_0 < E$, for $x > 0$. The wave function for $x < 0$ is $\psi(x) = Ae^{ik_1x} + Be^{-ik_1x}$, representing incident and reflected particles, and for $x > 0$ is $\psi(x) = Ce^{ik_2x}$, representing transmitted particles. Use the conditions that both ψ

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

and its first derivative must be continuous at $x = 0$ to find the constants B and C in terms of k_1, k_2 and A.

40.36. Let ΔE_n be the energy difference between the adjacent energy levels E_n and E_{n+1} for a particle in a box. The ratio $R_n = \Delta E_n / E_n$ compares the energy of a level to the energy separation of the next higher energy level. a) For what value of n is R_n largest, and what is this largest R_n? (b) What does R_n approach as n becomes very large? How does this result compare to the classical value for this quantity?

40.37. An electron in a long, organic molecule used in a dye laser behaves approximately like a particle in a box with width 4.18 nm. What is the wavelength of the photon emitted when the electron undergoes a transition (a) from the first excited level to the ground level and (b) from the second excited level to the first excited level?

40.38. A particle is in the ground level of a box that extends from $x = 0$ to $x = L$. (a) What is the probability of finding the particle in the region between 0 and $L/4$? Calculate this by integrating $|\psi(x)|^2\,dx$, where ψ is normalised, from $x = 0$ to $x = L/4$. (b) What is the probability of finding the particle in the region $x = L/4$ to $x = L/2$? (c) How do the results of parts (a) and (b) compare? Explain. (d) Add the probabilities calculated in parts (a) and (b). (e) Are your results in parts (a), (b), and (d) consistent with Fig. 40.5b? Explain.

40.39. What is the probability of finding a particle in a box of length L in the region between $x = L/4$ and $x = 3L/4$ when the particle is in (a) the ground level and (b) the first excited level? (*Hint:* Integrate $|\psi(x)|^2\,dx$, where ψ is normalised, between $L/4$ and $3L/4$.) (c) Are your results in parts (a) and (b) consistent with Fig. 40.5b? Explain.

40.40. Consider a particle in a box with rigid walls at $x = 0$ and $x = L$. Let the particle be in the ground level. Calculate the probability $|\psi|^2\,dx$ that the particle will be found in the interval x to $x + dx$ for (a) $x = L/4$; (b) $x = L/2$; (c) $x = 3L/4$.

40.41. Repeat Problem 40.40 for a particle in the first excited level.

40.42. A particle is confined within a box with perfectly rigid walls at $x = 0$ and $x = L$. Although the magnitude of the instantaneous force exerted on the particle by the walls is infinite and the time over which it acts is zero, the impulse (that involves a product of force and time) is both finite and quantised. Show that the impulse exerted by the wall at $x = 0$ is $(nh/L)\hat{\imath}$ and that the impulse exerted by the wall at $x = L$ is $-(nh/L)\hat{\imath}$. (*Hint:* You may wish to review Section 8.1.)

40.43. A fellow student proposes that a possible wave function for a free particle with mass m (one for which the potential-energy function $U(x)$ is zero) is

$$\psi(x) = \begin{cases} e^{+\kappa x}, & x < 0 \\ e^{-\kappa x}, & x \geq 0 \end{cases}$$

where κ is a positive constant. (a) Graph this proposed wave function. (b) Show that the proposed wave function satisfies the Schrödinger equation for $x < 0$ if the energy is $E = -\hbar^2\kappa^2/2m$—that is, if the energy of the particle is *negative*. (c) Show that the proposed wave function also satisfies the Schrödinger equation for $x \geq 0$ with the same energy as in part (b). (d) Explain why the proposed wave function is nonetheless *not* an acceptable solution of the Schrödinger equation for a free particle. (*Hint:* What is the behaviour of the function at $x = 0$?) It is in fact impossible for a free particle (one for which $U(x) = 0$) to have an energy less than zero.

40.44. The penetration distance η in a finite potential well is the distance at which the wave function has decreased to $1/e$ of the wave function at the classical turning point:

$$\psi(x = L + \eta) = \frac{1}{e}\psi(L)$$

The penetration distance can be shown to be

$$\eta = \frac{\hbar}{\sqrt{2m(U_0 - E)}}$$

The probability of finding the particle beyond the penetration distance is nearly zero. (a) Find η for an electron having a kinetic energy of 13 eV in a potential well with $U_0 = 20$ ev. (b) Find η for a 20.0-MeV proton trapped in a 30.0 MeV deep potential well.

40.45. (a) For the finite potential well of Fig. 40.6, what relationships among the constants A and B of Eq. (40.17) and C and D of Eq. (40.19) are obtained by applying the boundary condition that ψ be continuous at $x = 0$ and at $x = L$? (b) What relationships among A, B, C, and D are obtained by applying the boundary condition that $d\psi/dx$ be continuous at $x = 0$ and at $x = L$?

40.46. An electron with initial kinetic energy 5.5 eV encounters a square potential barrier with height 10.0 eV. What is the width of the barrier if the electron has a 0.10% probability of tunnelling through the barrier?

40.47. A particle with mass m and total energy E tunnels through a square barrier of height U_0 and width L. When the transmission coefficient is *not* much less than unity, it is given by

$$T = \left[1 + \frac{(U_0 \sinh \kappa L)^2}{4E(U_0 - E)}\right]^{-1}$$

where $\sinh \kappa L = (e^{\kappa L} - e^{-\kappa L})/2$ is the hyperbolic sine of κL. (a) Show that if $\kappa L \gg 1$, this expression for T approaches Eq. (40.21). (b) Explain why the restriction $\kappa L \gg 1$ in part (a) implies either that the barrier is relatively wide or that the energy E is relatively low compared to U_0. (c) Show that as the particle's incident kinetic energy E approaches the barrier height U_0, T approaches $[1 + (kL/2)^2]^{-1}$, where $k = \sqrt{2mE}/\hbar$ is the wave number of the incident particle. (*Hint:* If $|z| \ll 1$, then $\sinh z \approx z$.)

40.48. A harmonic oscillator consists of a 0.020 kg mass on a spring. Its frequency is 1.50 Hz, and the mass has a speed of 0.360 m/s as it passes the equilibrium position. (a) What is the value of the quantum number n for its energy level? (b) What is the difference in energy between the levels E_n and E_{n+1}? Is this difference detectable?

40.49. For small amplitudes of oscillation the motion of a pendulum is simple harmonic. For a pendulum with a period of 0.500 s, find the ground-level energy and the energy difference between adjacent energy levels. Express your results in joules and in electron volts. Are these values detectable?

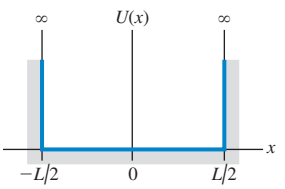
40.50. Some 164.9 nm photons are emitted in a $\Delta n = 1$ transition within a solid-state lattice. The lattice is modelled as electrons in a box having length 0.500 nm. What transition corresponds to the emitted light?

40.51. (a) Show by direct substitution in the Schrödinger equation for the one-dimensional harmonic oscillator that the wave function $\psi_0(x) = A_0 e^{-\alpha^2 x^2/2}$, where $\alpha^2 = m\omega/\hbar$, is a solution with energy corresponding to $n = 0$ in Eq. (40.26). (b) Find the normalisation constant A_0. (c) Find the classical turning points and show, in contrast, that the probability density has a maximum at $x = 0$.

40.52. (a) Show by direct substitution in the Schrödinger equation for the one-dimensional harmonic oscillator that the wave function $\psi_1(x) = A_1 x e^{-\alpha^2 x^2/2}$, where $\alpha^2 = m\omega/\hbar$, is a solution with energy corresponding to $n = 1$ in Eq. (40.26). (b) Find the normalisation constant A_1. (c) Show that the probability density has a minimum

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

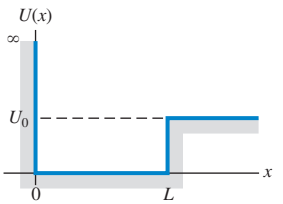
at $x = 0$ and maxima at $x = \pm 1/\alpha$, corresponding to the classical turning points for the ground state $n = 0$.



40.53. An isotropic harmonic oscillator has the potential-energy function $U(x, y, z) = \frac{1}{2}k'(x^2 + y^2 + z^2)$. (*Isotropic* means that the force constant k' is the same in all three coordinate directions.) (a) Show that for this potential, a solution to Eq. (40.29) is given by $\psi = \psi_{n_x}(x)\psi_{n_y}(y)\psi_{n_z}(z)$. In this expression, $\psi_{n_x}(x)$ is a solution to the one-dimensional harmonic oscillator Schrödinger equation, Eq. (40.22), with energy $E_{n_x} = \left(n_x + \frac{1}{2}\right)\hbar\omega$. The functions $\psi_{n_y}(y)$ and $\psi_{n_z}(z)$ are analogous one-dimensional wave functions for oscillations in the y- and z-directions. Find the energy associated with this ψ. (b) From your results in part (a) what are the ground-level and first-excited-level energies of the three-dimensional isotropic oscillator? (c) Show that there is only one state (one set of quantum numbers n_x, n_y, and n_z) for the ground level but three states for the first excited level.

40.54. An oscillator has the potential-energy function $U(x, y, z) = \frac{1}{2}k_1'(x^2 + y^2) + \frac{1}{2}k_2'z^2$, where $k_1' > k_2'$. This oscillator is called *anisotropic* because the force constant is not the same in all three coordinate directions. (a) Find a general expression for the energy levels of the oscillator (see Problem 40.53). (b) From your results in part (a), what are the ground-level and first-excited-level energies of this oscillator? (c) How many states (different sets of quantum numbers n_x, n_y, and n_z) are there for the ground level and for the first excited level? Compare to part (c) of Problem 40.53.

Challenge Problems



40.55. Section 40.1 considered a box with walls at $x = 0$ and $x = L$. Now consider a box with width L but centred at $x = 0$, so that it extends from $x = -L/2$ to $x = +L/2$ (Fig. 40.25). Note that this box is symmetrical about $x = 0$. (a) Consider possible wave functions of the form $\psi(x) = A \sin kx$. Apply the boundary conditions at the wall to obtain the allowed energy levels. (b) Another set of possible wave functions are functions of the form $\psi(x) = A \cos kx$. Apply the boundary conditions at the wall to obtain the allowed energy levels. (c) Compare the energies obtained in parts (a) and (b) to the set of energies given in Eq. (40.9). (d) An odd function f satisfies the condition $f(x) = -f(-x)$, and an even function g satisfies $g(x) = g(-x)$. Of the wave functions from parts (a) and (b), which are even and which are odd?

Figure **40.25** Challenge Problem 40.55.

40.56. Consider a potential well defined as $U(x) = \infty$ for $x < 0$, $U(x) = 0$ for $0 < x < L$, and $U(x) = U_0 > 0$ for $x > L$ (Fig. 40.26). Consider a particle with mass m and kinetic energy $E < U_0$ that is trapped in the well. (a) The boundary condition at the infinite wall $(x = 0)$ is $\psi(0) = 0$. What must the form of the function $\psi(x)$ for $0 < x < L$ be in order to satisfy both the Schrödinger equation and this boundary condition? (b) The wave function must remain finite as $x \to \infty$. What must the form of the function $\psi(x)$ for $x > L$ be in order to satisfy both the Schrödinger equation and this boundary condition at infinity? (c) Impose the boundary conditions that ψ and $d\psi/dx$ are continuous at $x = L$. Show that the energies of the allowed levels are obtained from solutions of the equation $k\cot kL = -\kappa$, where $k = \sqrt{2mE}/\hbar$ and $\kappa = \sqrt{2m(U_0 - E)}/\hbar$.

Figure **40.26** Challenge Problem 40.56.

40.57. It can be a challenge to solve the Schrödinger equation for the bound-state energy levels of an arbitrary potential well. An alternative approach that can yield good approximate results for the energy levels is the *WKB approximation* (named for the physicists Gregor Wentzel, Hendrik Kramers and Léon Brillouin, who pioneered its application to quantum mechanics). The WKB approximation begins from three physical statements: (i) According to de Broglie, the magnitude of momentum p of a quantum-mechanical particle is $p = h/\lambda$. (ii) The magnitude of momentum is related to the kinetic energy K by the relationship $K = p^2/2m$. (iii) If there are no nonconservative forces, then in Newtonian mechanics the energy E for a particle is constant and equal at each point to the sum of the kinetic and potential energies at that point: $E = K + U(x)$, where x is the coordinate. (a) Combine these three relationships to show that the wavelength of the particle at a coordinate x can be written as

$$\lambda(x) = \frac{h}{\sqrt{2m[E - U(x)]}}$$

Thus we envision a quantum-mechanical particle in a potential well $U(x)$ as being like a free particle, but with a wavelength $\lambda(x)$ that is a function of position. (b) When the particle moves into a region of increasing potential energy, what happens to its wavelength? (c) At a point where $E = U(x)$, Newtonian mechanics says that the particle has zero kinetic energy and must be instantaneously at rest. Such a point is called a *classical turning point*, since this is where a Newtonian particle must stop its motion and reverse direction. As an example, an object oscillating in simple harmonic motion with amplitude A moves back and forth between the points $x = -A$ and $x = +A$; each of these is a classical turning point, since there the potential energy $\frac{1}{2}k'x^2$ equals the total energy $\frac{1}{2}k'A^2$. In the WKB expression for $\lambda(x)$, what is the wavelength at a classical turning point? d) For a particle in a box with length L, the walls of the box are classical turning points (see Fig. 40.1). Furthermore, the number of wavelengths that fit within the box must be a half-integer (see Fig. 40.3), so that $L = (n/2)\lambda$ and hence $L/\lambda = n/2$, where $n = 1, 2, 3, \ldots$. [Note that this is a restatement of Eq. (40.7).] The WKB scheme for finding the allowed bound-state energy levels of an *arbitrary* potential well is an extension of these observations. It demands that for an allowed energy E, there must be a half-integer number of wavelengths between the classical turning points for that energy. Since the wavelength in the WKB approximation is not a constant but depends on x, the number of wavelengths between the classical turning points a and b for a given value of the energy is the integral of $1/\lambda(x)$ between those points:

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

$$\int_a^b \frac{dx}{\lambda(x)} = \frac{n}{2} \qquad (n = 1, 2, 3, \ldots)$$

Using the expression for $\lambda(x)$ you found in part (a), show that the *WKB condition for an allowed bound-state energy* can be written as

$$\int_a^b \sqrt{2m[E - U(x)]}\, dx = \frac{nh}{2} \qquad (n = 1, 2, 3, \ldots)$$

(e) As a check on the expression in part (d), apply it to a particle in a box with walls at $x = 0$ and $x = L$. Evaluate the integral and show that the allowed energy levels according to the WKB approximation are the same as those given by Eq. (40.9). (*Hint:* Since the walls of the box are infinitely high, the points $x = 0$ and $x = L$ are classical turning points for *any* energy E. Inside the box, the potential energy is zero.) (f) For the finite square well shown in Fig. 40.6, show that the WKB expression given in part (d) predicts the *same* bound-state energies as for an infinite square well of the same width. (*Hint:* Assume $E < U_0$. Then the classical turning points are at $x = 0$ and $x = L$.) This shows that the WKB approximation does a poor job when the potential-energy function changes discontinuously, as for a finite potential well. In the next two problems we consider situations in which the potential-energy function changes gradually and the WKB approximation is much more useful.

40.58. The WKB approximation (see Challenge Problem 40.57) can be used to calculate the energy levels for a harmonic oscillator. In this approximation, the energy levels are the solutions to the equation

$$\int_a^b \sqrt{2m[E - U(x)]}\, dx = \frac{nh}{2} \qquad n = 1, 2, 3, \ldots$$

Here E is the energy, $U(x)$ is the potential-energy function, and $x = a$ and $x = b$ are the classical turning points (the points at which E is equal to the potential energy, so the Newtonian kinetic energy would be zero). (a) Determine the classical turning points for a harmonic oscillator with energy E and force constant k'. (b) Carry out the integral in the WKB approximation and show that the energy levels in this approximation are $E_n = \hbar\omega$, where $\omega = \sqrt{k'/m}$ and $n = 1, 2, 3, \ldots$. (*Hint:* Recall that $\hbar = h/2\pi$. A useful standard integral is

$$\int \sqrt{A^2 - x^2}\, dx = \frac{1}{2}\left[x\sqrt{A^2 - x^2} + A^2 \arcsin\left(\frac{x}{|A|}\right)\right]$$

where arcsin denotes the inverse sine function. Note that the integrand is even, so the integral from $-x$ to x is equal to twice the integral from 0 to x.) (c) How do the approximate energy levels found in part (b) compare with the true energy levels given by Eq. (40.26)? Does the WKB approximation give an underestimate or an overestimate of the energy levels?

40.59. Protons, neutrons and many other particles are made of more fundamental particles called *quarks* and *antiquarks* (the antimatter equivalent of quarks). A quark and an antiquark can form a bound state with a variety of different energy levels, each of which corresponds to a different particle observed in the laboratory. As an example, the ψ particle is a low-energy bound state of a so-called charm quark and its antiquark, with a rest energy of 3097 MeV; the $\psi(2S)$ particle is an excited state of this same quark–antiquark combination, with a rest energy of 3686 MeV. A simplified representation of the potential energy of interaction between a quark and an antiquark is $U(x) = A|x|$ where A is a positive constant and x represents the distance between the quark and the antiquark. You can use the WKB approximation (see Challenge Problem 40.57) to determine the bound-state energy levels for this potential-energy function. In the WKB approximation, the energy levels are the solutions to the equation

$$\int_a^b \sqrt{2m[E - U(x)]}\, dx = \frac{nh}{2} \qquad (n = 1, 2, 3, \ldots)$$

Here E is the energy, $U(x)$ is the potential-energy function, and $x = a$ and $x = b$ are the classical turning points (the points at which E is equal to the potential energy, so the Newtonian kinetic energy would be zero). (a) Determine the classical turning points for the potential $U(x) = A|x|$ and for an energy E. (b) Carry out the above integral and show that the allowed energy levels in the WKB approximation are given by

$$E_n = \frac{1}{2m}\left(\frac{3mAh}{4}\right)^{2/3} n^{2/3} \qquad (n = 1, 2, 3, \ldots)$$

(*Hint:* The integrand is even, so the integral from $-x$ to x is equal to twice the integral from 0 to x.) (c) Does the difference in energy between successive levels increase, decrease, or remain the same as n increases? How does this compare to the behaviour of the energy levels for the harmonic oscillator? For the particle in a box? Can you suggest a simple rule that relates the difference in energy between successive levels to the shape of the potential-energy function?

41 ATOMIC STRUCTURE

LEARNING GOALS

By studying this chapter, you will be able to explain:

- How to describe the states of a hydrogen atom in terms of quantum numbers.
- How magnetic fields affect the orbital motion of atomic electrons.
- How we know that electrons have their own intrinsic angular momentum.
- How to analyse the structure of many-electron atoms.
- How x-rays emitted by atoms reveal their inner structure.

? Sodium (with 11 electrons per atom) is a highly reactive metal that burns spontaneously in air, while neon (with 10 electrons per atom) is an inert gas that undergoes almost no chemical reactions at all. How can just one extra electron make these two elements so dramatically different?

Some physicists claim that all of chemistry is contained in the Schrödinger equation. This is somewhat of an exaggeration, but this equation can teach us a great deal about the chemical behaviour of elements and the nature of chemical bonds. It provides insight into the periodic table of the elements and the microscopic basis of magnetism.

We can learn a great deal about the structure and properties of *all* atoms from the solutions to the Schrödinger equation for the hydrogen atom. These solutions have quantised values of angular momentum; we don't need to make a separate statement about quantisation as we did with the Bohr model. We label the states with a set of quantum numbers, which we'll use later with many-electron atoms as well. We'll find that the electron also has an intrinsic 'spin' angular momentum in addition to the orbital angular momentum associated with its motion.

We'll also encounter the exclusion principle, a kind of microscopic zoning ordinance that is the key to understanding many-electron atoms. This principle says that no two electrons in an atom can have the same quantum-mechanical state. Finally, we'll use the principles of this chapter to explain the characteristic x-ray spectra of atoms.

41.1 The Hydrogen Atom

Let's continue the discussion of the hydrogen atom that we began in Chapter 38. In the Bohr model, electrons move in circular orbits like Newtonian particles, but with quantised values of angular momentum. While this model gave the correct energy levels of the hydrogen atom, as deduced from spectra, it had many conceptual difficulties. It mixed classical physics with new and seemingly contradictory concepts. It provided no insight into the process by which photons are emitted and absorbed. It could not be generalised to atoms with more than one electron. It predicted the wrong magnetic properties for the hydrogen atom. And perhaps most important, its picture of the electron as a localised point particle

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

was inconsistent with the more general view we developed in Chapters 39 and 40. To go beyond the Bohr model, let's apply the Schrödinger equation to find the wave functions for stationary states (states of definite energy) of the hydrogen atom. As in Section 38.5, we include the motion of the nucleus by simply replacing the electron mass m with the reduced mass m_r.

The Schrödinger Equation for the Hydrogen Atom

We discussed the three-dimensional version of the Schrödinger equation in Section 40.5. The hydrogen-atom problem is best formulated in spherical coordinates (r, θ, ϕ), shown in Fig. 41.1; the potential energy is then simply

$$U(r) = -\frac{1}{4\pi\epsilon_0}\frac{e^2}{r} \tag{41.1}$$

The Schrödinger equation with this potential-energy function can be solved exactly; the solutions are combinations of familiar functions. Without going into a lot of detail, we can describe the most important features of the procedure and the results.

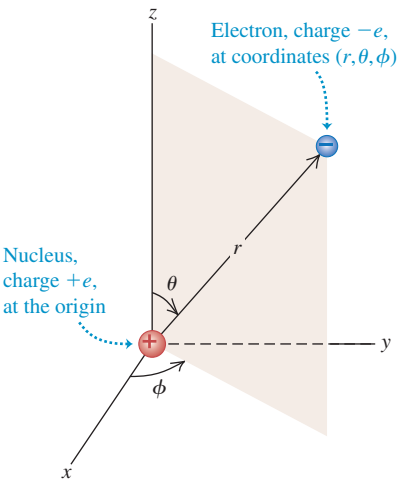
First, the solutions are obtained by a method called *separation of variables*, in which we express the wave function $\psi(r, \theta, \phi)$ as a product of three functions, each one a function of only one of the three coordinates:

$$\psi(r, \theta, \phi) = R(r)\Theta(\theta)\Phi(\phi) \tag{41.2}$$

That is, the function $R(r)$ depends *only* on r, $\Theta(\theta)$ depends *only* on θ, and $\Phi(\phi)$ depends *only* on ϕ. When we substitute Eq. (41.2) into the Schrödinger equation, we get three separate equations, each containing only one of the coordinates. This is an enormous simplification; it reduces the problem of solving a fairly complex *partial* differential equation with three independent variables to the much simpler problem of solving three separate *ordinary* differential equations with one independent variable each.

The physically acceptable solutions of these three equations are determined by *boundary conditions*. The radial function $R(r)$ must approach zero at large r, because we are describing *bound states* of the electron that are localised near the nucleus. This is analogous to the requirement that the harmonic-oscillator wave functions (see Section 40.4) must approach zero at large x. The angular functions $\Theta(\theta)$ and $\Phi(\phi)$ must be *periodic*. For example, (r, θ, ϕ) and $(r, \theta, \phi + 2\pi)$ describe the same point, so $\Phi(\phi + 2\pi)$ must equal $\Phi(\phi)$. Also, the angular functions must be *finite* for all relevant values of the angles. For example, there are solutions of the Θ equation that become infinite at $\theta = 0$ and $\theta = \pi$; these are unacceptable, since $\psi(r, \theta, \phi)$ must be normalisable.

The radial functions $R(r)$ turn out to be an exponential function $e^{-\alpha r}$ (where α is positive) multiplied by a polynomial in r. The functions $\Theta(\theta)$ are polynomials containing various powers of $\sin\theta$ and $\cos\theta$, and the functions $\Phi(\phi)$ are simply proportional to $e^{im_l\phi}$, where $i = \sqrt{-1}$ and m_l is an integer that may be positive, zero, or negative.



In the process of finding solutions that satisfy the boundary conditions, we also find the corresponding energy levels. Their energies, which we denote by E_n $(n = 1, 2, 3, \ldots)$, turn out to be *identical* to those from the Bohr model, as given by Eq. (38.18), with the electron rest mass m replaced by the reduced mass m_r. Rewriting that equation using $\hbar = h/2\pi$, we have

$$E_n = -\frac{1}{(4\pi\epsilon_0)^2}\frac{m_r e^4}{2n^2\hbar^2} = -\frac{13.60\text{ eV}}{n^2} \qquad \text{(energy levels of hydrogen)} \tag{41.3}$$

As in Section 38.5, we call n the **principal quantum number** for the level of energy E_n.

The result that Eq. (41.3) can be obtained from the Schrödinger equation is an important confirmation that this approach is valid. The Schrödinger analysis is

41.1 The Schrödinger equation for the hydrogen atom can be solved most readily using spherical coordinates.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

quite different from the Bohr model, both formally and conceptually, yet both yield the same energy-level scheme, a scheme that agrees with the energies determined from spectra. As we will see, the Schrödinger analysis can explain many more aspects of the hydrogen atom than can the Bohr model.

Quantisation of Orbital Angular Momentum

The solutions that satisfy the boundary conditions mentioned above also have quantised values of *orbital angular momentum*. That is, only certain discrete values of the magnitude and components of orbital angular momentum are permitted. In discussing the Bohr model in Section 38.5, we mentioned that quantisation of angular momentum was a result with little fundamental justification. With the Schrödinger equation it appears automatically!

The possible values of the magnitude L of orbital angular momentum $\vec{\boldsymbol{L}}$ are determined by the requirement that the $\Theta(\theta)$ function must be finite at $\theta = 0$ and $\theta = \pi$. In a level with energy E_n and principal quantum number n, the possible values of L are

$$L = \sqrt{l(l+1)}\hbar \qquad (l = 0, 1, 2, \ldots, n-1) \qquad \text{(magnitude of orbital angular momentum)} \tag{41.4}$$

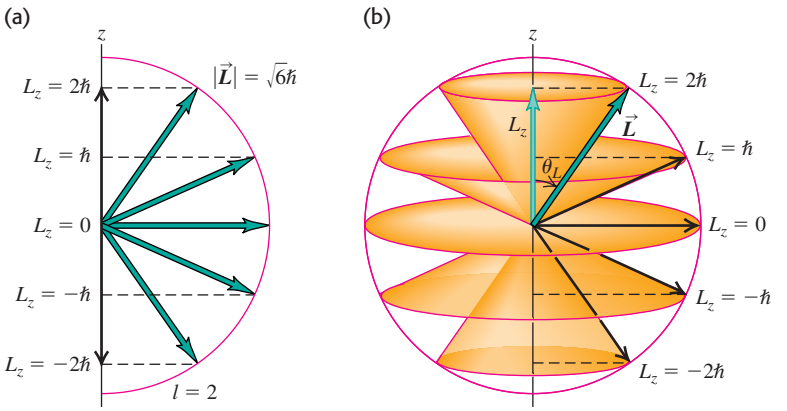
The *orbital angular-momentum quantum number* l is called the **orbital quantum number** for short. In the Bohr model, each energy level corresponded to a single value of angular momentum. Equation (41.4) shows that in fact there are n different possible values of L for the nth energy level.

An interesting feature of Eq. (41.4) is that the orbital angular momentum is *zero* for $l = 0$ states. This result disagrees with the Bohr model, in which the electron always moved in a circle of definite radius and L was never zero. The $l = 0$ wave functions ψ depend only on r; the $\Theta(\theta)$ and $\Phi(\phi)$ functions for these states are constants. Thus the wave functions for $l = 0$ states are spherically symmetric; there is nothing in their probability distribution $|\psi|^2$ to favour one direction over any other, and there is no orbital angular momentum.

The permitted values of the *component* of $\vec{\boldsymbol{L}}$ in a given direction, say the z-component L_z, are determined by the requirement that the $\Phi(\phi)$ function must equal $\Phi(\phi + 2\pi)$. The possible values of L_z are

$$L_z = m_l\hbar \qquad (m_l = 0, \pm 1, \pm 2, \ldots, \pm l) \qquad \text{(components of orbital angular momentum)} \tag{41.5}$$

We see that m_l can be zero or a positive or negative integer up to, but no larger in magnitude than, l. That is, $|m_l| \le l$. For example, if $l = 1$, m_l can equal 1, 0 or -1. For reasons that will emerge later, we call m_l the *orbital magnetic quantum number* or **magnetic quantum number** for short.



The component L_z can never be quite as large as L (unless both are zero). For example, when $l = 2$, the largest possible value of m_l is also 2; then Eqs. (41.4) and (41.5) give

$$L = \sqrt{2(2+1)}\hbar = \sqrt{6}\hbar = 2.45\hbar$$
$$L_z = 2\hbar$$

Figure 41.2 (next page) shows the situation. The minimum value of the angle θ_L between the vector $\vec{\boldsymbol{L}}$ and the z-axis is given by

$$\theta_L = \arccos\frac{L_z}{L} = \arccos\frac{2}{2.45} = 35.3°$$

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

41.2 (a) When $l = 2$, the magnitude of $\vec{L}$ is $\sqrt{6}\hbar = 2.45\hbar$, but the direction of $\vec{L}$ is not definite. In this semiclassical vector picture, $\vec{L}$ makes an angle of 35.3° with the z-axis when the z-component has its maximum value of $2\hbar$. (b) Cones of the possible directions of $\vec{L}$.

That $|L_z|$ is always less than L is also required by the uncertainty principle. Suppose we could know the precise *direction* of the orbital angular momentum vector. Then we could let that be the direction of the z-axis, and L_z would equal L. This corresponds to a particle moving in the xy-plane only, in which case the z-component of the linear momentum $\vec{p}$ would be zero with no uncertainty Δp_z. Then the uncertainty principle $\Delta z\,\Delta p_z \geq \hbar$ requires infinite uncertainty Δz in the coordinate z. This is impossible for a localised state; we conclude that we can't know the direction of $\vec{L}$ precisely. Thus, as we've already stated, the component of $\vec{L}$ in a given direction can never be quite as large as its magnitude L. Also, if we can't know the direction of $\vec{L}$ precisely, we can't determine the components L_x and L_y precisely. Thus we show *cones* of possible directions for $\vec{L}$ in Fig. 41.2b.

You may wonder why we have singled out the z-axis for special attention. There's no fundamental reason for this; the atom certainly doesn't care what coordinate system we use. The point is that we can't determine all three components of orbital angular momentum with certainty, so we arbitrarily pick one as the component we want to measure. When we discuss interactions of the atom with a magnetic field, we will consistently choose the positive z-axis to be in the direction of $\vec{B}$.

Quantum Number Notation

The wave functions for the hydrogen atom are determined by the values of three quantum numbers n, l, and m_l. The energy E_n is determined by the principal quantum number n according to Eq. (41.3). The magnitude of orbital angular momentum is determined by the orbital quantum number l, as in Eq. (41.4). The component of orbital angular momentum in a specified axis direction (customarily the z-axis) is determined by the magnetic quantum number m_l, as in Eq. (41.5). The energy does not depend on the values of l or m_l (Fig. 41.3), so for each energy level E_n given by Eq. (41.3), there is more than one distinct state having the same energy but different quantum numbers. The existence of more than one distinct state with the same energy is called **degeneracy**; it has no counterpart in the Bohr model.

States with various values of the orbital quantum number l are often labelled with letters, according to the following scheme:

$l = 0$: s states
$l = 1$: p states
$l = 2$: d states
$l = 3$: f states
$l = 4$: g states
$l = 5$: h states

and so on alphabetically. This seemingly irrational choice of the letters s, p, d and f originated in the early days of spectroscopy and has no fundamental

41.3 The energy for an orbiting satellite depends on the average distance between the satellite and the centre of the earth. It does *not* depend on whether the orbit is circular (with a large orbital angular momentum L) or elliptical (in which case L is smaller). In the same way, the energy of a hydrogen atom does not depend on the orbital angular momentum.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

significance. In an important form of *spectroscopic notation* that we'll use often, a state with $n = 2$ and $l = 1$ is called a $2p$ state; a state with $n = 4$ and $l = 0$ is a $4s$ state; and so on. Only s states $(l = 0)$ are spherically symmetric.

Here's another bit of notation. The radial extent of the wave functions increases with the principal quantum number n, and we can speak of a region of space associated with a particular value of n as a **shell**. Especially in discussions of many-electron atoms, these shells are denoted by capital letters:

$n = 1$: K shell
$n = 2$: L shell
$n = 3$: M shell
$n = 4$: N shell

and so on alphabetically. For each n, different values of l correspond to different *subshells*. For example, the L shell $(n = 2)$ contains the $2s$ and $2p$ subshells.

Table 41.1 shows some of the possible combinations of the quantum numbers n, l, and m_l for hydrogen-atom wave functions. The spectroscopic notation and the shell notation for each are also shown.

Table 41.1 Quantum States of the Hydrogen Atom

n	l	m_l	Spectroscopic Notation	Shell
1	0	0	$1s$	K
2	0	0	$2s$	L
2	1	$-1, 0, 1$	$2p$	
3	0	0	$3s$	
3	1	$-1, 0, 1$	$3p$	M
3	2	$-2, -1, 0, 1, 2$	$3d$	
4	0	0	$4s$	N
and so on				

Problem-Solving Strategy 41.1 Atomic Structure

IDENTIFY *the relevant concepts*: Many problems in atomic structure can be solved just by reference to the quantum numbers that describe the total energy E, the magnitude of the orbital angular momentum $\vec{L}$, the z-component of $\vec{L}$ and other properties of an atom.

SET UP *the problem*: Decide what the target variable is and collect the equations that you will use to determine its value. These may include Eqs. (41.3), (41.4) and (41.5).

EXECUTE *the solution* as follows:

1. Be sure you know the possible values of the quantum numbers n, l, and m_l for the hydrogen atom. They are all integers; n is always greater than zero, l can be zero or positive up to $n - 1$, and m_l can range from $-l$ to l. Be able to count the number of (n, l, m_l) states in each shell (K, L, M, and so on) and subshell ($3s$, $3p$, $3d$, and so on). You should know how to construct, not simply memorise, Table 41.1.
2. Solve for the target variable.

EVALUATE *your answer*: When you check numerical values, it's helpful to be familiar with some typical magnitudes. For example, the electric potential energy of a proton and electron that are -0.10 nm apart (typical of atomic dimensions) is about -15 eV. Visible light (emitted in a number of transitions between states of the hydrogen atom) has wavelengths around 500 nm and frequencies around 5×10^{14} Hz. You'll find other typical magnitudes in Problem-Solving Strategy 39.1 (Section 39.1).

Example 41.1 Counting hydrogen states

How many distinct (n, l, m_l) states of the hydrogen atom with $n = 3$ are there? Find the energy of these states.

SOLUTION

IDENTIFY: This problem uses the relationships among the principal quantum number n, orbital quantum number l, magnetic quantum number m_l, and energy of a state for the hydrogen atom.

SET UP: To determine the number of states, we use the idea that l can have integer values from 0 to $n - 1$ and that m_l can have values from $-l$ to l. The energy of any particular state is given by Eq. (41.3).

EXECUTE: When $n = 3$, l can be 0, 1, or 2. When $l = 0$, m_l can be only 0 (1 state). When $l = 1$, m_l can be -1, 0 or 1 (3 states). When $l = 2$, m_l can be -2, -1, 0, 1 or 2 (5 states). The total num-

Continued

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

ber of (n, l, m_l) states with $n = 3$ is therefore $1 + 3 + 5 = 9$. (In Section 41.3 we'll find that the total number of $n = 3$ states is in fact twice this, or 18, because of electron spin.)

The energies of these states are all the same because the energy depends only on n. According to Eq. (41.3), with $n = 3$,

$$E_3 = \frac{-13.60\ \text{eV}}{3^2} = -1.51\ \text{eV}$$

EVALUATE: It's useful to remember that the ground level of hydrogen has $n = 1$ and $E_1 = -13.6$ eV. These excited states have a higher energy, as they must.

Example 41.2 Angular momentum in an excited level of hydrogen

Consider the $n = 4$ states of hydrogen. (a) What is the maximum magnitude L of the orbital angular momentum? (b) What is the maximum value of L_z? (c) What is the minimum angle between $\vec{L}$ and the z-axis? Give your answers to parts (a) and (b) in terms of $\hbar$.

SOLUTION

IDENTIFY: We are again being asked to relate the principal quantum number n and the orbital quantum number l for a hydrogen atom. We also need the connection between the value of l and the magnitude and possible directions of the orbital angular momentum vector.

SET UP: We use Eq. (41.4) in part (a) to determine the maximum value of L; then we use Eq. (41.5) in part (b) to determine the maximum value of L_z. The minimum angle between $\vec{L}$ and the z-axis occurs when L_z is maximum (so that $\vec{L}$ is most nearly aligned with the positive z-axis).

EXECUTE: (a) When $n = 4$, the maximum value of the orbital angular-momentum quantum number l is $(n - 1) = (4 - 1) = 3$; from Eq. (41.4),

$$L = \sqrt{3(3 + 1)}\hbar = \sqrt{12}\hbar = 3.464\hbar$$

(b) For $l = 3$ the maximum value of the magnetic quantum number m_l is 3; from Eq. (41.5),

$$L_z = 3\hbar$$

(c) The *minimum* allowed angle between $\vec{L}$ and the z-axis corresponds to the *maximum* allowed values of L_z and m_l (Fig. 41.2b shows an $l = 2$ example). For the state with $l = 3$ and $m_l = 3$,

$$\theta_{\text{min}} = \arccos\frac{(L_z)_{\text{max}}}{L} = \arccos\frac{3\hbar}{3.464\hbar} = 30.0°$$

EVALUATE: As a check, you can verify that the angle is larger than 30.0° for all states with smaller values of l.

Electron Probability Distributions

Rather than picturing the electron as a point particle moving in a precise circle, the Schrödinger equation gives a *probability distribution* surrounding the nucleus. Because the hydrogen-atom probability distributions are three-dimensional, they are harder to visualise than the two-dimensional circular orbits of the Bohr model. It's helpful to look at the *radial probability distribution function* $P(r)$—that is, the probability per radial length for the electron to be found at various distances from the proton. From Section 39.5 the probability for finding the electron in a small volume element dV is $|\psi|^2\, dV$. (We assume that ψ is normalised—that is, that the integral of $|\psi|^2\, dV$ over all space equals unity so that there is 100% probability of finding the electron somewhere in the universe.) Let's take as our volume element a thin spherical shell with inner radius r and outer radius $r + dr$. The volume dV of this shell is approximately its area $4\pi r^2$ multiplied by its thickness dr:

$$dV = 4\pi r^2\, dr \tag{41.6}$$

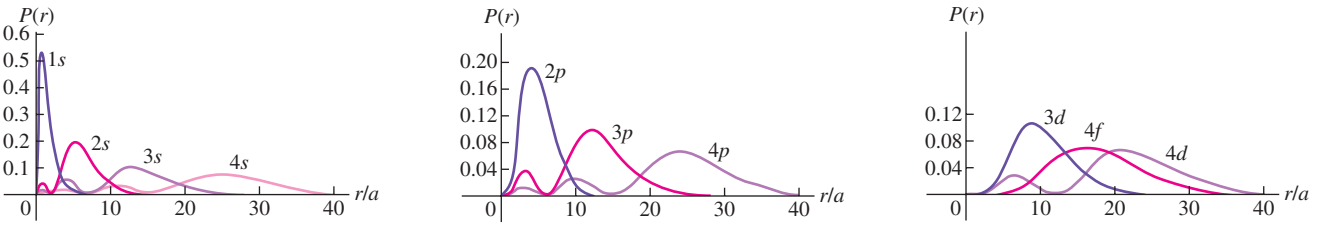
We denote by $P(r)\ dr$ the probability of finding the particle within the radial range dr; then

$$P(r)\ dr = |\psi|^2\, dV = |\psi|^2 4\pi r^2\, dr \qquad \text{(probability that the electron is between } r \text{ and } r + dr) \tag{41.7}$$

For wave functions that depend on θ and ϕ as well as r, we use the value of $|\psi|^2$ averaged over all angles in Eq. (41.7).

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

41.4 Radial probability distribution functions $P(r)$ for several hydrogen-atom wave functions, plotted as functions of the ratio r/a [see Eq. (41.8)]. For each function, the number of maxima is $(n - l)$. The curves for which $l = n - 1$ $(1s, 2p, 3d, \ldots)$ have only one maximum, located at $r = n^2a$.



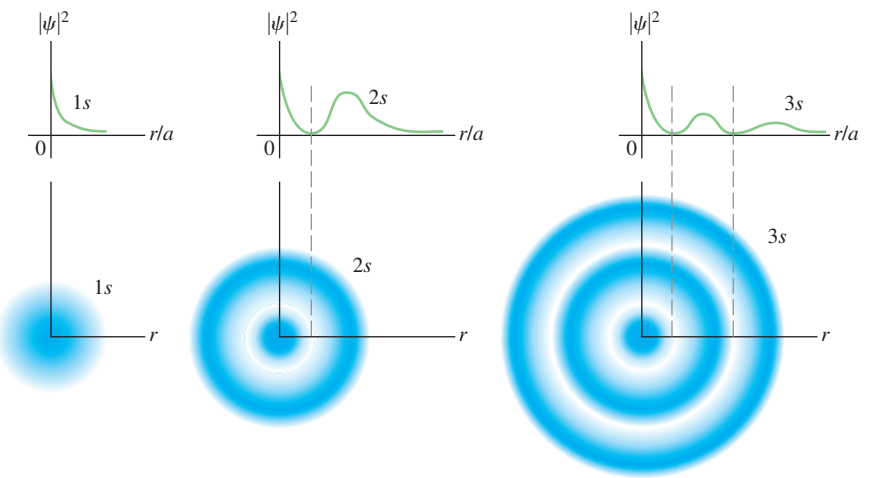


Figure 41.4 shows graphs of $P(r)$ for several hydrogen-atom wave functions. The r scales are labelled in multiples of a, the smallest distance between the electron and the nucleus in the Bohr model:

$$a = \frac{\epsilon_0 h^2}{\pi m_r e^2} = \frac{4\pi\epsilon_0\hbar^2}{m_r e^2} = 5.29 \times 10^{-11}\ \text{m} \qquad \begin{matrix}\text{(smallest } r,\\ \text{Bohr model)}\end{matrix} \qquad (41.8)$$

Just as for a particle in a box (see Section 40.1), there are some positions where the probability is zero. But again, the uncertainty principle tells us not to worry; we can't localise the electron exactly anyway. Note that for the states having the largest possible l for each n (such as $1s$, $2p$, $3d$ and $4f$ states), $P(r)$ has a single maximum at n^2a. For these states, the electron is most likely to be found at the distance from the nucleus that is predicted by the Bohr model, $r = n^2a$.

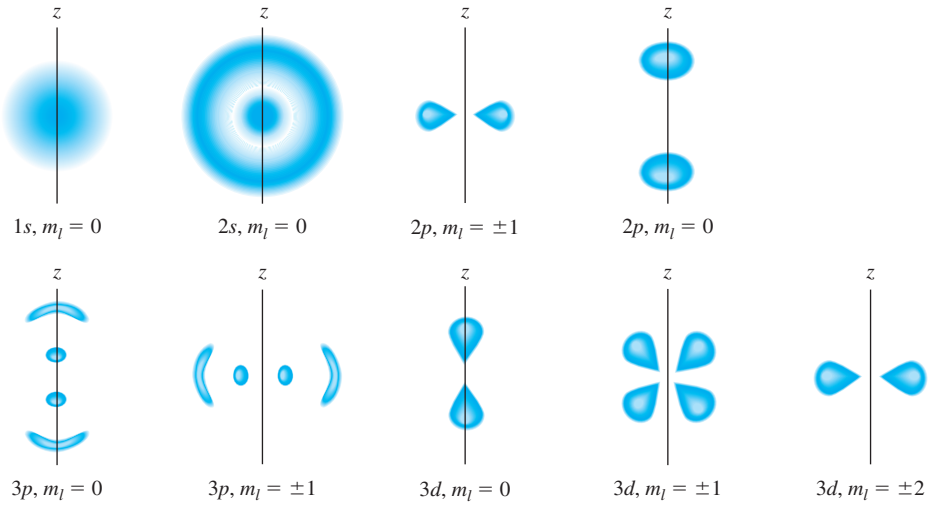

Figure 41.4 shows *radial* probability distribution functions $P(r) = 4\pi r^2|\psi|^2$, which indicate the relative probability of finding the electron within a thin spherical shell of radius r. By contrast, Figs. 41.5 and 41.6 show the *three-dimensional* probability distribution functions $|\psi|^2$, which indicate the relative probability of finding the electron within a small box at a given position. The darker the blue 'cloud', the greater the value of $|\psi|^2$. Figure 41.5 shows cross-sections of the spherically symmetric probability clouds for the lowest three s subshells, for which $|\psi|^2$ depends only on the radial coordinate r. Figure 41.6 (next page) shows cross-sections of the clouds for other electron states for which $|\psi|^2$ depends on both r and θ. In *any* stationary state of the hydrogen atom, $|\psi|^2$ is independent of ϕ.

41.5 Three-dimensional probability distribution functions $|\psi|^2$ for the spherically symmetric $1s$, $2s$ and $3s$ hydrogen-atom wave functions.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

41.6 Cross-sections of three-dimensional probability distributions for a few quantum states of the hydrogen atom. They are not to the same scale. Mentally rotate each drawing about the z-axis to obtain the three-dimensional representation of $|\psi|^2$. For example, the $2p$, $m_l = \pm 1$ probability distribution looks like a fuzzy donut.

Example 41.3 A hydrogen wave function

The ground-state wave function for hydrogen (a $1s$ state) is

$$\psi_{1s}(r) = \frac{1}{\sqrt{\pi a^3}} e^{-r/a}$$

(a) Verify that this function is normalised. (b) What is the probability that the electron will be found at a distance less than a from the nucleus?

SOLUTION

IDENTIFY: We need to show that this wave function satisfies the condition that the probability of finding the electron *somewhere* is 1. We then need to find the probability that it will be found in the region $r < a$.

SET UP: In part (a) we carry out the integral $\int |\psi|^2 \, dV$ over all space; if it is equal to 1, the wave function is normalised. In part (b) we carry out the same integral over a spherical volume that extends from the origin (the nucleus) out to a distance a from the nucleus.

EXECUTE: (a) Since the wave function depends only on the radial coordinate r, we can choose our volume elements to be spherical shells of radius r, thickness dr, and volume dV given by Eq. (41.6). We then have

$$\int_{\text{all space}} |\psi_{1s}|^2 \, dV = \int_0^\infty \frac{1}{\pi a^3} e^{-2r/a} (4\pi r^2 \, dr) = \frac{4}{a^3} \int_0^\infty r^2 e^{-2r/a} \, dr$$

The following indefinite integral can be found in a table of integrals or by integrating by parts:

$$\int r^2 e^{-2r/a} \, dr = \left(-\frac{ar^2}{2} - \frac{a^2 r}{2} - \frac{a^3}{4} \right) e^{-2r/a}$$

Evaluating this between the limits $r = 0$ and $r = \infty$ is simple; it is zero at $r = \infty$ because of the exponential factor, and at $r = 0$ only the last term in the parentheses survives. Thus the value of the integral is $a^3/4$. Putting it all together, we find

$$\int_0^\infty |\psi_{1s}|^2 \, dV = \frac{4}{a^3} \int_0^\infty r^2 e^{-2r/a} \, dr = \frac{4}{a^3} \frac{a^3}{4} = 1$$

The wave function *is* normalised.

(b) To find the probability P that the electron is found within $r < a$, we carry out the same integration but with the limits 0 and a. We'll leave the details to you (see Exercise 41.13). From the upper limit we get $-5e^{-2}a^3/4$; the final result is

$$P = \int_0^a |\psi_{1s}|^2 4\pi r^2 \, dr = \frac{4}{a^3} \left(-\frac{5a^3 e^{-2}}{4} + \frac{a^3}{4} \right)$$
$$= 1 - 5e^{-2} = 0.323$$

EVALUATE: Our results tell us that in a ground state we expect to find the electron at a distance from the nucleus less than a about $\frac{1}{3}$ of the time and at a greater distance about $\frac{2}{3}$ of the time. It's hard to tell, but in Fig. 41.4, about $\frac{2}{3}$ of the area under the $1s$ curve is at distances greater than a (that is, $r/a > 1$).

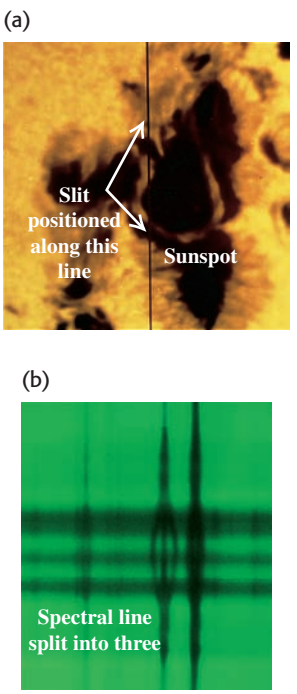
Hydrogenlike Atoms

Two generalisations that we discussed with the Bohr model in Section 38.5 are equally valid in the Schrödinger analysis. First, if the 'atom' is not composed of a single proton and a single electron, the reduced mass m_r of the system will give

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

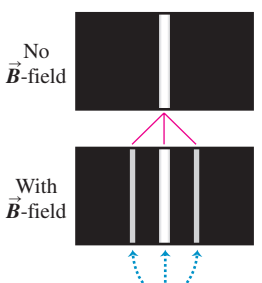
changes in Eqs. (41.3) and (41.8) that are substantial with some exotic systems. One example is *positronium*, composed of a positron and an electron (see Fig. 38.21). Second, our analysis is applicable to single-electron ions, such as He^+, Li^{2+}, and so on. For such ions we replace e^2 by Ze^2 in Eqs. (41.3) and (41.8), where Z is the number of protons (the **atomic number**). This replacement will far overshadow the small change in the reduced mass m_r in these equations.

The Schrödinger analysis of the hydrogen atom is a lot more complex, both conceptually and mathematically, than the Newtonian analysis of planetary motion or the semiclassical Bohr model. It deals with probabilities rather than certainties, and it predicts discrete rather than continuous values of energy and angular momentum. But this analysis enables us to understand phenomena for which classical mechanics and electromagnetism are inadequate. Added complexity is the price we pay for expanded understanding.



Test Your Understanding of Section 41.1 Rank the following states of the hydrogen atom in order from highest to lowest probability of finding the electron in the vicinity of $r = 5a$: (i) $n = 1, l = 0, m_l = 0$; (ii) $n = 2, l = 1, m_l = +1$; (iii) $n = 2, l = 1, m_l = 0$.

41.2 The Zeeman Effect



The **Zeeman effect** is the splitting of atomic energy levels and the associated spectrum lines when the atoms are placed in a magnetic field (Fig. 41.7). This effect confirms experimentally the quantisation of angular momentum. The discussion in this section, which assumes that the only angular momentum is the *orbital* angular momentum of a single electron, also shows why we call m_l the magnetic quantum number.

Atoms contain charges in motion, so it should not be surprising that magnetic forces cause changes in that motion and in the energy levels. As early as the middle of the 19th century, physicists speculated that the sources of visible light might be vibrating electric charge on an atomic scale. In 1896 the Dutch physicist Pieter Zeeman was the first to show that in the presence of a magnetic field, some spectrum lines were split into groups of closely spaced lines (Fig. 41.8). This effect now bears his name.

41.7 Magnetic effects on the spectrum of sunlight. (a) The slit of a spectrograph is positioned along the black line crossing a portion of a sunspot. (b) The 0.4-T magnetic field in the sunspot (a thousand times greater than the earth's field) splits the middle spectral line into three lines.

41.8 The normal Zeeman effect. Compare with Fig. 41.7b.

When an excited gas is placed in a magnetic field, the interaction of orbital magnetic moments with the field splits individual spectral lines of the gas into sets of three lines.

Magnetic Moment of an Orbiting Electron

Let's begin our analysis of the Zeeman effect by reviewing the concept of *magnetic dipole moment* or *magnetic moment*, introduced in Section 27.7. A plane current loop with vector area $\vec{A}$ carrying current I has a magnetic moment $\vec{\mu}$ given by

$$\vec{\mu} = I\vec{A} \tag{41.9}$$

When a magnetic dipole of moment $\vec{\mu}$ is placed in a magnetic field $\vec{B}$, the field exerts a torque $\vec{\tau} = \vec{\mu} \times \vec{B}$ on the dipole. The potential energy U associated with this interaction is given by Eq. (27.27):

$$U = \vec{\mu} \cdot \vec{B} \tag{41.10}$$

Now let's use Eqs. (41.9) and (41.10) and the Bohr model to look at the interaction of a hydrogen atom with a magnetic field. The orbiting electron (speed v) is equivalent to a current loop with radius r and area πr^2. The average current I is the average charge per unit time that passes a point of the orbit. This is equal to the charge magnitude e divided by the time T for one revolution, given by

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

$T = 2\pi r/v$. Thus $I = ev/2\pi r$, and from Eq. (41.9) the magnitude μ of the magnetic moment is

$$\mu = IA = \frac{ev}{2\pi r}\pi r^2 = \frac{evr}{2} \tag{41.11}$$

We can also express this in terms of the magnitude L of the orbital angular momentum. From Eq. (10.28), $L = mvr$ for a particle in a circular orbit, so Eq. (41.11) becomes

$$\mu = \frac{e}{2m}L \tag{41.12}$$

The ratio of the magnitude of $\vec{\boldsymbol{\mu}}$ to the magnitude of $\vec{\boldsymbol{L}}$ is $\mu/L = e/2m$ and is called the *gyromagnetic ratio*.

In the Bohr model, $L = nh/2\pi = n\hbar$, where $n = 1, 2, \ldots$. For an $n = 1$ state (a ground state), Eq. (41.12) becomes $\mu = (e/2m)\hbar$. This quantity is a natural unit for magnetic moment; it is called one **Bohr magneton**, denoted by μ_B:

$$\mu_B = \frac{e\hbar}{2m} \qquad \text{(definition of the Bohr magneton)} \tag{41.13}$$

Evaluating Eq. (41.2) Eq. (41.13) gives

$$\mu_B = 5.788 \times 10^{-5}\ \text{eV/T} = 9.274 \times 10^{-24}\ \text{J/T or A} \cdot \text{m}^2$$

Note that the units J/T and $\text{A} \cdot \text{m}^2$ are equivalent. We defined this quantity previously in (optional) Section 28.8.

While the Bohr model suggests that the orbital motion of an atomic electron gives rise to a magnetic moment, this model does *not* give correct predictions about magnetic interactions. As an example, the Bohr model predicts that an electron in a hydrogen-atom ground state has an orbital magnetic moment equal in magnitude to μ_B. But the Schrödinger picture tells us that such a ground-state electron is in an s state with zero angular momentum, so the orbital magnetic moment must be *zero!* To get the correct results, we must describe the states by using Schrödinger wave functions.

It turns out that in the Schrödinger formulation, electrons have the same ratio of μ to L (gyromagnetic ratio) as in the Bohr model—namely, $e/2m$. Suppose the magnetic field $\vec{\boldsymbol{B}}$ is directed along the $+z$-axis. From Eq. (41.10) the interaction energy U of the atom's magnetic moment with the field is

$$U = -\mu_z B \tag{41.14}$$

where μ_z is the z-component of the vector $\vec{\boldsymbol{\mu}}$.

Now we use Eq. (41.12) to find μ_z, recalling that e is the *magnitude* of the electron charge and that the actual charge is $-e$. Because the electron charge is negative, the orbital angular momentum and magnetic moment vectors are opposite. We find

$$\mu_z = -\frac{e}{2m}L_z \tag{41.15}$$

For the Schrödinger wave functions, $L_z = m_l\hbar$, with $m_l = 0, \pm 1, \pm 2, \ldots, \pm l$, so

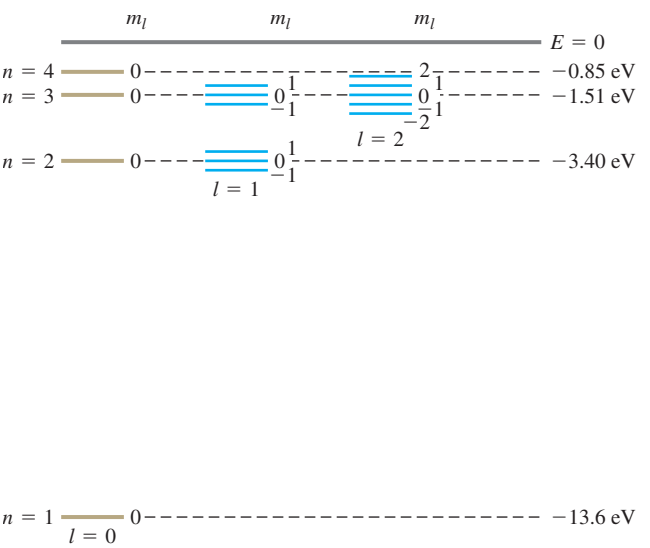
$$\mu_z = -\frac{e}{2m}L_z = -m_l\frac{e\hbar}{2m} \tag{41.16}$$

CAUTION **Two uses of the symbol m** Be careful not to confuse the electron mass m with the magnetic quantum number m_l.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

Finally, we can express the interaction energy, Eq. (41.14), as

$$U = -\mu_z B = m_l \frac{e\hbar}{2m} B \qquad (m_l = 0, \pm 1, \pm 2, \ldots, \pm l) \tag{41.17}$$



(orbital magnetic interaction energy)

In terms of the Bohr magneton $\mu_B = e\hbar/2m$,

$$U = m_l \mu_B B \qquad \text{(orbital magnetic interaction energy)} \tag{41.18}$$

The effect of the magnetic field is to shift the energy of each orbital state by an amount U. The interaction energy U depends on the value of m_l because m_l determines the orientation of the orbital magnetic moment relative to the magnetic field. This dependence is the reason m_l is called the magnetic quantum number.

Because the values of m_l range from $-l$ to $+l$ in steps of one, an energy level with a particular value of the orbital quantum number l contains $(2l + 1)$ different orbital states. Without a magnetic field these states all have the same energy; that is, they are degenerate. The magnetic field removes this degeneracy. In the presence of a magnetic field they are split into $2l + 1$ distinct energy levels; adjacent levels differ in energy by $(e\hbar/2m)B = \mu_B B$. The effect on the energy levels of hydrogen is shown in Fig. 41.9. Spectral lines corresponding to transitions from one set of levels to another set are correspondingly split and appear as a series of three closely spaced spectral lines replacing a single line. As the following example shows, the splitting of spectral lines is quite small because the value of $\mu_B B$ is small even for substantial magnetic fields.

41.9 Energy-level diagram for hydrogen, showing the splitting of energy levels resulting from the interaction of the electron's orbital magnetic moment with an external magnetic field. Values of m_l are shown adjacent to the various levels. Relative magnitudes of splittings are exaggerated for clarity. The $n = 4$ splittings are not shown; can you draw them in?

Example 41.4 An atom in a magnetic field

An atom in a state with $l = 1$ emits a photon with wavelength 600.000 nm as it decays to a state with $l = 0$. If the atom is placed in a magnetic field with magnitude $B = 2.00$ T, determine the shifts in the energy levels and in the wavelength resulting from the interaction of the magnetic field and the atom's orbital magnetic moment.

SOLUTION

IDENTIFY: This problem concerns the splitting in atomic energy levels caused by a magnetic field (the Zeeman effect).

SET UP: We use Eq. (41.17) or (41.18) to determine the shifts in the energy levels. The relationship $E = hc/\lambda$ between the energy

Continued

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

and wavelength of a photon then lets us calculate the wavelengths emitted during transitions from the $l = 1$ states to the $l = 0$ state.

EXECUTE: The energy of a 600 nm photon is

$$E = \frac{hc}{\lambda} = \frac{(4.14 \times 10^{-15}\ \text{eV} \cdot \text{s})(3.00 \times 10^{8}\ \text{m/s})}{600 \times 10^{-9}\ \text{m}} = 2.07\ \text{eV}$$

Hence, if there is no external magnetic field, the difference in energy between the $l = 0$ and $l = 1$ levels is 2.07 eV.

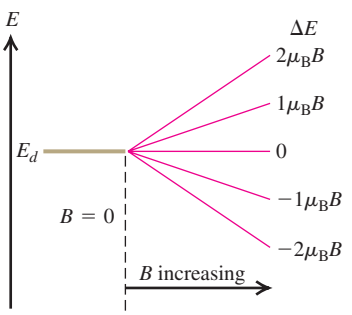
With a 2.00 T field present, Eq. (41.18) shows that there is no shift of the $l = 0$ state (which has $m_l = 0$). For the $l = 1$ states, the splitting of levels is given by

$$\begin{aligned} U &= m_l \mu_B B = m_l (5.788 \times 10^{-5}\ \text{eV/T})(2.00\ \text{T}) \\ &= m_l (1.16 \times 10^{-4}\ \text{eV}) = m_l (1.85 \times 10^{-23}\ \text{J}) \end{aligned}$$

When $l = 1$, the possible values of m_l are -1, 0 and $+1$, and the three corresponding levels are separated by equal intervals of 1.16×10^{-4} eV. This is a small fraction of the 2.07 eV photon energy:

$$\frac{1.16 \times 10^{-4}\ \text{eV}}{2.07\ \text{eV}} = 5.60 \times 10^{-5}$$

The corresponding *wavelength* shifts are approximately $(5.60 \times 10^{-5})(600\ \text{nm}) = 0.034$ nm. The original 600.000 nm line is split into a triplet with wavelengths 599.966, 600.000 and 600.034 nm.



EVALUATE: Even though 2.00 T would be a strong field in most laboratories, the wavelength splittings are extremely small. Nonetheless, modern spectrographs have more than enough chromatic resolving power to measure these splittings (see Section 36.5).

Selection Rules

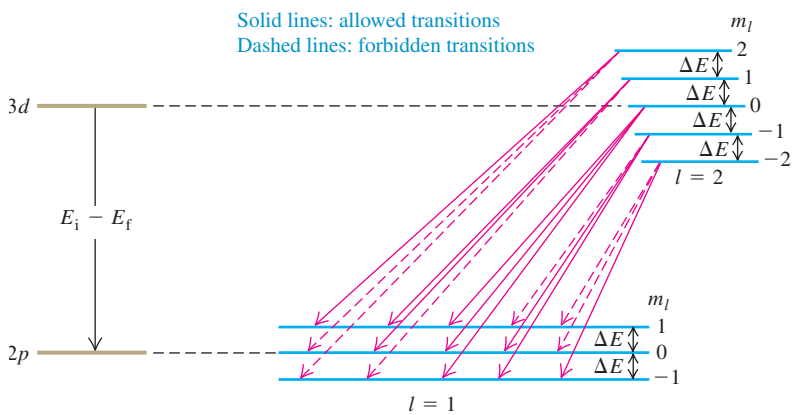


Figure 41.10 shows what happens to a set of d states $(l = 2)$ as the magnetic field increases. The five states, $m_l = -2, -1, 0, 1$ and 2, are degenerate (have the same energy) with zero field, but the increasing field spreads the states out and removes their degeneracy. Figure 41.11 shows the splittings of the $3d$ and $2p$ states. Equal energy differences $(e\hbar/2m)B = \mu_B B$ separate adjacent levels. In the absence of a magnetic field, a transition from a $3d$ to a $2p$ state would yield a single spectral line with photon energy $E_i - E_f$. With the levels split as shown, it might seem that there are five possible photon energies.

In fact, there are only three possibilities. Not all combinations of initial and final levels are possible because of a restriction associated with conservation of angular momentum. The photon ordinarily carries off one unit $(\hbar)$ of angular momentum, which leads to the requirements that in a transition l must change by 1 and m_l must change by 0 or ± 1. These requirements are called **selection rules**. Transitions that obey these rules are called *allowed transitions*; those that don't are *forbidden transitions*. The allowed transitions are shown by solid arrows in Fig. 41.11. You should count the possible transition energies to convince yourself that the nine solid arrows give only three possible energies; the zero-field value $E_i - E_f$, and that value plus or minus $\Delta E = (e\hbar/2m)B = \mu_B B$. The corresponding spectral lines are shown.

What we have described is called the *normal* Zeeman effect. It is based entirely on the orbital angular momentum of the electron. In fact, there's nothing particularly *normal* about it. It leaves out a very important consideration: the *spin* angular momentum, the subject of the next section.

41.10 Splitting of the energy levels of a d state $(l = 2)$ caused by an external magnetic field, assuming only an orbital magnetic moment.

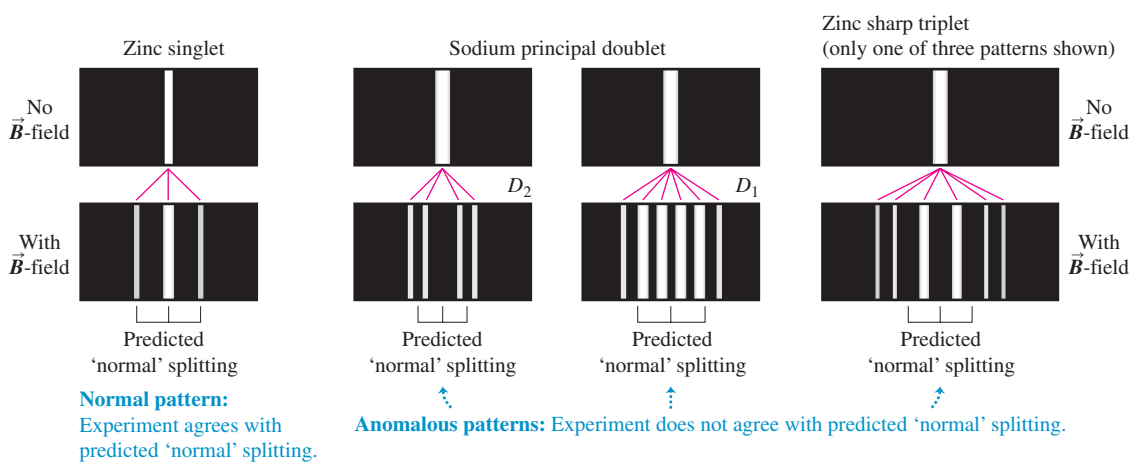
41.11 The cause of the normal Zeeman effect. The magnetic field splits the levels, but selection rules allow transitions with only three different energy changes, giving three different photon frequencies and wavelengths.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

Test Your Understanding of Section 41.2 In this section we assumed that the magnetic field points in the positive z-direction. Would the results be affected if the magnetic field pointed in the positive x-direction?

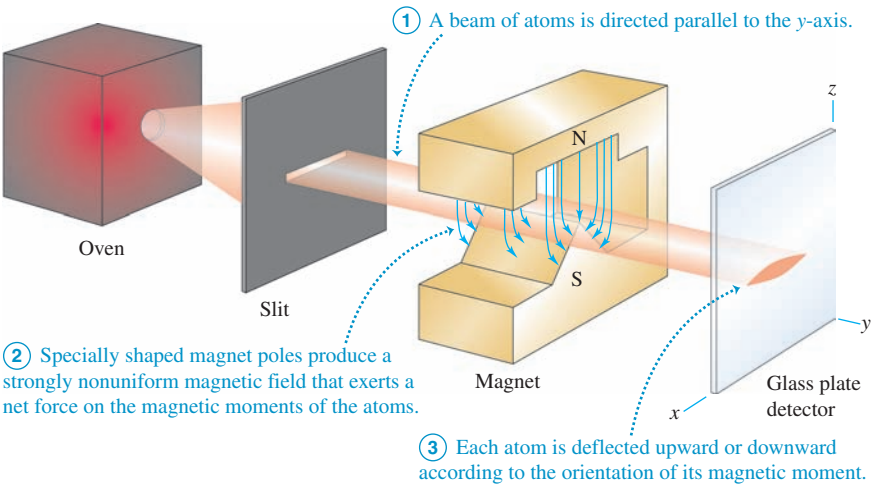
41.3 Electron Spin

Despite the success of the Schrödinger equation in predicting the energy levels of the hydrogen atom, experimental observations indicate that it doesn't tell the whole story of the behaviour of electrons in atoms. First, spectroscopists have found magnetic-field splitting into other than the three lines we've explained, sometimes unequally spaced. Before this effect was understood, it was called the *anomalous* Zeeman effect to distinguish it from the 'normal' effect discussed in the preceding section. Both kinds of splittings are shown in Fig. 41.12.



Second, some energy levels show splittings that resemble the Zeeman effect even when there is *no* external magnetic field. For example, when the lines in the hydrogen spectrum are examined with a high-resolution spectrograph, some lines are found to consist of sets of closely spaced lines called *multiplets*. Similarly, the orange-yellow line of sodium, corresponding to the transition $4p \rightarrow 3s$ of the outer electron, is found to be a doublet $(\lambda = 589.0, 589.6\ \text{nm})$, suggesting that the $4p$ level might in fact be two closely spaced levels. The Schrödinger equation in its original form didn't predict any of this.

The Stern–Gerlach Experiment



Similar anomalies appeared in 1922 in atomic-beam experiments performed in Germany by Otto Stern and Walter Gerlach. When they passed a beam of neutral atoms through a nonuniform magnetic field (Fig. 41.13, next page), atoms were deflected according to the orientation of their magnetic moments with respect to the field. These experiments demonstrated the quantisation of angular momentum in a very direct way. If there were only orbital angular momentum, the deflections would split the beam into an odd number $(2l + 1)$ of different components. However, some atomic beams were split into an *even* number of components. If we use a different symbol j for an angular momentum quantum number, setting $2j + 1$ equal to an even number gives $j = \frac{1}{2}, \frac{3}{2}, \frac{5}{2}, \ldots$, suggesting a half-integer angular momentum. This can't be understood on the basis of the Bohr model and similar pictures of atomic structure.

In 1925 two graduate students in the Netherlands, Samuel Goudsmidt and George Uhlenbeck, proposed that the electron might have some additional motion.

41.12 Illustrations of the normal and anomalous Zeeman effects for two elements, zinc and sodium. The brackets under each illustration show the 'normal' splitting predicted by neglecting the effect of electron spin.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

41.13 The Stern–Gerlach experiment.

Using a semiclassical model, they suggested that the electron might behave like a spinning sphere of charge instead of a particle. If so, it would have an additional *spin* angular momentum and magnetic moment. If these were quantised in much the same way as *orbital* angular momentum and magnetic moment, they might help to explain the observed energy-level anomalies.

An Analogy for Electron Spin

To introduce the concept of **electron spin**, let's start with an analogy. The earth travels in a nearly circular orbit around the sun, and at the same time it *rotates* on its axis. Each motion has its associated angular momentum, which we call the *orbital* and *spin* angular momentum, respectively. The total angular momentum of the earth is the vector sum of the two. If we were to model the earth as a single point, it would have no moment of inertia about its spin axis and thus no spin angular momentum. But when our model includes the finite size of the earth, spin angular momentum becomes possible.

In the Bohr model, suppose the electron is not just a point charge but a small spinning sphere moving in orbit. Then the electron has not only orbital angular momentum but also spin angular momentum associated with the rotation of its mass about its axis. The sphere carries an electric charge, so the spinning motion leads to current loops and to a magnetic moment, as we discussed in Section 27.7. In a magnetic field, the *spin* magnetic moment has an interaction energy in addition to that of the *orbital* magnetic moment (the normal Zeeman-effect interaction discussed in Section 41.2). We should see additional Zeeman shifts due to the spin magnetic moment.

As we mentioned, such shifts *are* indeed observed in precise spectroscopic analysis. This and a variety of other experimental evidence have shown conclusively that the electron *does* have spin angular momentum and a spin magnetic moment that do not depend on its orbital motion but are intrinsic to the electron itself.

Spin Quantum Numbers

Like orbital angular momentum, the spin angular momentum of an electron (denoted by $\vec{S}$) is found to be *quantised*. Suppose we have some apparatus that measures a particular component of $\vec{S}$, say the z-component S_z. We find that the only possible values are

$$S_z = \pm\frac{1}{2}\hbar \qquad \text{(components of spin angular momentum)} \qquad (41.19)$$

This relationship is reminiscent of the expression $L_z = m_l\hbar$ for the z-component of orbital angular momentum, except that $|S_z|$ is *one-half* of $\hbar$ instead of an

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

integer multiple. Equation (41.19) also suggests that the magnitude S of the spin angular momentum is given by an expression analogous to Eq. (41.4) with the orbital quantum number l replaced by the **spin quantum number** $s = \frac{1}{2}$:

$$S = \sqrt{\frac{1}{2}\left(\frac{1}{2}+1\right)}\hbar = \sqrt{\frac{3}{4}}\hbar \qquad \text{(magnitude of spin angular momentum)} \tag{41.20}$$

The electron is often called a 'spin-$\frac{1}{2}$ particle'.

The Bohr model is an oversimplified picture of electron behaviour. In quantum mechanics, in which the Bohr orbits are superseded by probability distributions $|\psi|^2$, we can't really *picture* electron spin. If we visualise a probability distribution as a cloud surrounding the nucleus, then we can imagine many tiny spin arrows distributed throughout the cloud, either all with components in the $+z$-direction or all with components in the $-z$-direction. But don't take this picture too seriously.

To label completely the state of the electron in a hydrogen atom, we now need a fourth quantum number m_s to specify the electron spin orientation. For an electron we give m_s the value $+\frac{1}{2}$ or $-\frac{1}{2}$ to agree with Eq. (41.19):

$$S_z = m_s\hbar \quad \left(m_s = \pm\frac{1}{2}\right) \qquad \text{(allowed values of } m_s \text{ and } S_z \text{ for an electron)} \tag{41.21}$$

The spin angular momentum vector $\vec{\boldsymbol{S}}$ can have only two orientations in space relative to the z-axis: '*spin up*' with a z-component of $+\frac{1}{2}\hbar$ and '*spin down*' with a z-component of $-\frac{1}{2}\hbar$.

The z-component of the associated spin magnetic moment (μ_z) turns out to be related to S_z by

$$\mu_z = -(2.00232)\frac{e}{2m}S_z \tag{41.22}$$

where $-e$ and m are (as usual) the charge and mass of the electron. When the atom is placed in a magnetic field, the interaction energy $-\vec{\boldsymbol{\mu}}\cdot\vec{\boldsymbol{B}}$ of the spin magnetic dipole moment with the field causes further splittings in energy levels and in the corresponding spectrum lines.

Equation (41.22) shows that the gyromagnetic ratio for electron spin is approximately *twice* as great as the value $e/2m$ for *orbital* angular momentum and magnetic dipole moment. This result has no classical analog. But in 1928 Paul Dirac developed a relativistic generalisation of the Schrödinger equation for electrons. His equation gave a spin gyromagnetic ratio of exactly $2(e/2m)$. It took another two decades to develop the area of physics called *quantum electrodynamics*, abbreviated QED, which predicts the value we've given to 'only' six significant figures as 2.00232. In fact, QED now predicts a value that agrees with a recent (2006) measurement of $2.00231930436170(152)$, making QED the most precise theory in all science.

Example 41.5 Spin magnetic interaction energy

Calculate the interaction energy for an electron in an $l = 0$ state (with no orbital magnetic moment) in a magnetic field with magnitude 2.00 T.

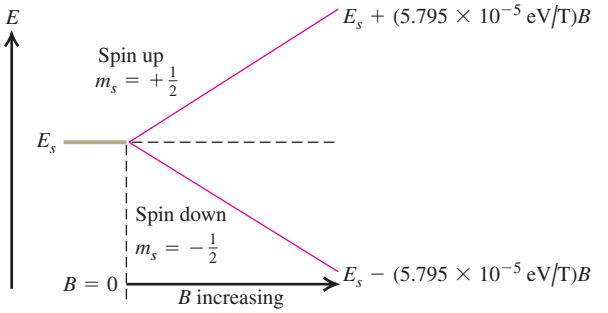
SOLUTION

IDENTIFY: Since there is no orbital magnetic moment, the only magnetic interaction is that between the $\vec{\boldsymbol{B}}$ field and the magnetic moment $\vec{\boldsymbol{\mu}}$ due to the electron spin $\vec{\boldsymbol{S}}$.

SET UP: The interaction energy is $U = -\vec{\boldsymbol{\mu}}\cdot\vec{\boldsymbol{B}}$ as in Eq. (41.10). Just as in Section 41.2, we take $\vec{\boldsymbol{B}}$ to be in the positive z-direction so that the interaction energy can be written in the form $U = -\mu_z B$ [Eq. (41.14)]. The z-component of the magnetic moment is given in terms of S_z by Eq. (41.22), and S_z is given by Eq. (41.19).

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

EXECUTE: Combining Eqs. (41.14), (41.19) and (41.22), we have



$$\begin{aligned} U &= -\left[-(2.00232)\left(\frac{e}{2m}\right)\left(\pm\frac{1}{2}\hbar\right)B\right] \\ &= \pm\frac{1}{2}(2.00232)\left(\frac{e\hbar}{2m}\right)B = \pm(1.00116)\mu_B B \\ &= \pm(1.00116)(9.274\times10^{-24}\,\text{J/T})(2.00\,\text{T}) \\ &= \pm1.86\times10^{-23}\,\text{J} = \pm1.16\times10^{-5}\,\text{eV} \end{aligned}$$

The positive value of U corresponds to $S_z = +\frac{1}{2}\hbar$ (spin up) and the negative value of U to $S_z = -\frac{1}{2}\hbar$ (spin down).

EVALUATE: Let's check the *sign* of our results. If the electron is spin down, the spin angular momentum $\vec{S}$ points generally opposite to $\vec{B}$, and hence the magnetic moment $\vec{\mu}$ (which is opposite to $\vec{S}$ because the electron charge is negative) points generally parallel to $\vec{B}$. From Eq. (41.10), $U = -\vec{\mu}\cdot\vec{B}$, the interaction energy is negative if $\vec{\mu}$ and $\vec{B}$ are parallel. Our results show that U is indeed negative in this case. In a similar way, we can argue that U must be positive for a spin-up electron, which is just what we calculated.

The red lines in Fig. 41.14 show how increasing the magnetic field magnitude affects the interaction energies for the two different spin states. The quantity $5.795\times10^{-5}\,\text{eV/T}$ is just $(1.00116)\mu_B$. The graphs are straight lines because, as Eq. (41.14) shows, U is proportional to B.

41.14 An $l = 0$ level of a single electron is split by interaction of the spin magnetic moment with a magnetic field.

Spin-Orbit Coupling

As has already been mentioned, the spin magnetic dipole moment also gives splitting of energy levels even when there is *no* external field. One cause involves the orbital motion of the electron. In the Bohr model, observers moving with the electron would see the positively charged nucleus revolving around them (just as to earthbound observers the sun seems to be orbiting the earth). This apparent motion of charge causes a magnetic field at the location of the electron, as measured in the electron's moving frame of reference. The resulting interaction with the spin magnetic moment causes a twofold splitting of this level, corresponding to the two possible orientations of electron spin.

Discussions based on the Bohr model can't be taken too seriously, but a similar result can be derived from the Schrödinger equation. The interaction energy U can be expressed in terms of the scalar product of the angular-momentum vectors $\vec{L}$ and $\vec{S}$. This effect is called **spin-orbit coupling**; it is responsible for the small energy difference between the two closely spaced, lowest excited levels of sodium shown in Fig. 38.10a and for the corresponding doublet (589.0, 589.6 nm) in the spectrum of sodium.

Example 41.6 An effective magnetic field

Calculate the effective magnetic field experienced by the electron in the 3*p* levels of the sodium atom.

SOLUTION

IDENTIFY: The two lines in the sodium doublet result from transitions from the two 3*p* levels, which are split by spin-orbit coupling, to the 3*s* level, which is *not* split because it has $L = 0$. We picture the spin-orbit coupling as an interaction between the electron spin magnetic moment and an effective magnetic field due to the nucleus. Hence this example is like Example 41.5 in reverse: There we were given B and found the difference between the energies of the two spin states; here we use the energy difference to find B.

SET UP: The difference in energy between the two 3*p* levels is equal to the difference in energy between the two photons of the sodium doublet. We use this relationship and the results of Example 41.5 to determine our target variable, the effective magnetic field strength B.

EXECUTE: The energies of the two photons are

$$E = \frac{hc}{\lambda} = \frac{(4.136\times10^{-15}\,\text{eV}\cdot\text{s})(2.998\times10^{8}\,\text{m/s})}{589.0\times10^{-9}\,\text{m}} = 2.1052\,\text{eV}$$

and

$$E = \frac{hc}{\lambda} = \frac{(4.136\times10^{-15}\,\text{eV}\cdot\text{s})(2.998\times10^{8}\,\text{m/s})}{589.6\times10^{-9}\,\text{m}} = 2.1031\,\text{eV}$$

Continued

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

Hence the energy difference between the two $3p$ levels is

$$2.1052\ \text{eV} - 2.1031\ \text{eV} = 0.0021\ \text{eV} = 3.4 \times 10^{-22}\ \text{J}$$

The spin-orbit interaction raises one level and lowers the other, each by 1.7×10^{-22} J, half this difference. From Example 41.5, the amount each state is raised or lowered is $|U| = (1.00116)\mu_B B$, so

$$B = \left|\frac{U}{(1.00116)\mu_B}\right| = \frac{1.7 \times 10^{-22}\ \text{J}}{9.28 \times 10^{-24}\ \text{J/T}} = 18\ \text{T}$$

EVALUATE: This result tells us that the effective magnetic field experienced by an atomic electron is *very* strong. To produce a steady field of this magnitude in the laboratory requires state-of-the-art electromagnets.

Combining Orbital and Spin Angular Momenta

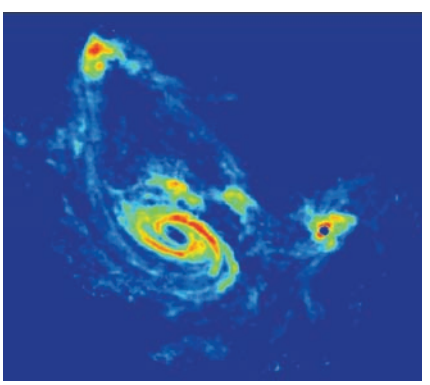
The orbital and spin angular momenta ($\vec{L}$ and $\vec{S}$, respectively) can combine in various ways. We define the total angular momentum $\vec{J}$ as

$$\vec{J} = \vec{L} + \vec{S} \tag{41.23}$$

The possible values of the magnitude J are given in terms of a quantum number j by

$$J = \sqrt{j(j+1)}\,\hbar \tag{41.24}$$

We can then have states in which $j = |l \pm \frac{1}{2}|$. The $l + \frac{1}{2}$ states correspond to the case in which the vectors $\vec{L}$ and $\vec{S}$ have parallel z-components, while for the $l - \frac{1}{2}$ states, $\vec{L}$ and $\vec{S}$ have antiparallel z-components. For example, when $l = 1$, j can be $\frac{1}{2}$ or $\frac{3}{2}$. In another spectroscopic notation these p states are labelled ${}^2P_{1/2}$ and ${}^2P_{3/2}$, respectively. The superscript is the number of possible spin orientations, the letter P (now capitalised) indicates states with $l = 1$, and the subscript is the value of j. We used this scheme to label the energy levels of the sodium atom in Fig. 38.10a.



The various line splittings resulting from magnetic interactions are collectively called *fine structure*. There are also additional, much smaller splittings associated with the fact that the *nucleus* of the atom has a magnetic dipole moment that interacts with the orbital and/or spin magnetic dipole moments of the electrons. These effects are called *hyperfine structure*. For example, the ground level of hydrogen is split into two states, separated by only 5.9×10^{-6} eV. The photon that is emitted in the transitions between these states has a wavelength of 21 cm. Radio astronomers use this wavelength to map clouds of interstellar hydrogen gas that are too cold to emit visible light (Fig. 41.15).

41.15 In a visible-light image (top), these three distant galaxies appear to be unrelated. But in fact these galaxies are connected by immense streamers of hydrogen gas, as shown by the false-colour image (bottom) made with a radio telescope tuned to the 21 cm wavelength emitted by hydrogen atoms.

Galaxies in visible light (negative image; galaxies appear dark)

Radio image at wavelength 21 cm

Test Your Understanding of Section 41.3 In which of the following situations is the magnetic moment of an electron perfectly aligned with a magnetic field that points in the positive z-direction? (i) $m_s = +\frac{1}{2}$; (ii) $m_s = -\frac{1}{2}$; (iii) both (i) and (ii); (iv) neither (i) nor (ii).

41.4 Many-Electron Atoms and the Exclusion Principle

So far, our analysis of atomic structure has concentrated on the hydrogen atom. That's natural; neutral hydrogen, with only one electron, is the simplest atom. If we can't understand hydrogen, we certainly can't understand anything more complex. But now let's move to many-electron atoms.

In general, an atom in its normal (electrically neutral) state has Z electrons and Z protons. Recall from Section 41.1 that we call Z the *atomic number*. The total electric charge of such an atom is exactly zero because the neutron has no charge while the proton and electron charges have the same magnitude but opposite sign.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

We can apply the Schrödinger equation to this general atom. However, the complexity of the analysis increases very rapidly with increasing Z. Each of the Z electrons interacts not only with the nucleus but also with every other electron. The wave functions and the potential energy are functions of $3Z$ coordinates, and the equation contains second derivatives with respect to all of them. The mathematical problem of finding solutions of such equations is so complex that it has not been solved exactly even for the neutral helium atom, which has only two electrons.

Fortunately, various approximation schemes are available. The simplest approximation is to ignore all interactions between electrons and consider each electron as moving under the action only of the nucleus (considered to be a point charge). In this approximation the wave function for each electron is a function like those for the hydrogen atom, specified by four quantum numbers (n, l, m_l, m_s); the nuclear charge is Ze instead of e. This requires replacement of every factor of e^2 in the wave functions and the energy levels by Ze^2. In particular, the energy levels are given by Eq. (41.3) with e^4 replaced by Z^2e^4:

$$E_n = -\frac{1}{(4\pi\epsilon_0)^2}\frac{m_r Z^2 e^4}{2n^2\hbar^2} = -\frac{Z^2}{n^2}(13.6\text{ eV}) \tag{41.25}$$

This approximation is fairly drastic; when there are many electrons, their interactions with each other are as important as the interaction of each with the nucleus. So this model isn't very useful for quantitative predictions.

The Central-Field Approximation

A less drastic and more useful approximation is to think of all the electrons together as making up a charge cloud that is, on average, *spherically symmetric*. We can then think of each individual electron as moving in the total electric field due to the nucleus and this averaged-out cloud of all the other electrons. There is a corresponding spherically symmetric potential-energy function $U(r)$. This picture is called the **central-field approximation**; it provides a useful starting point for the understanding of atomic structure. If you are disappointed that we have to make approximations at such an early stage in our discussion, keep in mind that we are dealing with problems that initially defied all attempts at analysis, with or without approximations.

In the central-field approximation we can again deal with one-electron wave functions. The Schrödinger equation differs from the equation for hydrogen only in that the $1/r$ potential-energy function is replaced by a different function $U(r)$. But it turns out that $U(r)$ does not enter the differential equations for $\Theta(\theta)$ and $\Phi(\phi)$, so those angular functions are exactly the same as for hydrogen, and the orbital angular-momentum *states* are also the same as before. The quantum numbers l, m_l and m_s have the same meaning as before, and the magnitude and z-component of the orbital angular momentum are again given by Eqs. (41.4) and (41.5).

The radial wave functions and probabilities are different than for hydrogen because of the change in $U(r)$, so the energy levels are no longer given by Eq. (41.3). We can still label a state using the four quantum numbers (n, l, m_l, m_s). In general, the energy of a state now depends on both n and l, rather than just on n as with hydrogen. The restrictions on values of the quantum numbers are the same as before:

$$n \geq 1 \qquad 0 \leq l \leq n-1 \qquad |m_l| \leq l \qquad m_s = \pm\frac{1}{2} \qquad \text{(allowed values of quantum numbers)} \tag{41.26}$$

The Exclusion Principle

To understand the structure of many-electron atoms, we need an additional principle, the *exclusion principle*. To see why this principle is needed, let's consider the lowest-energy state or *ground state* of a many-electron atom. In the

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

one-electron states of the central-field model, there is a lowest-energy state (corresponding to an $n = 1$ state of hydrogen). We might expect that in the ground state of a complex atom, *all* the electrons should be in this lowest state. If so, then we should see only gradual changes in physical and chemical properties when we look at the behaviour of atoms with increasing numbers of electrons (Z).

Such gradual changes are *not* what is observed. Instead, properties of elements vary widely from one to the next, with each element having its own distinct personality. For example, the elements fluorine, neon and sodium have 9, 10 and 11 electrons, respectively, per atom. Fluorine $(Z = 9)$ is a *halogen*; it tends strongly to form compounds in which each fluorine atom acquires an extra electron. Sodium $(Z = 11)$ is an *alkali metal*; it forms compounds in which each sodium atom *loses* an electron. Neon $(Z = 10)$ is a *noble gas*, forming no compounds at all. Such observations show that in the ground state of a complex atom the electrons *cannot* all be in the lowest-energy states. But why not?

41.16 The key to understanding the periodic table of the elements was the discovery by Wolfgang Pauli (1900–1958) of the exclusion principle. Pauli received the 1945 Nobel Prize in physics for his accomplishment. This photo shows Pauli (on the left) and Niels Bohr watching the physics of a toy top spinning on the floor.

The key to this puzzle, discovered by the Austrian physicist Wolfgang Pauli (Fig. 41.16) in 1925, is called the **exclusion principle**. This principle states that **no two electrons can occupy the same quantum-mechanical state** in a given system. That is, **no two electrons in an atom can have the same values of all four quantum numbers (n, l, m_l, m_s).** Each quantum state corresponds to a certain distribution of the electron 'cloud' in space. Therefore the principle also says, in effect, that no more than two electrons with opposite values of the quantum number m_s can occupy the same region of space. We shouldn't take this last statement too seriously because the electron probability functions don't have sharp, definite boundaries. But the exclusion principle limits the amount that electron wave functions can overlap. Think of it as the quantum-mechanical analog of a university rule that allows only one student per desk.

CAUTION **The meaning of the exclusion principle** Don't confuse the exclusion principle with the electric repulsion between electrons. While both effects tend to keep electrons within an atom separated from each other, they are very different in character. Two electrons can always be pushed closer together by adding energy to combat electric repulsion; in contrast, *nothing* can overcome the exclusion principle and force two electrons into the same quantum-mechanical state.

Table 41.2 lists some of the sets of quantum numbers for electron states in an atom. It's similar to Table 41.1 (Section 41.1), but we've added the number of states in each subshell and shell. Because of the exclusion principle, the 'number of states' is the same as the *maximum* number of electrons that can be found in those states. For each state, m_s can be either $+\frac{1}{2}$ or $-\frac{1}{2}$.

As with the hydrogen wave functions, different states correspond to different spatial distributions; electrons with larger values of n are concentrated at larger distances from the nucleus. Figure 41.4 (Section 41.1) shows this effect. When an atom has more than two electrons, they can't all huddle down in the low-energy $n = 1$ states nearest to the nucleus because there are only two of these states; the exclusion principle forbids multiple occupancy of a state. Some electrons are

Table 41.2 Quantum States of Electrons in the First Four Shells

n	l	m_l	Spectroscopic Notation	Number of States		Shell
1	0	0	$1s$	2		K
2	0	0	$2s$	2	8	L
2	1	−1, 0, 1	$2p$	6		
3	0	0	$3s$	2		
3	1	−1, 0, 1	$3p$	6	18	M
3	2	−2, −1, 0, 1, 2	$3d$	10		
4	0	0	$4s$	2		
4	1	−1, 0, 1	$4p$	6		
4	2	−2, −1, 0, 1, 2	$4d$	10	32	N
4	3	−3, −2, −1, 0, 1, 2, 3	$4f$	14

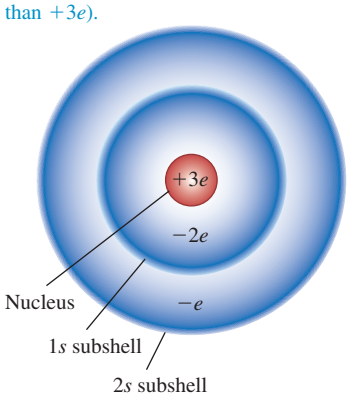
forced into states farther away, with higher energies. Each value of n corresponds roughly to a region of space around the nucleus in the form of a spherical *shell*. Hence we speak of the K shell as the region that is occupied by the electrons in the $n = 1$ states, the L shell as the region of the $n = 2$ states, and so on. States with the same n but different l form *subshells*, such as the $3p$ subshell.

The Periodic Table

We can use the exclusion principle to derive the most important features of the structure and chemical behaviour of multielectron atoms, including the periodic table of the elements. Let's imagine constructing a neutral atom by starting with a bare nucleus with Z protons and then adding Z electrons, one by one. To obtain the ground state of the atom as a whole, we fill the lowest-energy electron states (those closest to the nucleus, with the smallest values of n and l) first, and we use successively higher states until all the electrons are in place. The chemical properties of an atom are determined principally by interactions involving the outermost, or *valence*, electrons, so we particularly want to learn how these electrons are arranged.

Let's look at the ground-state electron configurations for the first few atoms (in order of increasing Z). For hydrogen the ground state is $1s$; the single electron is in a state $n = 1$, $l = 0$, $m_l = 0$, and $m_s = \pm\frac{1}{2}$. In the helium atom $(Z = 2)$, *both* electrons are in $1s$ states, with opposite spins; one has $m_s = -\frac{1}{2}$ and the other has $m_s = +\frac{1}{2}$. We denote the helium ground state as $1s^2$. (The superscript 2 is not an exponent; the notation $1s^2$ tells us that there are two electrons in the $1s$ subshell. Also, the superscript 1 is understood, as in $2s$.) For helium the K shell is completely filled, and all others are empty. Helium is a noble gas; it has no tendency to gain or lose an electron, and it forms no compounds.

Lithium $(Z = 3)$ has three electrons. In its ground state, two are in $1s$ states and one is in a $2s$ state, so we denote the lithium ground state as $1s^2 2s$. On average, the $2s$ electron is considerably farther from the nucleus than are the $1s$ electrons (Fig. 41.17). According to Gauss's law, the *net* charge Q_{encl} attracting the $2s$ electron is nearer to $+e$ than to the value $+3e$ it would have without the two $1s$ electrons present. As a result, the $2s$ electron is loosely bound; only 5.4 eV is required to remove it, compared with the 30.6 eV given by Eq. (41.25) with $Z = 3$ and $n = 2$. In chemical behaviour, lithium is an *alkali metal*. It forms ionic compounds in which each lithium atom loses an electron and has a valence of $+1$.



Next is beryllium $(Z = 4)$; its ground-state configuration is $1s^2 2s^2$, with its two valence electrons filling the s subshell of the L shell. Beryllium is the first of the *alkaline earth* elements, forming ionic compounds in which the valence of the atoms is $+2$.

Table 41.3 shows the ground-state electron configurations of the first 30 elements. The L shell can hold eight electrons. At $Z = 10$, both the K and L shells are filled, and there are no electrons in the M shell. We expect this to be a particularly stable configuration, with little tendency to gain or lose electrons. This element is neon, a noble gas with no known compounds. The next element after neon is sodium $(Z = 11)$, with filled K and L shells and one electron in the M shell. Its 'noble-gas-plus-one-electron' structure resembles that of lithium; both are alkali metals. The element *before* neon is fluorine, with $Z = 9$. It has a vacancy in the L shell and has an affinity for an extra electron to fill the shell. Fluorine forms ionic compounds in which it has a valence of -1. This behaviour is characteristic of the *halogens* (fluorine, chlorine, bromine, iodine and astatine), all of which have 'noble-gas-minus-one' configurations (Fig. 41.18).

Proceeding down the list, we can understand the regularities in chemical behaviour displayed by the **periodic table of the elements** (Appendix D) on the basis of electron configurations. The similarity of elements in each *group* (vertical column) of the periodic table is the result of similarity in outer-electron configuration. All the noble gases (helium, neon, argon, krypton, xenon and radon) have filled-shell or filled-shell plus filled p subshell configurations. All the alkali metals (lithium, sodium, potassium, rubidium, cesium and francium) have

41.17 Schematic representation of the charge distribution in a lithium atom. The nucleus has a charge of $+3e$.

On average, the $2s$ electron is considerably farther from the nucleus than the $1s$ electrons. Therefore, it experiences a net nuclear charge of approximately $+3e - 2e = +e$ (rather than $+3e$).

41.18 Salt (sodium chloride, NaCl) dissolves readily in water, making seawater salty, thanks to the electron configurations of sodium and chlorine. Sodium can easily lose an electron to form an Na^+ ion, and chlorine can easily gain an electron to form a Cl^- ion. These ions are held in solution because they are attracted to the polar ends of water molecules (see Fig. 21.31a).

Table 41.3 Ground-State Electron Configurations

Element	Symbol	Atomic Number (Z)	Electron Configuration
Hydrogen	H	1	$1s$
Helium	He	2	$1s^2$
Lithium	Li	3	$1s^2 2s$
Beryllium	Be	4	$1s^2 2s^2$
Boron	B	5	$1s^2 2s^2 2p$
Carbon	C	6	$1s^2 2s^2 2p^2$
Nitrogen	N	7	$1s^2 2s^2 2p^3$
Oxygen	O	8	$1s^2 2s^2 2p^4$
Fluorine	F	9	$1s^2 2s^2 2p^5$
Neon	Ne	10	$1s^2 2s^2 2p^6$
Sodium	Na	11	$1s^2 2s^2 2p^6 3s$
Magnesium	Mg	12	$1s^2 2s^2 2p^6 3s^2$
Aluminium	Al	13	$1s^2 2s^2 2p^6 3s^2 3p$
Silicon	Si	14	$1s^2 2s^2 2p^6 3s^2 3p^2$
Phosphorus	P	15	$1s^2 2s^2 2p^6 3s^2 3p^3$
Sulphur	S	16	$1s^2 2s^2 2p^6 3s^2 3p^4$
Chlorine	Cl	17	$1s^2 2s^2 2p^6 3s^2 3p^5$
Argon	Ar	18	$1s^2 2s^2 2p^6 3s^2 3p^6$
Potassium	K	19	$1s^2 2s^2 2p^6 3s^2 3p^6 4s$
Calcium	Ca	20	$1s^2 2s^2 2p^6 3s^2 3p^6 4s^2$
Scandium	Sc	21	$1s^2 2s^2 2p^6 3s^2 3p^6 4s^2 3d$
Titanium	Ti	22	$1s^2 2s^2 2p^6 3s^2 3p^6 4s^2 3d^2$
Vanadium	V	23	$1s^2 2s^2 2p^6 3s^2 3p^6 4s^2 3d^3$
Chromium	Cr	24	$1s^2 2s^2 2p^6 3s^2 3p^6 4s 3d^5$
Manganese	Mn	25	$1s^2 2s^2 2p^6 3s^2 3p^6 4s^2 3d^5$
Iron	Fe	26	$1s^2 2s^2 2p^6 3s^2 3p^6 4s^2 3d^6$
Cobalt	Co	27	$1s^2 2s^2 2p^6 3s^2 3p^6 4s^2 3d^7$
Nickel	Ni	28	$1s^2 2s^2 2p^6 3s^2 3p^6 4s^2 3d^8$
Copper	Cu	29	$1s^2 2s^2 2p^6 3s^2 3p^6 4s 3d^{10}$
Zinc	Zn	30	$1s^2 2s^2 2p^6 3s^2 3p^6 4s^2 3d^{10}$

'noble-gas-plus-one' configurations. All the alkaline earth metals (beryllium, magnesium, calcium, strontium, barium and radium) have 'noble-gas-plus-two' configurations, and all the halogens (fluorine, chlorine, bromine, iodine and astatine) have 'noble-gas-minus-one' structures.

A slight complication occurs with the M and N shells because the $3d$ and $4s$ subshell levels ($n = 3$, $l = 2$, and $n = 4$, $l = 0$, respectively) have similar energies. (We'll discuss in the next subsection why this happens.) Argon $(Z = 18)$ has all the $1s$, $2s$, $2p$, $3s$ and $3p$ subshells filled, but in potassium $(Z = 19)$ the additional electron goes into a $4s$ energy state rather than a $3d$ state (because the $4s$ state has slightly lower energy).

The next several elements have one or two electrons in the $4s$ subshell and increasing numbers in the $3d$ subshell. These elements are all metals with rather similar chemical and physical properties; they form the first *transition series*, starting with scandium $(Z = 21)$ and ending with zinc $(Z = 30)$, for which all the $3d$ and $4s$ subshells are filled.

Something similar happens with $Z = 57$ through $Z = 71$, which have one or two electrons in the $6s$ subshell but only partially filled $4f$ and $5d$ subshells. These are the *rare earth* elements; they all have very similar physical and chemical properties. Yet another such series, called the *actinide* series, starts with $Z = 91$.

Screening

We have mentioned that in the central-field picture, the energy levels depend on l as well as n. Let's take sodium $(Z = 11)$ as an example. If 10 of its electrons fill its K and L shells, the energies of some of the states for the remaining electron are found experimentally to be

$3s$ states: -5.138 eV
$3p$ states: -3.035 eV
$3d$ states: -1.521 eV
$4s$ states: -1.947 eV

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

The 3*s* states are the lowest (most negative); one is the ground state for the 11th electron in sodium. The energy of the 3*d* states is quite close to the energy of the $n = 3$ state in hydrogen. The surprise is that the 4*s* state energy is 0.426 eV *below* the 3*d* state, even though the 4*s* state has larger *n*.

We can understand these results using Gauss's law and the radial probability distribution. For any spherically symmetric charge distribution, the electric-field magnitude at a distance *r* from the centre is $Q_{\text{encl}}/4\pi\epsilon_0 r^2$, where Q_{encl} is the total charge enclosed within a sphere with radius *r*. Mentally remove the outer (valence) electron atom from a sodium atom. What you have left is a spherically symmetric collection of 10 electrons (filling the *K* and *L* shells) and 11 protons, so $Q_{\text{encl}} = -10e + 11e = +e$. If the 11th electron is completely outside this collection of charges, it is attracted by an effective charge of $+e$, not $+11e$. This is a more extreme example of the effect depicted in Fig. 41.17.

This effect is called **screening**; the 10 electrons *screen* 10 of the 11 protons, leaving an effective net charge of $+e$. In general, an electron that spends all its time completely outside a positive charge $Z_{\text{eff}}e$ has energy levels given by the hydrogen expression with e^2 replaced by $Z_{\text{eff}}e^2$. From Eq. (41.25) this is

$$E_n = -\frac{Z_{\text{eff}}^2}{n^2}(13.6\text{ eV}) \qquad \text{(energy levels with screening)} \qquad (41.27)$$

If the 11th electron in the sodium atom is completely outside the remaining charge distribution, then $Z_{\text{eff}} = 1$.

CAUTION **Different equations for different atoms** Equations (41.3), (41.25) and (41.27) all give values of E_n in terms of $(13.6\text{ eV})/n^2$, but they don't apply in general to the same atoms. Equation (41.3) is *only* for hydrogen. Equation (41.25) is only for the case in which there is no interaction with any other electron (and is thus accurate only when the atom has just one electron). Equation (41.27) is useful when one electron is screened from the nucleus by other electrons.

Now let's use the radial probability functions shown in Fig. 41.4 to explain why the energy of a sodium 3*d* state is approximately the same as the $n = 3$ value of hydrogen, −1.51 eV. The distribution for the 3*d* state (for which *l* has the maximum value $n - 1$) has one peak, and its most probable radius is *outside* the positions of the electrons with $n = 1$ or 2. (Those electrons also are pulled closer to the nucleus than in hydrogen because they are less effectively screened from the positive charge $11e$ of the nucleus.) Thus in sodium a 3*d* electron spends most of its time well outside the $n = 1$ and $n = 2$ states (the *K* and *L* shells). The 10 electrons in these shells screen almost all but one of the 11 protons, leaving a net charge of about $Z_{\text{eff}}e = (1)e$. Then, from Eq. (41.27), the corresponding energy is approximately $-(1)^2(13.6\text{ eV})/3^2 = -1.51$ eV. This approximation is very close to the experimental value of −1.521 eV.

Looking again at Fig. (41.4), we see that the radial probability density for the 3*p* state (for which $l = n - 2$) has two peaks and that for the 3*s* state $(l = n - 3)$ has three peaks. For sodium the first small peak in the 3*p* distribution gives a 3*p* electron a higher probability (compared to the 3*d* state) of being *inside* the charge distributions for the electrons in the $n = 2$ states. That is, a 3*p* electron is less completely screened from the nucleus than is a 3*d* electron because it spends some of its time within the filled *K* and *L* shells. Thus for the 3*p* electrons, Z_{eff} is greater than unity. From Eq. (41.27) the 3*p* energy is lower (more negative) than the 3*d* energy of −1.521 eV. The actual value is −3.035 eV. A 3*s* electron spends even more time within the inner electron shells than a 3*p* electron does, giving an even larger Z_{eff} and an even more negative energy.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

Example 41.7 Determining Z_{eff} experimentally

The measured energy of a $3s$ state of sodium is -5.138 eV. Calculate the value of Z_{eff}.

SOLUTION

IDENTIFY: Sodium has a single electron in the M shell outside filled K and L shells. The K and L electrons partially screen the single M electron from the charge of the nucleus; our goal is to determine the extent of this screening.

SET UP: For this state we are given $n = 3$ and $E_n = -5.138$ eV, so we can use Eq. (41.27) to determine Z_{eff}.

EXECUTE: Solving Eq. (41.27) for Z_{eff}, we have

$$Z_{\text{eff}}^2 = -\frac{n^2 E_n}{13.6\text{ eV}} = -\frac{3^2(-5.138\text{ eV})}{13.6\text{ eV}} = 3.40$$

$$Z_{\text{eff}} = 1.84$$

EVALUATE: The effective charge attracting a $3s$ electron is $1.84e$. Sodium's 11 protons are screened by an average of $11 - 1.84 = 9.16$ electrons instead of 10 electrons because of the penetration of the inner $(K$ and $L)$ shells by the $3s$ electron.

Each alkali metal (lithium, sodium, potassium, rubidium and cesium) has one more electron than the corresponding noble gas (helium, neon, argon, krypton and xenon). This extra electron is mostly outside the other electrons in the filled shells and subshells. Therefore all the alkali metals behave similarly to sodium.

Example 41.8 Energies for a valence electron

The valence electron in potassium has a $4s$ ground state. Calculate the approximate energy of the state having the smallest Z_{eff}, and discuss the relative energies of the $4s$, $4p$, $4d$ and $4f$ states.

SOLUTION

IDENTIFY: The state with the smallest Z_{eff} is the one that spends the most time outside the inner filled shells and subshells, so that it is most effectively screened from the charge of the nucleus.

SET UP: Once we have determined which state has the smallest Z_{eff}, we can use Eq. (41.27) to determine the energy of this state.

EXECUTE: A $4f$ state has $n = 4$ and $l = 3 = 4 - 1$. Thus it is the state of largest orbital angular momentum for $n = 4$, and thus the state in which the electron spends the most time outside the electron charge clouds of the inner filled shells and subshells. This makes Z_{eff} for a $4f$ state close to unity. Equation (41.27) then gives

$$E_4 = -\frac{Z_{\text{eff}}^2}{n^2}(13.6\text{ eV}) = -\frac{1^2}{4^2}(13.6\text{ eV}) = -0.85\text{ eV}$$

This approximation agrees with the measured energy to the precision given.

An electron in a $4d$ state spends a bit more time within the inner shells, and its energy is therefore a bit more negative (measured to be -0.94 eV). For the same reason, a $4p$ state has an even lower energy (measured to be -2.73 eV), and a $4s$ state has the lowest energy (measured to be -4.339 eV).

EVALUATE: We can extend this analysis to the singly ionised alkaline earth elements: Be^+, Mg^+, Ca^+, Sr^+ and Ba^+. For any allowed value of n, the highest-l state $(l = n - 1)$ of the one remaining outer electron sees an effective charge of almost $+2e$, so for these states, $Z_{\text{eff}} = 2$. A $3d$ state for Mg^+, for example, has an energy of about $-2^2(13.6\text{ eV})/3^2 = -6.0$ eV.

Test Your Understanding of Section 41.4 If electrons did *not* obey the exclusion principle, would it be easier or more difficult to remove the first electron from sodium?

41.5 X-ray Spectra

X-ray spectra provide yet another example of the richness and power of the Schrödinger equation and of the model of atomic structure that we derived from it in the preceding section. In Section 38.7 we discussed x-ray production on the basis of the photon concept. With the development of x-ray diffraction techniques (see Section 36.6) by von Laue, Bragg and others, beginning in 1912, it became possible to measure x-ray wavelengths quite precisely (to within 0.1% or less).

Detailed studies of x-ray spectra showed a continuous spectrum of wavelengths (Fig. 41.19, next page), with *minimum* wavelength (corresponding to *maximum* frequency and photon energy) determined by the accelerating voltage

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

V_{AC} in the x-ray tube, according to the relationship derived in Section 38.7 for *bremsstrahlung* processes:

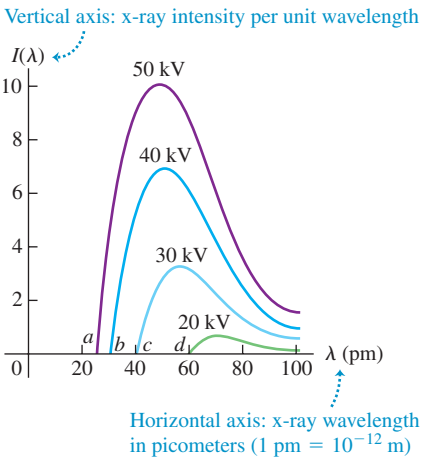
$$\lambda_{\text{min}} = \frac{hc}{eV_{AC}} \tag{41.28}$$

This continuous-spectrum radiation is nearly independent of the target material in the x-ray tube.

Moseley's Law and Atomic Energy Levels

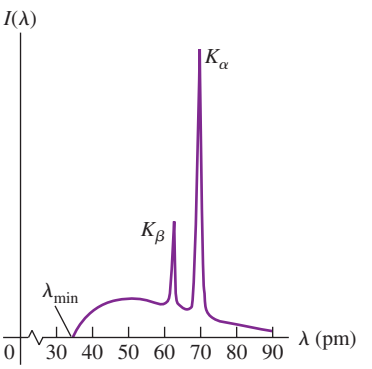
Depending on the accelerating voltage and the target element, we may find sharp peaks superimposed on this continuous spectrum, as in Fig. 41.20. These peaks are at different wavelengths for different elements; they form what is called a *characteristic x-ray spectrum* for each target element. In 1913 the British scientist H. G. J. Moseley studied these spectra in detail using x-ray diffraction techniques. He found that the most intense short-wavelength line in the characteristic x-ray spectrum from a particular target element, called the K_α line, varied smoothly with that element's atomic number Z (Fig. 41.21). This is in sharp contrast to optical spectra, in which elements with adjacent Z-values have spectra that often bear no resemblance to each other.

Moseley found that the relationship could be expressed in terms of x-ray frequencies f by a simple formula called *Moseley's law*:

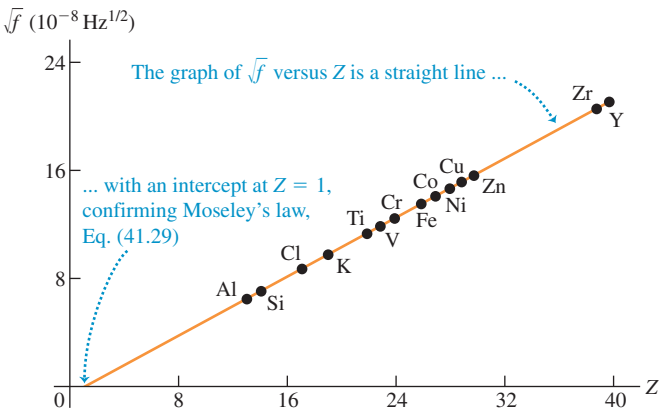


$$f = (2.48 \times 10^{15}\ \text{Hz})(Z - 1)^2 \qquad \text{(Moseley's law)} \tag{41.29}$$

Moseley's discovery of this formula is comparable to Balmer's discovery of the empirical formula, Eq. (38.8), for the wavelengths in the spectrum of hydrogen.



But Moseley went far beyond this empirical relationship; he showed how characteristic x-ray spectra could be understood on the basis of energy levels of atoms in the target. His analysis was based on the Bohr model, published in the same year. We will recast it somewhat, using the ideas of atomic structure discussed in Section 41.4. First recall that the *outer* electrons of an atom are responsible for optical spectra. Their excited states are usually only a few electron volts above their ground state. In transitions from excited states to the ground state, they usually emit photons in or near the visible region.



Characteristic x-rays, by contrast, are emitted in transitions involving the *inner* shells of a complex atom. We mentioned these briefly in Section 38.7. In an x-ray tube the electrons may strike the target with enough energy to knock electrons out of the inner shells of the target atoms. These inner electrons are much closer to the nucleus than are the electrons in the outer shells; they are much more tightly bound, and hundreds or thousands of electron volts may be required to remove them.

41.19 These graphs show the continuous spectrum of x-rays produced by a tungsten target when it is struck by electrons that were accelerated by a voltage V_{AC}. The four curves are for different values of V_{AC}; points a, b, c and d show the minimum wavelength for each voltage.

41.20 Graph of intensity per unit wavelength as a function of wavelength for x-rays produced with an accelerating voltage of 35 kV and a molybdenum target. The curve is a smooth function similar to Fig. 41.19, but with two sharp spikes corresponding to part of the characteristic x-ray spectrum for molybdenum.

41.21 The square root of Moseley's measured frequencies of the K_α line for 14 elements.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

Suppose one electron is knocked out of the K shell. This process leaves a vacancy, which we'll call a *hole*. (One electron remains in the K shell.) The hole can then be filled by an electron falling in from one of the outer shells, such as the L, M, N, . . . shell. This transition is accompanied by a decrease in the energy of the atom (because *less* energy would be needed to remove an electron from an L, M, N, . . . shell), and an x-ray photon is emitted with energy equal to this decrease. Each state has definite energy, so the emitted x-rays have definite wavelengths; the emitted spectrum is a *line* spectrum.

We can estimate the energy and frequency of K_α x-ray photons using the concept of *screening*. A K_α x-ray photon is emitted when an electron in the L shell $(n = 2)$ drops down to fill a hole in the K shell $(n = 1)$. As the electron drops down, it is attracted by the Z protons in the nucleus screened by the one remaining electron in the K shell. We therefore approximate the energy by Eq. (41.27), with $Z_{\text{eff}} = Z - 1$, $n_{\text{i}} = 2$, and $n_{\text{f}} = 1$. The energy before the transition is

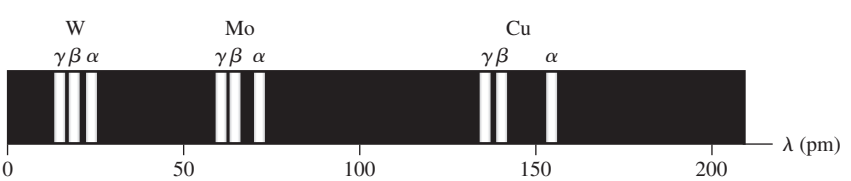
$$E_{\text{i}} \approx -\frac{(Z-1)^2}{2^2}(13.6\text{ eV}) = -(Z-1)^2(3.4\text{ eV})$$

and the energy after the transition is

$$E_{\text{f}} \approx -\frac{(Z-1)^2}{1^2}(13.6\text{ eV}) = -(Z-1)^2(13.6\text{ eV})$$

The energy of the K_α x-ray photon is $E_{K\alpha} = E_{\text{i}} - E_{\text{f}} \approx (Z-1)^2(-3.4\text{ eV} + 13.6\text{ eV})$.That is,

$$E_{K\alpha} \approx (Z-1)^2(10.2\text{ eV}) \tag{41.30}$$



The frequency of any photon is its energy divided by Planck's constant:

$$f = \frac{E}{h} \approx \frac{(Z-1)^2(10.2\text{ eV})}{4.136 \times 10^{-15}\text{ eV}\cdot\text{s}} = (2.47 \times 10^{15}\text{ Hz})(Z-1)^2$$

This relationship agrees almost exactly with Moseley's experimental law, Eq. (41.29). Indeed, considering the approximations we have made, the agreement is better than we have a right to expect. But our calculation does show how Moseley's law can be understood on the bases of screening and transitions between energy levels.

The hole in the K shell may also be filled by an electron falling from the M or N shell, assuming that these are occupied. If so, the x-ray spectrum of a large group of atoms of a single element shows a series, named the K series, of three lines, called the K_α, K_β, and K_γ lines. These three lines result from transitions in which the K-shell hole is filled by an L, M, or N electron, respectively. Figure 41.22 shows the K series for tungsten $(Z = 74)$, molybdenum $(Z = 42)$, and copper $(Z = 29)$.

There are other series of x-ray lines, called the L, M and N series that are produced after the ejection of electrons from the L, M and N shells rather than the K shell. Electrons in these outer shells are farther away from the nucleus and are not held as tightly as are those in the K shell. Their removal requires less energy, and the x-ray photons that are emitted when these vacancies are filled have lower energy than those in the K series.

41.22 Wavelengths of the K_α, K_β and K_γ lines of tungsten (W), molybdenum (Mo) and copper (Cu).

The three lines in each series are called the K_α, K_β and K_γ lines. The K_α line is produced by the transition of an L electron to the vacancy in the K shell, the K_β line by an M electron and the K_γ line by an N electron.

Example 41.9 Chemical analysis by x-ray emission

You measure the K_α wavelength for an unknown element, obtaining the value 0.0709 nm. What is the element?

SOLUTION

IDENTIFY: To determine which element this is, we need to know its atomic number Z. We can do this using Moseley's law, which relates the frequency of an element's K_α x-ray emission line to that element's atomic number Z.

SET UP: We use the relationship $f = c/\lambda$ to calculate the frequency for the K_α line, and then use Eq. (41.29) to find the corresponding value of the atomic number Z. We then consult the periodic table (Appendix D) to determine which element has this atomic number.

EXECUTE: The frequency is

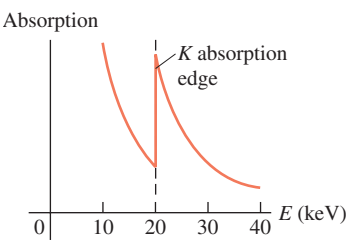
$$f = \frac{c}{\lambda} = \frac{3.00 \times 10^8 \text{ m/s}}{0.0709 \times 10^{-9} \text{ m}} = 4.23 \times 10^{18} \text{ Hz}$$

Solving Moseley's law for Z,

$$Z = 1 + \sqrt{\frac{f}{2.48 \times 10^{15} \text{ Hz}}} = 1 + \sqrt{\frac{4.23 \times 10^{18} \text{ Hz}}{2.48 \times 10^{15} \text{ Hz}}} = 42.3$$

We know that Z has to be an integer; we conclude that $Z = 42$, corresponding to the element molybdenum.

EVALUATE: If you're worried that our calculation did not give an integer for Z, remember that Moseley's law is an empirical relationship. There are slight variations from one atom to another due to differences in the structure of the electron shells. Nonetheless, this example suggests the power of Moseley's law.



Niels Bohr commented that it was Moseley's observations, not the alpha-particle scattering experiments of Rutherford, Geiger and Marsden (see Section 38.4), that truly convinced physicists that the atom consists of a positive nucleus surrounded by electrons in motion. Unlike Bohr or Rutherford, Moseley did not receive a Nobel Prize for his important work; these awards are given only to living scientists, and Moseley was killed in combat during the First World War.

X-ray Absorption Spectra

We can also observe x-ray *absorption* spectra. Unlike optical spectra, the absorption wavelengths are usually not the same as those for emission, especially in many-electron atoms, and do not give simple line spectra. For example, the K_α emission line results from a transition from the L shell to a hole in the K shell. The reverse transition doesn't occur in atoms with $Z \geq 10$ because in the atom's ground state, there is no vacancy in the L shell. To be absorbed, a photon must have enough energy to move an electron to an empty state. Since empty states are only a few electron volts in energy below the free-electron continuum, the minimum absorption energies in many-electron atoms are about the same as the minimum energies that are needed to remove an electron from its shell. Experimentally, if we gradually increase the accelerating voltage and hence the maximum photon energy, we observe sudden increases in absorption when we reach these minimum energies. These sudden jumps of absorption are called *absorption edges* (Fig. 41.23).

Characteristic x-ray spectra provide a very useful analytical tool. Satellite-borne x-ray spectrometers are used to study x-ray emission lines from highly excited atoms in distant astronomical sources. X-ray spectra are also used in air-pollution monitoring and in studies of the abundance of various elements in rocks.

41.23 When a beam of x-rays is passed through a slab of molybdenum, the extent to which the beam is absorbed depends on the energy E of the x-ray photons. A sharp increase in absorption occurs at the K absorption edge at 20 keV. Photons with energies above this value can excite an electron from the K shell into an empty state.

Test Your Understanding of Section 41.5 A beam of photons is passed through a sample of high-temperature atomic hydrogen. At what photon energy would you expect there to be an absorption edge like that shown in Fig. 41.23? (i) 13.60 eV; (ii) 3.40 eV; (iii) 1.51 eV; (iv) all of these; (v) none of these.

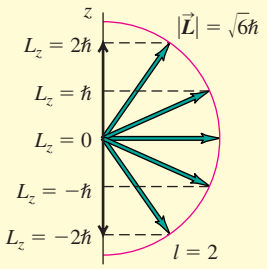
CHAPTER 41 SUMMARY

The hydrogen atom: The Schrödinger equation for the hydrogen atom gives the same energy levels as the Bohr model. If the nucleus has charge Ze, there is an additional factor of Z^2 in the numerator of Eq. (41.3). The possible magnitudes L of orbital angular momentum are given by Eq. (41.4), and the possible values of the z-component of orbital angular momentum are given by Eq. (41.5) (See Examples 41.1 and 41.2.)

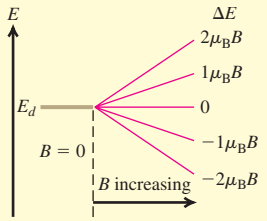
The probability that an atomic electron is between r and $r + dr$ from the nucleus is $P(r)\,dr$, given by Eq. (41.7). Atomic distances are often measured in units of a, the smallest distance between the electron and the nucleus in the Bohr model. (See Example 41.3.)



$$E_n = -\frac{1}{(4\pi\epsilon_0)^2}\frac{m_r e^4}{2n^2\hbar^2} = -\frac{13.60\text{ eV}}{n^2}$$
(energy levels of hydrogen) (41.3)

$$L = \sqrt{l(l+1)}\,\hbar \quad (l = 0, 1, 2, \ldots, n-1) \tag{41.4}$$

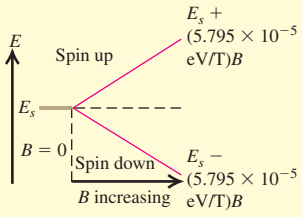
$$L_z = m_l\hbar \quad (m_l = 0, \pm1, \pm2, \ldots, \pm l) \tag{41.5}$$



$$P(r)\,dr = |\psi|^2\,dV = |\psi|^2\,4\pi r^2\,dr \tag{41.7}$$

$$a = \frac{\epsilon_0 h^2}{\pi m_r e^2} = \frac{4\pi\epsilon_0\hbar^2}{m_r e^2} = 5.29\times10^{-11}\text{ m} \tag{41.8}$$

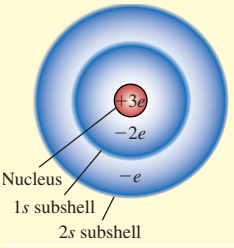
The Zeeman effect: The interaction energy of an electron (mass m) with magnetic quantum number m_l in a magnetic field $\vec{B}$ along the $+z$-direction is given by Eq. (41.17) or (41.18), where $\mu_B = e\hbar/2m$ is called the Bohr magneton. (See Example 41.4.)



$$U = -\mu_z B = m_l\frac{e\hbar}{2m}B = m_l\mu_B B \quad (m_l = 0, \pm1, \pm2, \ldots, \pm l)$$
(41.17), (41.18)

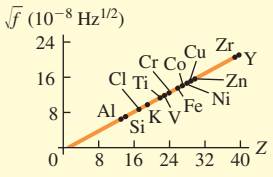
Electron spin: An electron has an intrinsic spin angular momentum of magnitude S, given by Eq. (41.20). The possible values of the z-component of the spin angular momentum are $S_z = m_s\hbar$, where $m_s = \pm\frac{1}{2}$. (See Examples 41.5 and 41.6.)

$$S = \sqrt{\frac{1}{2}\left(\frac{1}{2}+1\right)}\,\hbar = \sqrt{\frac{3}{4}}\,\hbar \tag{41.20}$$



$$S_z = \pm\frac{1}{2}\hbar \tag{41.19}$$

Many-electron atoms: In a hydrogen atom, the quantum numbers n, l, m_l and m_s of the electron have certain allowed values given by Eq. (41.26). In a many-electron atom, the quantum numbers for each electron are the same, but the energy levels depend on both n and l because of screening, the partial cancellation of the field of the nucleus by the inner electrons. If the effective (screened) charge attracting an electron is $Z_{\text{eff}}e$, the energies of the levels are given approximately by Eq. (41.27). (See Examples 41.7 and 41.8.)



$$n \geq 1 \qquad 0 \leq l \leq n-1$$
$$|m_l| \leq l \qquad m_s = \pm\frac{1}{2} \tag{41.26}$$

$$E_n = -\frac{Z_{\text{eff}}^2}{n^2}(13.6\text{ eV}) \tag{41.27}$$

X-ray spectra: Moseley's law states that the frequency of a K_α x-ray from a target with atomic number Z is given by Eq. (41.29). Characteristic x-ray spectra result from transitions to a hole in an inner energy level of an atom. (See Example 41.9.)

$$f = (2.48\times10^{15}\text{ Hz})(Z-1)^2 \tag{41.29}$$

Answer to Chapter Opening Question ?

Neon is inert because it has filled K and L shells, while sodium is very reactive because its 11th electron is loosely bound in an M shell. See Section 41.1 for more details.

Answers to Test Your Understanding Questions

41.1 Answer: (ii) and (iii) (tie), (i) An electron in a state with principal quantum number n is most likely to be found at $r = n^2a$. This is independent of the values of the quantum numbers l and m_l. Hence an electron with $n = 2$ (most likely to be found at $r = 4a$) is more likely to be found near $r = 5a$ than an electron with $n = 1$ (most likely to be found at $r = a$).

41.2 Answer: no All that matters is the component of the electron's orbital magnetic moment along the direction of $\vec{B}$. We called this μ_z in Eq. (41.14) because we *defined* the positive z-axis to be in the direction of $\vec{B}$. In reality, the names of the axes are entirely arbitrary.

41.3 Answer: (iv) In order for the magnetic moment to be perfectly aligned with the z-direction, the z-component of the spin vector $\vec{S}$ would have to have the same absolute value as $\vec{S}$. However, the possible values of S_z are $\pm\frac{1}{2}\hbar$ [Eq. (41.19)] while the magnitude of the spin vector is $S = \sqrt{\frac{3}{4}}\hbar$ [Eq. (41.20)]. Hence $\vec{S}$ can never be perfectly aligned with any one direction in space.

41.4 Answer: more difficult If there were no exclusion principle, all 11 electrons in the sodium atom would be in the level of lowest energy (the $1s$ level) and the configuration would be $1s^{11}$. Consequently, it would be more difficult to remove the first electron. (In a real sodium atom the valence electron is in a screened $3s$ state, which has a comparatively high energy.)

41.5 Answer: (iv) An absorption edge appears if the photon energy is just high enough to remove an electron in a given energy level from the atom. In a sample of high-temperature hydrogen we expect to find atoms whose electron is in the ground level $(n = 1)$, the first excited level $(n = 2)$, and the second excited level $(n = 3)$. From Eq. (41.3) these levels have energies $E_n = (-13.60\text{ eV})/n^2 = -13.60\text{ eV}, -3.40\text{ eV}$ and -1.51 eV (see Fig. 38.9b).

PROBLEMS

For instructor-assigned homework, go to **www.pearson.com.au/masteringphysics** MP

Exercises

Section 41.1 The Hydrogen Atom

41.1. An electron is in the hydrogen atom with $n = 3$. (a) Find the possible values of L and L_z for this electron, in units of $\hbar$. (b) For each value of L, find all the possible angles between L and the z-axis.

41.2. An electron is in the hydrogen atom with $n = 5$. (a) Find the possible values of L and L_z for this electron, in units of $\hbar$. (b) For each value of L, find all the possible angles between L and the z-axis. (c) What are the maximum and minimum values of the magnitude of the angle between L and the z-axis?

41.3. The orbital angular momentum of an electron has a magnitude of $4.716 \times 10^{-34}\text{ kg} \cdot \text{m}^2/\text{s}$. What is the angular-momentum quantum number l for this electron?

41.4. Consider states with angular-momentum quantum number $l = 2$. (a) In units of $\hbar$, what is the largest possible value of L_z? (b) In units of $\hbar$, what is the value of L? Which is larger: L or the maximum possible L_z? (c) For each allowed value of L_z, what angle does the vector $\vec{L}$ make with the $+z$-axis? How does the minimum angle for $l = 2$ compare to the minimum angle for $l = 3$ calculated in Example 41.2?

41.5. Calculate, in units of $\hbar$, the magnitude of the maximum orbital angular momentum for an electron in a hydrogen atom for states with a principal quantum number of 2, 20 and 200. Compare each with the value of $n\hbar$ postulated in the Bohr model. What trend do you see?

41.6. (a) Make a chart showing all the possible sets of quantum numbers l and m_l for the states of the electron in the hydrogen atom when $n = 5$. How many combinations are there? (b) What are the energies of these states?

41.7. Problem-Solving Strategy 41.1 claims that the electric potential energy of a proton and an electron 0.10 nm apart has magnitude 15 eV. Verify this claim.

41.8. (a) What is the probability that an electron in the $1s$ state of a hydrogen atom will be found at a distance less than $a/2$ from the nucleus? (b) Use the results of part (a) and of Example 41.3 to calculate the probability that the electron will be found at distances between $a/2$ and a from the nucleus.

41.9. (a) For the wave function $\psi(r, \theta, \phi) = R(r)\Theta(\theta)\Phi(\phi)$ with $\Phi(\phi) = Ae^{im_l\phi}$, show that $|\psi|^2$ is independent of ϕ. (b) What value must A have if $\Phi(\phi)$ is to satisfy the normalisation condition $\int_0^{2\pi} |\Phi(\phi)|^2 d\phi = 1$?

41.10. For ordinary hydrogen, the reduced mass of the electron and proton is $m_r = 0.99946m$, where m is the electron mass (see Section 38.5). For each of the following cases, find the numerical coefficient of $-1/n^2$ in Eq. (41.3) and the energy of the photon emitted in a transition from the $n = 2$ level to the $n = 1$ level: (a) a hydrogen atom in which the nucleus is taken to be infinitely massive, so $m_r = m$; (b) positronium (see Section 38.5), for which $m_r = m/2$ exactly; (c) muonium, an atom composed of a muon and a proton (see Problem 38.59), for which $m_r = 185.8m$.

41.11. Find the numerical value of a in Eq. (41.8) for (a) a hydrogen atom in which the nucleus is taken to be infinitely massive, so $m_r = m$; (b) positronium (see Section 38.5), for which $m_r = m/2$ exactly; (c) muonium, an atom composed of a muon and a proton

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

(see Problem 38.59), for which $m_r = 185.8m$. In part (a), a becomes a_0, the Bohr radius.

41.12. Show that $\Phi(\phi) = e^{im_l\phi} = \Phi(\phi + 2\pi)$ (that is, show that $\Phi(\phi)$ is periodic with period 2π) if and only if m_l is restricted to the values $0, \pm1, \pm2, \ldots$. (*Hint:* Euler's formula states that $e^{i\phi} = \cos\phi + i\sin\phi$.)

41.13. In Example 41.3 fill in the missing details that show that $P = 1 - 5e^{-2}$.

Section 41.2 The Zeeman Effect

41.14. A hydrogen atom is in a d state. In the absence of an external magnetic field the states with different m_l values have (approximately) the same energy. Consider the interaction of the magnetic field with the atom's orbital magnetic dipole moment. (a) Calculate the splitting (in electron volts) of the m_l levels when the atom is put in a 0.400 T magnetic field that is in the $+z$-direction. (b) Which m_l level will have the lowest energy? (c) Draw an energy-level diagram that shows the d levels with and without the external magnetic field.

41.15. A hydrogen atom in the $5g$ state is placed in a magnetic field of 0.600 T that is in the z-direction. (a) Into how many levels is this state split by the interaction of the atom's orbital magnetic dipole moment with the magnetic field? (b) What is the energy separation between adjacent levels? (c) What is the energy separation between the level of lowest energy and the level of highest energy?

41.16. A hydrogen atom undergoes a transition from a $2p$ state to the $1s$ ground state. In the absence of a magnetic field, the energy of the photon emitted is 122 nm. The atom is then placed in a strong magnetic field in the z-direction. Ignore spin effects; consider only the interaction of the magnetic field with the atom's orbital magnetic moment. (a) How many different photon wavelengths are observed for the $2p \rightarrow 1s$ transition? What are the m_l values for the initial and final states for the transition that leads to each photon wavelength? (b) One observed wavelength is exactly the same with the magnetic field as without. What are the initial and final m_l values for the transition that produces a photon of this wavelength? (c) One observed wavelength with the field is longer than the wavelength without the field. What are the initial and final m_l values for the transition that produces a photon of this wavelength? (d) Repeat part (c) for the wavelength that is shorter than the wavelength in the absence of the field.

41.17. A hydrogen atom in a $3p$ state is placed in a uniform external magnetic field $\vec{B}$. Consider the interaction of the magnetic field with the atom's orbital magnetic dipole moment. (a) What field magnitude B is required to split the $3p$ state into multiple levels with an energy difference of 2.71×10^{-5} eV between adjacent levels? (b) How many levels will there be?

Section 41.3 Electron Spin

41.18. A hydrogen atom in the $n = 1$, $m_s = -\frac{1}{2}$ state is placed in a magnetic field with a magnitude of 0.480 T in the $+z$-direction. (a) Find the magnetic interaction energy (in electron volts) of the electron with the field. (b) Is there any orbital magnetic dipole moment interaction for this state? Explain. Can there be an orbital magnetic dipole moment interaction for $n \neq 1$?

41.19. Calculate the energy difference between the $m_s = \frac{1}{2}$ ('spin up') and $m_s = -\frac{1}{2}$ ('spin down') levels of a hydrogen atom in the $1s$ state when it is placed in a 1.45-T magnetic field in the *negative* z-direction. Which level, $m_s = \frac{1}{2}$ or $m_s = -\frac{1}{2}$, has the lower energy?

41.20. List the different possible combinations of l and j for a hydrogen atom in the $n = 3$ level.

41.21. A hydrogen atom in a particular orbital angular momentum state is found to have j quantum numbers $\frac{7}{2}$ and $\frac{9}{2}$. What is the letter that labels the value of l for the state?

41.22. The hyperfine interaction in a hydrogen atom between the magnetic dipole moment of the proton and the spin magnetic dipole moment of the electron splits the ground level into two levels separated by 5.9×10^{-6} eV. (a) Calculate the wavelength and frequency of the photon emitted when the atom makes a transition between these states, and compare your answer to the value given at the end of Section 41.3. In what part of the electromagnetic spectrum does this lie? Such photons are emitted by cold hydrogen clouds in interstellar space; by detecting these photons, astronomers can learn about the number and density of such clouds. (b) Calculate the effective magnetic field experienced by the electron in these states (see Fig. 41.14). Compare your result to the effective magnetic field due to the spin-orbit coupling calculated in Example 41.6.

41.23. (a) If you treat an electron as a classical spherical object with a radius of 1.0×10^{-17} m, what angular speed is necessary to produce a spin angular momentum of magnitude $\sqrt{\frac{3}{4}}\hbar$? (b) Use $v = r\omega$ and the result of part (a) to calculate the speed v of a point at the electron's equator. What does your result suggest about the validity of this model?

Section 41.4 Many-Electron Atoms and the Exclusion Principle

41.24. For germanium $(\text{Ge}, Z = 32)$, make a list of the number of electrons in each subshell $(1s, 2s, 2p, \ldots)$. Use the allowed values of the quantum numbers along with the exclusion principle; do *not* refer to Table 41.3.

41.25. Make a list of the four quantum numbers n, l, m_l and m_s for each of the 10 electrons in the ground state of the neon atom. Do *not* refer to Table 41.2 or 41.3.

41.26. For magnesium, the first ionisation potential is 7.6 eV. The second ionisation potential (additional energy required to remove a second electron) is almost twice this, 15 eV, and the third ionisation potential is much larger, about 80 eV. How can these numbers be understood?

41.27. The $5s$ electron in rubidium (Rb) sees an effective charge of $2.771e$. Calculate the ionisation energy of this electron.

41.28. The energies of the $4s$, $4p$ and $4d$ states of potassium are given in Example 41.8. Calculate Z_{eff} for each state. What trend do your results show? How can you explain this trend?

41.29. (a) The doubly charged ion N^{2+} is formed by removing two electrons from a nitrogen atom. What is the ground-state electron configuration for the N^{2+} ion? (b) Estimate the energy of the least strongly bound level in the L shell of N^{2+}. (c) The doubly charged ion P^{2+} is formed by removing two electrons from a phosphorus atom. What is the ground-state electron configuration for the P^{2+} ion? (d) Estimate the energy of the least strongly bound level in the M shell of P^{2+}.

41.30. (a) The energy of the $2s$ state of lithium is -5.391 eV. Calculate the value of Z_{eff} for this state. (b) The energy of the $4s$ state of potassium is -4.339 eV. Calculate the value of Z_{eff} for this state. (c) Compare Z_{eff} for the $2s$ state of lithium, the $3s$ state of sodium (see Example 41.7), and the $4s$ state of potassium. What trend do you see? How can you explain this trend?

41.31. Estimate the energy of the highest-l state for (a) the L shell of Be^+ and (b) the N shell of Ca^+.

Section 41.5 X-ray Spectra

41.32. A K_α x-ray emitted from a sample has an energy of 7.46 keV. Of which element is the sample made?

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

41.33. Calculate the frequency, energy (in keV) and wavelength of the K_α x-ray for the elements (a) calcium (Ca, $Z = 20$); (b) cobalt (Co, $Z = 27$); (c) cadmium (Cd, $Z = 48$).

Problems

41.34. (a) What is the lowest possible energy (in electron volts) of an electron in hydrogen if its orbital angular momentum is $\sqrt{12}\hbar$? (b) What are the largest and smallest values of the z-component of the orbital angular momentum (in terms of $\hbar$) for the electron in part (a)? (c) What are the largest and smallest values of the spin angular momentum (in terms of $\hbar$) for the electron in part (a)? (d) What are the largest and smallest values of the orbital angular momentum (in terms of $\hbar$) for an electron in the M shell of hydrogen?

41.35. Consider an electron in hydrogen having total energy -0.5440 eV. (a) What are the possible values of its orbital angular momentum (in terms of $\hbar$)? (b) What wavelength of light would it take to excite this electron to the next higher shell? Is this photon visible to humans?

41.36. (a) Show all the distinct states for an electron in the N shell of hydrogen. Include all four quantum numbers. (b) For an f-electron in the N shell, what is the largest possible orbital angular momentum and the greatest positive value for the component of this angular momentum along any chosen direction (the z-axis)? What is the magnitude of its spin angular momentum? Express these quantities in units of $\hbar$. (c) For an electron in the d state of the N shell, what are the maximum and minimum angles between its angular momentum vector and any chosen direction (the z-axis)? (d) What is the largest value of the orbital angular momentum for an f-electron in the M shell?

41.37. (a) The energy of an electron in the $4s$ state of sodium is -1.947 eV. What is the effective net charge of the nucleus 'seen' by this electron? On the average, how many electrons screen the nucleus? (b) For an outer electron in the $4p$ state of potassium, on the average 17.2 inner electrons screen the nucleus. (i) What is the effective net charge of the nucleus 'seen' by this outer electron? (ii) What is the energy of this outer electron?

41.38. For a hydrogen atom, the probability $P(r)$ of finding the electron within a spherical shell with inner radius r and outer radius $r + dr$ is given by Eq. (41.7). For a hydrogen atom in the $1s$ ground state, at what value of r does $P(r)$ have its maximum value? How does your result compare to the distance between the electron and the nucleus for the $n = 1$ state in the Bohr model (Eq. 41.8)?

41.39. Consider a hydrogen atom in the $1s$ state. (a) For what value of r is the potential energy $U(r)$ equal to the total energy E? Express your answer in terms of a. This value of r is called the *classical turning point*, since this is where a Newtonian particle would stop its motion and reverse direction. (b) For r greater than the classical turning point, $U(r) > E$. Classically, the particle cannot be in this region, since the kinetic energy cannot be negative. Calculate the probability of the electron being found in this classically forbidden region.

41.40. *Rydberg atoms* are atoms whose outermost electron is in an excited state with a *very* large principal quantum number. Rydberg atoms have been produced in the laboratory and detected in interstellar space. (a) Why do all neutral Rydberg atoms with the same n value have essentially the same ionisation energy, independent of the total number of electrons in the atom? (b) What is the ionisation energy for a Rydberg atom with a principal quantum number of 350? What is the radius in the Bohr model of the Rydberg electron's orbit? (c) Repeat part (b) for $n = 650$.

41.41. The wave function for a hydrogen atom in the $2s$ state is

$$\psi_{2s}(r) = \frac{1}{\sqrt{32\pi a^3}}\left(2 - \frac{r}{a}\right)e^{-r/2a}$$

(a) Verify that this function is normalised. (b) In the Bohr model, the distance between the electron and the nucleus in the $n = 2$ state is exactly $4a$. Calculate the probability that an electron in the $2s$ state will be found at a distance less than $4a$ from the nucleus.

41.42. The normalised wave function for a hydrogen atom in the $2s$ state is given in Problem 41.41. (a) For a hydrogen atom in the $2s$ state, at what value of r is $P(r)$ maximum? How does your result compare to $4a$, the distance between the electron and the nucleus in the $n = 2$ state of the Bohr model? (b) At what value of r (other than $r = 0$ or $r = \infty$) is $P(r)$ equal to zero, so that the probability of finding the electron at that separation from the nucleus is zero? Compare your result to Fig. 41.5.

41.43. (a) For an excited state of hydrogen, show that the smallest angle that the orbital angular momentum vector $\vec{\boldsymbol{L}}$ can have with the z-axis is

$$(\theta_L)_{\text{min}} = \arccos\left(\frac{n-1}{\sqrt{n(n-1)}}\right)$$

(b) What is the corresponding expression for $(\theta_L)_{\text{max}}$, the largest possible angle between $\vec{\boldsymbol{L}}$ and the z-axis?

41.44. (a) If the value of L_z is known, we cannot know either L_x or L_y precisely. But we can know the value of the quantity $\sqrt{L_x^2 + L_y^2}$. Write an expression for this quantity in terms of l, m_l, and $\hbar$. (b) What is the meaning of $\sqrt{L_x^2 + L_y^2}$? (c) For a state of nonzero orbital angular momentum, find the maximum and minimum values of $\sqrt{L_x^2 + L_y^2}$. Explain your results.

41.45. The normalised radial wave function, Eq. (41.2), for the $2p$ state of the hydrogen atom is $R_{2p} = (1/\sqrt{24a^5})re^{-r/2a}$. After we average over the angular variables, the radial probability function becomes $P(r)\,dr = (R_{2p})^2 r^2\,dr$. At what value of r is $P(r)$ for the $2p$ state a maximum? Compare your results to the radius of the $n = 2$ state in the Bohr model.

41.46. In a Stern-Gerlach experiment, the deflecting force on the atom is $F_z = -\mu_z(dB_z/dz)$, where μ_z is given by Eq. (41.22) and dB_z/dz is the magnetic-field gradient. In a particular experiment the magnetic-field region is 50.0 cm long; assume the magnetic-field gradient is constant in this region. A beam of silver atoms enters the magnetic field with a speed of 525 m/s. What value of dB_z/dz is required to give a separation of 1.0 mm between the two spin components as they exit the field? (Note: The magnetic dipole moment of silver is the same as that for hydrogen, since its valence electron is in an $l = 0$ state.)

41.47. Consider the transition from a $3d$ to a $2p$ state of hydrogen in an external magnetic field. Assume that the effects of electron spin can be ignored (which is not actually the case) so that the magnetic field interacts only with the orbital angular momentum. Identify each allowed transition by the m_l values of the initial and final states. For each of these allowed transitions, determine the shift of the transition energy from the zero-field value and show that there are three different transition energies.

41.48. An atom in a $3d$ state emits a photon of wavelength 475.082 nm when it decays to a $2p$ state. (a) What is the energy (in electron volts) of the photon emitted in this transition? (b) Use the selection rules described in Section 41.2 to find the allowed transitions if the atom is now in an external magnetic field of 3.500 T. Ignore the effects of the electron's spin. (c) For the case in part (b), if the energy of the $3d$ state was originally -8.50000 eV with no

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

magnetic field present, what will be the energies of the states into which it splits in the magnetic field? (d) What are the allowed wavelengths of the light emitted during transition in part (b)?

41.49. While studying the spectrum of a gas cloud in space, an astronomer magnifies a spectral line that results from a transition from a p state to an s state. She finds that the line at 575.050 nm has actually split into three lines, with adjacent lines 0.0462 nm apart, indicating that the gas is in an external magnetic field. (Ignore effects due to electron spin.) What is the strength of the external magnetic field?

41.50. A hydrogen atom makes a transition from an $n = 3$ state to an $n = 2$ state (the Balmer H_α line) while in a magnetic field in the $+z$-direction and with magnitude 1.40 T. (a) If the magnetic quantum number is $m_l = 2$ in the initial $(n = 3)$ state and $m_l = 1$ in the final $(n = 2)$ state, by how much is each energy level shifted from the zero-field value? (b) By how much is the wavelength of the H_α line shifted from the zero-field value? Is the wavelength increased or decreased? Disregard the effect of electron spin. [Hint: Use the result of Problem 39.56(c).]

41.51. A large number of hydrogen atoms in $1s$ states are placed in an external magnetic field that is in the $+z$-direction. Assume that the atoms are in thermal equilibrium at room temperature, $T = 300\text{K}$. According to the Maxwell-Boltzmann distribution (see Section 38.6), what is the ratio of the number of atoms in the $m_s = \frac{1}{2}$ state to the number in the $m_s = -\frac{1}{2}$ state when the magnetic-field magnitude is (a) 5.00×10^{-5} T (approximately the earth's field); (b) 0.500 T; (c) 5.00 T?

41.52. An electron in a hydrogen atom is in the $2p$ state. In a simple model of the atom, assume that the electron circles the proton in an orbit with radius r equal to the Bohr-model radius for $n = 2$. Assume that the speed v of the orbiting electron can be calculated by setting $L = mvr$ and taking L to have the quantum-mechanical value for a $2p$ state. In the frame of the electron, the proton orbits with radius r and speed v. Model the orbiting proton as a circular current loop, and calculate the magnetic field it produces at the location of the electron.

41.53. In another universe, the electron is a spin-$\frac{3}{2}$ rather than a spin-$\frac{1}{2}$ particle, but all other physics are the same as in our universe. In this universe, (a) what are the atomic numbers of the lightest two inert gases? (b) What is the ground-state electron configuration of sodium?

41.54. For an ion with nuclear charge Z and a single electron, the electric potential energy is $-Ze^2/4\pi\epsilon_0 r$ and the expression for the energies of the states and for the normalised wave functions are obtained from those for hydrogen by replacing e^2 by Ze^2. Consider the N^{6+} ion, with seven protons and one electron. (a) What is the ground-state energy in electron volts? (b) What is the ionisation energy, the energy required to remove the electron from the N^{6+} ion if it is initially in the ground state? (c) What is the distance a [given for hydrogen by Eq. (41.8)] for this ion? (d) What is the wavelength of the photon emitted when the N^{6+} ion makes a transition from the $n = 2$ state to the $n = 1$ ground state?

41.55. A hydrogen atom in an $n = 2$, $l = 1$, $m_l = -1$ state emits a photon when it decays to an $n = 1$, $l = 0$, $m_l = 0$ ground state. (a) In the absence of an external magnetic field, what is the wavelength of this photon? (b) If the atom is in a magnetic field in the $+z$-direction and with a magnitude of 2.20 T, what is the shift in the wavelength of the photon from the zero-field value? Does the magnetic field increase or decrease the wavelength? Disregard the effect of electron spin. [*Hint:* Use the result of Problem 39.56(c).]

41.56. A lithium atom has three electrons, and the $^2S_{1/2}$ ground-state electron configuration is $1s^2 2s$. The $1s^2 2p$ excited state is split into two closely spaced levels, $^2P_{3/2}$ and $^2P_{1/2}$, by the spin-orbit interaction (see Example 41.6 in Section 41.3). A photon with wavelength 67.09608 μm is emitted in the $^2P_{3/2} \rightarrow {}^2S_{1/2}$ transition, and a photon with wavelength 67.09761 μm is emitted in the $^2P_{1/2} \rightarrow {}^2S_{1/2}$ transition. Calculate the effective magnetic field seen by the electron in the $1s^2 2p$ state of the lithium atom. How does your result compare to that for the 3p level of sodium found in Example 41.6?

41.57. Estimate the minimum and maximum wavelengths of the characteristic x-rays emitted by (a) vanadium $(Z = 23)$ and (b) rhenium $(Z = 45)$. Discuss any approximations that you make.

41.58. Electrons in the lower of two spin states in a magnetic field can absorb a photon of the right frequency and move to the higher state. (a) Find the magnetic-field magnitude B required for this transition in a hydrogen atom with $n = 1$ and $l = 0$ to be induced by microwaves with wavelength λ. (b) Calculate the value of B for a wavelength of 3.50 cm.

41.59. (a) Show that the total number of atomic states (including different spin states) in a shell of principal quantum number n is $2n^2$. [*Hint:* The sum of the first N integers $1 + 2 + 3 + \cdots + N$ is equal to $N(N + 1)/2$.] (b) Which shell has 50 states?

41.60. (a) If the intrinsic spin angular momentum S of the earth had the same limitations as that of the electron, what would be the angular velocity of our planet's spin on its axis? To get a reasonable answer but simplify the calculations, assume that the earth is uniform throughout. (b) Could we, in principle, use the method of part (a) to determine the angular velocity of the electron's spin? Why?

Challenge Problems

41.61. Each of $2N$ electrons (mass m) is free to move along the x-axis. The potential-energy function for each electron is $U(x) = \frac{1}{2}k'x^2$, where k' is a positive constant. The electric and magnetic interactions between electrons can be ignored. Use the exclusion principle to show that the minimum energy of the system of $2N$ electrons is $\hbar N^2\sqrt{k'/m}$. (*Hint:* See Section 40.4 and the hint given in Problem 41.59.)

41.62. Consider a simple model of the helium atom in which two electrons, each with mass m, move around the nucleus (charge $+2e$) in the same circular orbit. Each electron has orbital angular momentum $\hbar$ (that is, the orbit is the smallest-radius Bohr orbit), and the two electrons are always on opposite sides of the nucleus. Ignore the effects of spin. (a) Determine the radius of the orbit and the orbital speed of each electron. [*Hint:* Follow the procedure used in Section 38.5 to derive Eqs. (38.12) and (38.13). Each electron experiences an attractive force from the nucleus and a repulsive force from the other electron.] (b) What is the total kinetic energy of the electrons? (c) What is the potential energy of the system (the nucleus and the two electrons)? (d) In this model, how much energy is required to remove both electrons to infinity? How does this compare to the experimental value of 79.0 eV?

41.63. Repeat the calculation of Problem 41.39 for a one-electron ion with nuclear charge Z. (See Problem 41.54.) How does the probability of the electron being found in the classically forbidden region depend on Z?

MOLECULES AND CONDENSED MATTER

42

? In 2002 a 10 000-year-old Antarctic ice shelf roughly the size of Kangaroo Island abruptly collapsed in response to increasing summer temperatures. What property of carbon dioxide molecules in our atmosphere makes them a potent agent for triggering higher average temperatures worldwide?

LEARNING GOALS

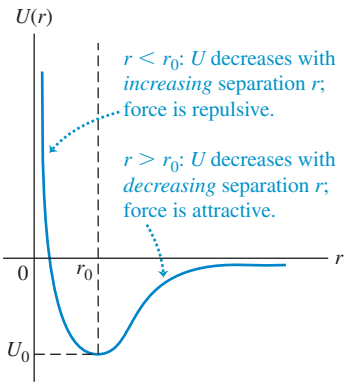
By studying this chapter, you will be able to explain:

- The various types of bonds that hold atoms together.
- How the rotational and vibrational dynamics of molecules are revealed by molecular spectra.
- How and why atoms form into crystalline structures.
- How to use the energy-band concept to explain the electrical properties of solids.
- A simple model for metals that explains many of their physical properties.
- How the character of a semiconductor can be radically transformed by adding small amounts of an impurity.
- Some of the technological applications of semiconductor devices.
- Why certain materials become superconductors at low temperature.

In Chapter 41 we discussed the structure and properties of isolated atoms. But such atoms are the exception; usually we find atoms combined to form molecules or more extended structures we call condensed matter (liquid or solid). It's the attractive forces between atoms, called molecular bonds, that causes them to combine. In this chapter we'll study several kinds of bonds as well as the energy levels and spectra associated with diatomic molecules. We will see that just as atoms have quantised energies determined by the quantum-mechanical state of their electrons, so molecules have quantised energies determined by their rotational and vibrational states.

The same physical principles behind molecular bonds also apply to the study of condensed matter, in which various types of bonding occur. We'll explore the concept of energy bands and see how it helps us understand the properties of solids. Then we'll look more closely at the properties of a special class of solids called semiconductors. Devices using semiconductors are found in every radio, TV, pocket calculator and computer used today; they have revolutionised the entire field of electronics during the past half-century.

42.1 Types of Molecular Bonds



We can use our discussion of atomic structure in Chapters 41 as a basis for exploring the nature of *molecular bonds*, the interactions that hold atoms together to form stable structures such as molecules and solids.

Ionic Bonds

The **ionic bond** is an interaction between oppositely charged *ionised* atoms. The most familiar example is sodium chloride (NaCl), in which the sodium atom gives its one 3*s* electron to the chlorine atom, filling the vacancy in the 3*p* subshell of chlorine.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

42.1 When the separation r between two oppositely charged ions is large, the potential energy $U(r)$ is proportional to $1/r$ as for point charges and the force is attractive. As r decreases, the charge clouds of the two atoms overlap and the force becomes less attractive. If r is less than the equilibrium separation r_0, the force is repulsive.

Let's look at the energy balance in this transaction. Removing the 3*s* electron from a neutral sodium atom requires 5.138 eV of energy; this is called the *ionisation energy* or *ionisation potential* of sodium. The neutral chlorine atom can attract an extra electron into the vacancy in the 3*p* subshell, where it is incompletely screened by the other electrons and therefore is attracted to the nucleus. This state has 3.613 eV lower energy than a neutral chlorine atom and a distant free electron; 3.613 eV is the magnitude of the *electron affinity* of chlorine. Thus creating the well-separated Na^+ and Cl^- ions requires a net investment of only 5.138 eV − 3.613 eV = 1.525 eV. When the two oppositely charged ions are brought together by their mutual attraction, the magnitude of their negative potential energy is determined by how closely they can approach each other. This in turn is limited by the exclusion principle, which forbids extensive overlap of the electron clouds of the two ions. As the distance decreases, the exclusion principle distorts the charge clouds, so the ions no longer interact like point charges and the interaction eventually becomes repulsive (Fig. 42.1).

The minimum electric potential energy for NaCl turns out to be −5.7 eV at a separation of 0.24 nm The net energy released in creating the ions and letting them come together to the equilibrium separation of 0.24 nm is 5.7 eV − 1.525 eV = 4.2 eV. Thus, if the kinetic energy of the ions is neglected, 4.2 eV is the *binding energy* of the NaCl molecule, the energy that is needed to dissociate the molecule into separate neutral atoms.

Example 42.1 Electric potential energy of the NaCl molecule

Find the electric potential energy of Na^+ and Cl^- ions separated by 0.24 nm if they can be treated as point charges.

SOLUTION

IDENTIFY: We use the ideas from Section 23.1 about the electric potential energy of two point charges.

SET UP: Equation (23.9) tells us that the electric potential energy of two point charges q and q_0 separated by a distance r is $U = qq_0/4\pi\epsilon_0 r$.

EXECUTE: The two charges are $q = +e$ (for Na^+) and $q_0 = -e$ (for Cl^-), and the separation is $r = 0.24\text{ nm} = 0.24 \times 10^{-9}\text{ m}$. From Eq. (23.9),

$$U = -\frac{1}{4\pi\epsilon_0}\frac{e^2}{r_0} = -(9.0 \times 10^9\ \text{N}\cdot\text{m}^2/\text{C}^2)\frac{(1.6 \times 10^{-19}\ \text{C})^2}{0.24 \times 10^{-9}\ \text{m}}$$
$$= -9.6 \times 10^{-19}\ \text{J} = -6.0\ \text{eV}$$

EVALUATE: This result agrees fairly well with the observed value of −5.7 eV. The difference is because at the equilibrium separation the ions don't behave exactly like point charges; at this separation the electron clouds of the two ions are overlapping.

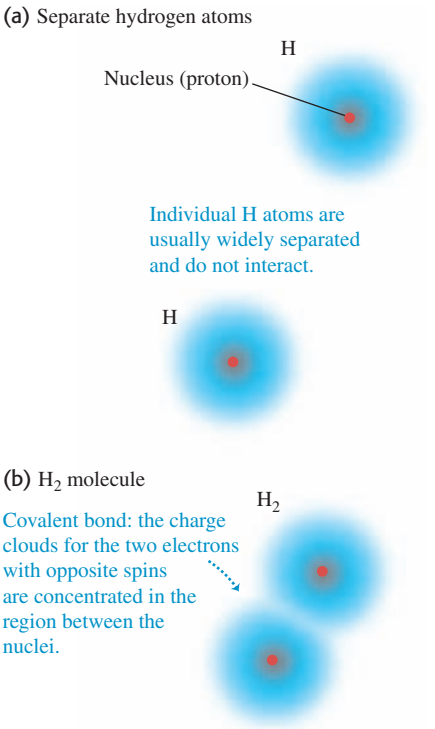
Covalent Bonds

Ionic bonds are interactions between charge distributions that are nearly spherically symmetric; hence they are not highly directional. They can involve more than one electron per atom. The alkaline earth elements form ionic compounds in which an atom loses *two* electrons; an example is $Mg^{2+}(Cl^-)_2$. Loss of more than two electrons is relatively rare; instead, a different kind of bond comes into operation.

The **covalent bond** is characterised by a more egalitarian participation of the two atoms than occurs with the ionic bond. The simplest covalent bond is found in the hydrogen molecule, a structure containing two protons and two electrons. This bond is shown schematically in Fig. 42.2. As the separate atoms (Fig. 42.2a) come together, the electron wave functions are distorted and become more concentrated in the region between the two protons (Fig. 42.2b). The net attraction of the electrons for each proton more than balances the repulsion of the two protons and of the two electrons.

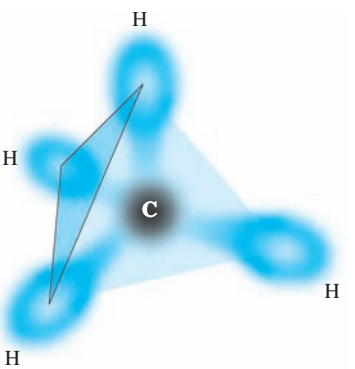
Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

The attractive interaction is then supplied by a *pair* of electrons, one contributed by each atom, with charge clouds that are concentrated primarily in the region between the two atoms. The energy of the covalent bond in the hydrogen molecule H_2 is -4.48 eV.



As we saw in Chapter 41, the exclusion principle permits two electrons to occupy the same region of space (that is, to be in the same spatial quantum state) only when they have opposite spins. When the spins are parallel, the exclusion principle forbids the molecular state that would be most favourable from energy considerations (with both electrons in the region between atoms). Opposite spins are an essential requirement for a covalent bond, and no more than two electrons can participate in such a bond.

However, an atom with several electrons in its outermost shell can form several covalent bonds. The bonding of carbon and hydrogen atoms, of central importance in organic chemistry, is an example. In the *methane* molecule (CH_4) the carbon atom is at the centre of a regular tetrahedron, with a hydrogen atom at each corner. The carbon atom has four electrons in its L shell, and each of these four electrons forms a covalent bond with one of the four hydrogen atoms (Fig. 42.3). Similar patterns occur in more complex organic molecules.



Because of the role played by the exclusion principle, covalent bonds are highly directional. In the methane molecule the wave function for each of carbon's four valence electrons is a combination of the $2s$ and $2p$ wave functions called a *hybrid wave function*. The probability distribution for each one has a lobe protruding towards a corner of a tetrahedron. This symmetrical arrangement minimises the overlap of wave functions for the electron pairs, minimising their repulsive potential energy.

Ionic and covalent bonds represent two extremes in molecular bonding, but there is no sharp division between the two types. Often there is a *partial* transfer of one or more electrons from one atom to another. As a result, many molecules that have dissimilar atoms have electric dipole moments—that is, a preponderance of positive charge at one end and of negative charge at the other. Such molecules are called *polar* molecules. Water molecules have large electric dipole moments; these are responsible for the exceptionally large dielectric constant of liquid water (see Sections 24.4 and 24.5).

42.2 Covalent bond in a hydrogen molecule.

42.3 Schematic diagram of the methane (CH_4) molecule. The carbon atom is at the centre of a regular tetrahedron and forms four covalent bonds with the hydrogen atoms at the corners. Each covalent bond includes two electrons with opposite spins, forming a charge cloud that is concentrated between the carbon atom and a hydrogen atom.

van der Waals Bonds

Ionic and covalent bonds, with typical bond energies of 1 to 5 eV, are called *strong bonds*. There are also two types of weaker bonds. One of these, the **van der Waals bond**, is an interaction between the electric dipole moments of atoms or molecules; typical energies are 0.1 eV or less. The bonding of water molecules in the liquid and solid states results partly from dipole–dipole interactions.

No atom has a permanent electric dipole moment, nor do many molecules. However, fluctuating charge distributions can lead to fluctuating dipole moments; these in turn can induce dipole moments in neighbouring structures. Overall, the resulting dipole–dipole interaction is attractive, giving a weak bonding of atoms or molecules. The interaction potential energy drops off very quickly with distance r between molecules, usually as $1/r^6$. The liquefaction and solidification of the inert gases and of molecules such as H_2, O_2, and N_2 are due to induced-dipole van der Waals interactions. Not much thermal-agitation energy is needed to break these weak bonds, so such substances usually exist in the liquid and solid states only at very low temperatures.

Hydrogen Bonds

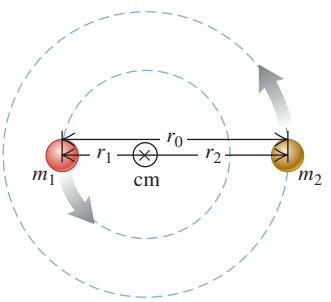
In the other type of weak bond, the **hydrogen bond**, a proton (H^+ ion) gets between two atoms, polarising them and attracting them by means of the induced dipoles. This bond is unique to hydrogen-containing compounds because only hydrogen has a singly ionised state with no remaining electron cloud; the hydrogen ion is a bare proton, much smaller than any other singly ionised atom. The

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

bond energy is usually less than 0.5 eV. The hydrogen bond plays an essential role in many organic molecules, including the cross-linking of polymer chains such as polyethylene and cross-link bonding between the two strands of the double-helix DNA molecule. Hydrogen bonding also plays a role in the structure of ice.

All these bond types hold the atoms together in *solids* as well as in molecules. Indeed, a solid is in many respects a giant molecule. Still another type of bonding, the *metallic bond*, comes into play in the structure of metallic solids. We'll return to this subject in Section 42.3.

Test Your Understanding of Section 42.1 If electrons obeyed the exclusion principle but did *not* have spin, how many electrons could participate in a covalent bond? (i) one; (ii) two; (iii) three; (iv) more than three.



42.2 Molecular Spectra

Molecules have energy levels that are associated with rotational motion of a molecule as a whole and with vibrational motion of the atoms relative to each other. Just as transitions between energy levels in atoms lead to atomic spectra, transitions between rotational and vibrational levels in molecules lead to *molecular spectra*.

Rotational Energy Levels

In this discussion we'll concentrate mostly on *diatomic* molecules, to keep things as simple as possible. In Fig. 42.4 we picture a diatomic molecule as a rigid dumbbell (two point masses m_1 and m_2 separated by a constant distance r_0) that can *rotate* about axes through its centre of mass, perpendicular to the line joining them. What are the energy levels associated with this motion?

42.4 A diatomic molecule modelled as two point masses m_1 and m_2 separated by a distance r_0. The distances of the masses from the centre of mass are r_1 and r_2, where $r_1 + r_2 = r_0$.

We showed in Section 10.5 that when a rigid body rotates with angular speed ω about a perpendicular axis through its centre of mass, the magnitude L of its angular momentum is given by Eq. (10.28), $L = I\omega$, where I is its moment of inertia about that symmetry axis. Its kinetic energy is given by Eq. (9.17), $K = \frac{1}{2}I\omega^2$. Combining these two equations, we find $K = L^2/2I$. There is no potential energy U, so the kinetic energy K is equal to the total mechanical energy E:

$$E = \frac{L^2}{2I} \tag{42.1}$$

Zero potential energy U means no dependence of U on θ or ϕ. But the potential-energy function U in the hydrogen atom also has no dependence on θ or ϕ. Thus the angular solutions to the Schrödinger equation for rigid-body rotation are the same as for the hydrogen atom, and the angular momentum is quantised in the same way. As in Eq. (41.4),

$$L^2 = l(l+1)\hbar^2 \qquad (l = 0, 1, 2 \ldots) \tag{42.2}$$

Combining Eqs. (42.1) and (42.2), we obtain the *rotational energy levels*:

$$E_l = l(l+1)\frac{\hbar^2}{2I} \qquad (l = 0, 1, 2, \ldots) \qquad \text{(rotational energy levels, diatomic molecule)} \tag{42.3}$$

42.5 The ground level and first four excited rotational energy levels for a diatomic molecule. The levels are not equally spaced.

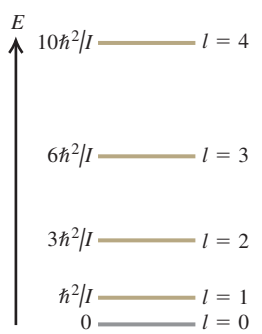


Figure 42.5 is an energy-level diagram showing these rotational levels. The ground level has zero quantum number l and zero energy E, corresponding to zero angular momentum (no rotation). The spacing of adjacent levels increases with increasing l.

We can express the moment of inertia I in Eqs. (42.1) and (42.3) in terms of the *reduced mass* m_r of the molecule:

$$m_r = \frac{m_1 m_2}{m_1 + m_2} \tag{42.4}$$

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

We introduced this quantity in Section 38.5 to accommodate the finite nuclear mass of the hydrogen atom. In Fig. 42.4 the distances r_1 and r_2 are the distances from the centre of mass to the nuclei of the atoms. By definition of the centre of mass, $m_1 r_1 = m_2 r_2$, and the figure also shows that $r_0 = r_1 + r_2$. Solving these equations for r_1 and r_2, we find

$$r_1 = \frac{m_2}{m_1 + m_2} r_0 \qquad r_2 = \frac{m_1}{m_1 + m_2} r_0 \tag{42.5}$$

The moment of inertia is $I = m_1 r_1^2 + m_2 r_2^2$; substituting Eq. (42.5), we find

$$I = m_1 \frac{m_2^2}{(m_1 + m_2)^2} r_0^2 + m_2 \frac{m_1^2}{(m_1 + m_2)^2} r_0^2 = \frac{m_1 m_2}{m_1 + m_2} r_0^2 \quad \text{or}$$

$$I = m_r r_0^2 \qquad \text{(moment of inertia of a diatomic molecule)} \tag{42.6}$$

The reduced mass enables us to reduce this two-body problem to an equivalent one-body problem (a particle of mass m_r moving around a circle with radius r_0), just as we did with the hydrogen atom. Indeed, the only difference between this problem and the hydrogen atom is the difference in the radial forces. To conserve angular momentum, the allowed transitions are determined by the same selection rule as for the hydrogen atom: In allowed transitions, l must change by exactly one unit.

Example 42.2 Rotational spectrum of carbon monoxide

The two nuclei in the carbon monoxide (CO) molecule are 0.1128 nm apart. The mass of the most common carbon atom is exactly 12 u, or 1.993×10^{-26} kg. The mass of the most common oxygen atom is 15.995 u $= 2.656 \times 10^{-26}$ kg. (a) Find the energies of the lowest three rotational energy levels. Express your results in electron volts. (b) Find the wavelength of the photon emitted in the transition from the $l = 2$ to the $l = 1$ level.

SOLUTION

IDENTIFY: This problem uses the ideas developed in this section about the rotational energy levels of molecules.

SET UP: We are given the distance r_0 between the atoms and their masses m_1 and m_2. We calculate the reduced mass m_r using Eq. (42.4), the moment of inertia I of the molecule using Eq. (42.6), and the energies of the levels using Eq. (42.3). The energy E of the emitted photon is equal to the difference in energy between the $l = 2$ and $l = 1$ levels. We determine the wavelength using the relationship $E = hc/\lambda$ for a photon.

EXECUTE: (a) Using Eq. (42.4), we find that the reduced mass is $m_r = 1.139 \times 10^{-26}$ kg. From Eq. (42.6),

$$I = m_r r_0^2 = (1.139 \times 10^{-26}\,\text{kg})(0.1128 \times 10^{-9}\,\text{m})^2$$
$$= 1.449 \times 10^{-46}\,\text{kg} \cdot \text{m}^2$$

The rotational levels are given by Eq. (42.3):

$$E_l = l(l+1)\frac{\hbar^2}{2I} = l(l+1)\frac{(1.0546 \times 10^{-34}\,\text{J} \cdot \text{s})^2}{2(1.449 \times 10^{-46}\,\text{kg} \cdot \text{m}^2)}$$
$$= l(l+1)(3.838 \times 10^{-23}\,\text{J}) = l(l+1)0.2395\ \text{meV}$$

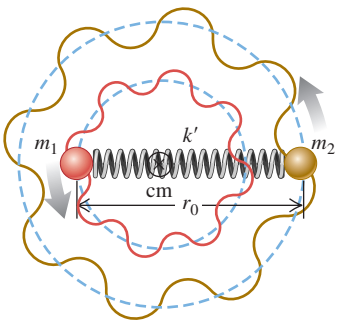
Substituting $l = 0, 1, 2$, we find

$$E_0 = 0 \qquad E_1 = 0.479\ \text{meV} \qquad E_2 = 1.437\ \text{meV}$$

(b) The photon energy is

$$E = E_2 - E_1 = 0.958\ \text{meV}$$

The photon wavelength is



$$\lambda = \frac{hc}{E} = \frac{(4.136 \times 10^{-15}\,\text{eV} \cdot \text{s})(3.00 \times 10^8\,\text{m/s})}{0.958 \times 10^{-3}\,\text{eV}}$$
$$= 1.29 \times 10^{-3}\,\text{m} = 1.29\,\text{mm}$$

EVALUATE: The difference between the first two rotational energy levels of CO is very small (about $\frac{1}{2}$ meV, where 1 meV $= 10^{-3}$ eV) compared to the difference between atomic energy levels (typically a few eV) associated with optical spectra. Hence a photon emitted by a CO molecule in a transition from the $l = 2$ to the $l = 1$ level has very low energy and a very long wavelength compared to visible light. Indeed, the wavelength calculated in part (b) is in the microwave part of the spectrum. Photon wavelengths for rotational transitions in other molecules are also long, falling within the microwave and far infrared regions of the spectrum.

In this example we were given the equilibrium separation between the atoms, also called the *bond length*, and we used it to calculate one of the wavelengths emitted by excited CO molecules. In actual experiments, scientists work this problem backward: By measuring the microwave emissions of a sample of diatomic molecules, they determine the moment of inertia of the molecule and hence the bond length.

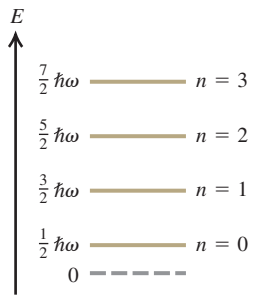
42.6 A diatomic molecule modelled as two point masses m_1 and m_2 connected by a spring with force constant k'.



Vibrational Energy Levels

Molecules are never completely rigid. In a more realistic model of a diatomic molecule we represent the connection between atoms not as a rigid rod but as a *spring* (Fig. 42.6). Then in addition to rotating, the atoms of the molecule can *vibrate* about their equilibrium positions along the line joining them. For small oscillations the restoring force can be taken as proportional to the displacement from the equilibrium separation r_0 (like a spring that obeys Hooke's law with a force constant k'), and the system is a harmonic oscillator. We discussed the quantum-mechanical harmonic oscillator in Section 40.4. The energy levels are given by Eq. (40.25), with the mass m replaced with the reduced mass m_r:

$$E_n = \left(n + \frac{1}{2}\right)\hbar\omega = \left(n + \frac{1}{2}\right)\hbar\sqrt{\frac{k'}{m_r}} \qquad (n = 0, 1, 2, \ldots) \tag{42.7}$$

(vibrational energy levels of a diatomic molecule)

42.7 The ground level and first three excited vibrational levels for a diatomic molecule, assuming small oscillations. The levels are equally spaced, with spacing $\Delta E = \hbar\omega$.

This represents a series of levels equally spaced in energy, with an energy separation of

$$\Delta E = \hbar\omega = \hbar\sqrt{\frac{k'}{m_r}} \tag{42.8}$$

Figure 42.7 is an energy-level diagram showing these vibrational levels. (Compare Fig. 40.18.)

CAUTION **Watch out for k, k' and K** We're again using k' for the force constant, this time to minimise confusion with Boltzmann's constant k, the gas constant per molecule (introduced in Section 18.3). Besides the quantities k and k', we also use the absolute temperature unit 1 K = 1 kelvin.

Example 42.3 Force constant of carbon monoxide

For the carbon monoxide molecule of Example 42.2, the spacing of vibrational energy levels is found to be $\Delta E = 0.2690$ eV. Find the force constant k' for the interatomic force.

SOLUTION

IDENTIFY: The key idea of this problem is that the vibrational energy levels of a diatomic molecule have a uniform spacing ΔE that depends on the force constant of the 'spring' force that holds the molecule together.

SET UP: We are given the value of ΔE, so we solve Eq. (42.8) for the force constant k' (our target variable).

EXECUTE: From Eq. (42.8),

$$k' = m_r\left(\frac{\Delta E}{\hbar}\right)^2 = (1.139 \times 10^{-26}\,\text{kg})\left(\frac{0.2690\,\text{eV}}{6.582 \times 10^{-16}\,\text{eV}\cdot\text{s}}\right)^2$$
$$= 1902\,\text{N/m}$$

EVALUATE: This corresponds to a fairly loose spring; to stretch a macroscopic spring with this force constant by 1.0 cm would require a pull of 19 N. Force constants for diatomic molecules are typically about 100 to 2000 N/m.

Rotation and Vibration Combined

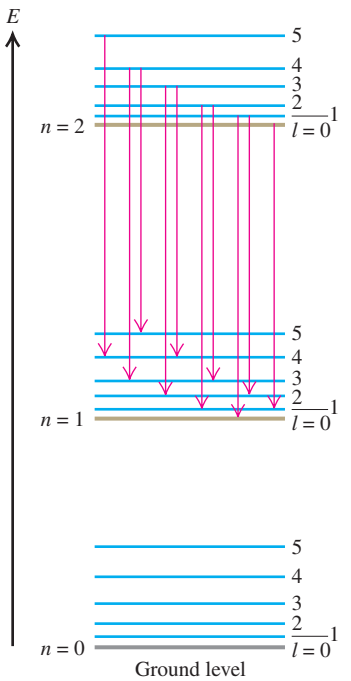
Visible-light photons have energies between 1.77 eV and 3.10 eV. The 0.2690 eV energy difference in Example 42.3 corresponds to a photon in the infrared region of the spectrum, though closer to the visible region than the photon in the *rotational* transition in Example 42.2. Vibrational energy differences, while usually much smaller than those that produce atomic spectra, are usually much *larger* than the rotational energy differences.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

When we include *both* rotational and vibrational energies, the energy levels for our diatomic molecule are

$$E_{nl} = l(l+1)\frac{\hbar^2}{2I} + \left(n + \frac{1}{2}\right)\hbar\sqrt{\frac{k'}{m_r}} \qquad (42.9)$$

The energy-level diagram is shown in Fig. 42.8. For each value of n there are many values of l, forming a series of closely spaced levels.



The arrows in Fig. 42.8 show several possible transitions in which a molecule goes from a level with $n = 2$ to a level with $n = 1$ by emitting a photon. Because the photon carries angular momentum, these molecular transitions obey a *selection rule* (see Section 41.3). This rule states that the angular momentum quantum number l must either increase by 1 or decrease by 1: $\Delta l = \pm 1$. An additional selection rule states that if the vibrational level changes, the vibrational quantum number n in Eq. (42.9) must increase by 1 $(\Delta n = 1)$ if a photon is absorbed or decrease by 1 $(\Delta n = -1)$ if a photon is emitted.

As an illustration of these selection rules, Fig. 42.8 shows that a molecule in the $n = 2$, $l = 4$ level can emit a photon and drop into the $n = 1$, $l = 5$ level $(\Delta n = -1, \Delta l = +1)$ or the $n = 1$, $l = 3$ level $(\Delta n = -1, \Delta l = -1)$, but is forbidden from making a $\Delta n = -1$, $\Delta l = 0$ transition into the $n = 1$, $l = 4$ level.

Transitions between states with various pairs of n-values give different series of spectrum lines, and the resulting spectrum has a series of *bands*. Each band corresponds to a particular vibrational transition, and each individual line in a band represents a particular rotational transition, with the selection rule $\Delta l = \pm 1$. A typical *band spectrum* is shown in Fig. 42.9.

All molecules can have excited states of the *electrons* in addition to the rotational and vibrational states that we have described. In general, these lie at higher energies than the rotational and vibrational states, and there is no simple rule relating them. When there is a transition between electronic states, the $\Delta n = \pm 1$ selection rule for the vibrational levels no longer holds.

42.8 Energy-level diagram for vibrational and rotational energy levels of a diatomic molecule. For each vibrational level (n) there is a series of more closely spaced rotational levels (l). Several transitions corresponding to a single band in a band spectrum are shown. These transitions obey the selection rule $\Delta l = \pm 1$.

42.9 A typical molecular band spectrum.

Example 42.4 Vibration-rotation spectrum of carbon monoxide

Again consider the CO molecule of Examples 42.2 and 42.3. Find the photon wavelength that is emitted when there is a change in its vibrational energy and its rotational energy is (a) initially zero and (b) finally zero.

SOLUTION

IDENTIFY: This problem uses the selection rules for the vibrational and rotational transitions of a diatomic molecule.

SET UP: In either case the energy of the emitted photon equals the difference between the initial and final energies of the molecule. Since a photon is emitted as the vibrational energy changes, the vibrational quantum number decreases by 1. For the case in part (a) the initial value of l is zero (no rotational energy), so the selection rule $\Delta l = \pm 1$ tells us that the *final* value of l is 1. For the case in part (b) the *final* value of l is zero, so the same selection rule tells us that the *initial* value of l is 1. Hence in part (a) the photon energy E is equal to the difference $\hbar\omega$ between adjacent vibrational energy levels *minus* the amount of rotational energy that the molecule *gains*, while in part (b) E is equal to $\hbar\omega$ *plus* the amount of rotational energy that the molecules *loses*. We use the results of Examples 42.2 and 42.3 to tell us the rotational and vibrational energy changes, respectively, and we use $E = hc/\lambda$ to determine the wavelengths (our target variables).

EXECUTE: (a) From Example 42.2 the energy difference between the $l = 0$ and $l = 1$ rotational levels of CO is 0.479 meV = 0.000479 eV, and from Example 42.3 the energy difference

Continued

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

between adjacent vibrational levels is 0.2690 eV. Hence the energy of this emitted photon is 0.2690 eV − 0.000479 eV = 0.2685 eV, and the photon wavelength is

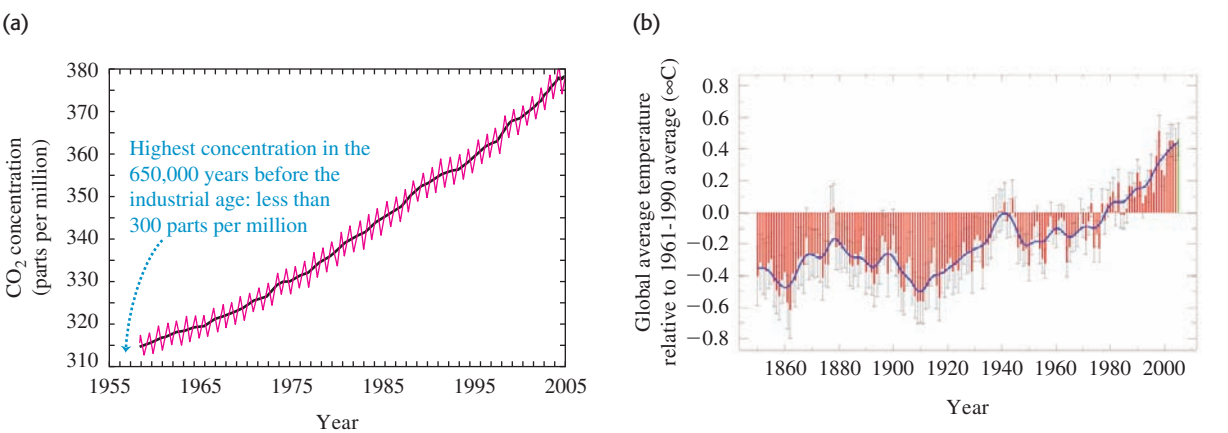
$$\lambda = \frac{hc}{E} = \frac{(4.136 \times 10^{-16}\ \text{eV} \cdot \text{s})(2.998 \times 10^{8}\ \text{m/s})}{0.2685\ \text{eV}}$$
$$= 4.618 \times 10^{-6}\ \text{m} = 4.618\ \mu\text{m}$$

(b) Now the photon has 0.2690 eV from the decrease in vibrational energy and 0.000479 eV from the decrease in rotational energy for a total of $E = 0.2695$ eV for the photon. The photon's wavelength is then

$$\lambda = \frac{hc}{E} = \frac{(4.136 \times 10^{-16}\ \text{eV} \cdot \text{s})(2.998 \times 10^{8}\ \text{m/s})}{0.2695\ \text{eV}}$$
$$= 4.601 \times 10^{-6}\ \text{m} = 4.601\ \mu\text{m}$$

EVALUATE: In part (b) the molecule loses more energy than it does in part (a), so the emitted photon must have greater energy and a shorter wavelength. This is just what our results show.

Complex Molecules



We can apply these same principles to more complex molecules. A molecule with three or more atoms has several different kinds or *modes* of vibratory motion. Each mode has its own set of energy levels, related to its frequency by Eq. (42.7). In nearly all cases the associated radiation lies in the infrared region of the electromagnetic spectrum.

Infrared spectroscopy has proved to be an extremely valuable analytical tool. It provides information about the strength, rigidity and length of molecular bonds and the structure of complex molecules. Also, because every molecule (like every atom) has its characteristic spectrum, infrared spectroscopy can be used to identify unknown compounds.

One molecule that can readily absorb and emit infrared radiation is carbon dioxide (CO_2), which is the fourth most abundant constituent of the earth's atmosphere (after nitrogen, oxygen and argon). This has important consequences for our planet's climate. To be in thermal equilibrium, the earth—which acts as a blackbody (see Section 38.8)—must radiate as much energy into space as it receives from the sun. The earth's surface temperature is such that most of the radiated energy is in the infrared part of the spectrum. However, CO_2 in the atmosphere absorbs some of this infrared radiation and re-radiates it towards the earth rather than allowing it to escape into space. In order to maintain thermal equilibrium, the earth's surface must compensate by increasing its temperature T and hence its total output of radiation (which is proportional to T^4). This means that our planet's surface temperature is higher than it would be if there were no atmospheric CO_2.

Measurements of air trapped in ancient Antarctic ice shows that over the past 650 000 years CO_2 has constituted less than 300 parts per million of our atmosphere. Since the beginning of the industrial age, however, the burning of fossil fuels such as coal and petroleum has elevated the atmospheric CO_2 concentration to unprecedented levels (Fig. 42.10a). As a consequence, since the 1950s the global

42.10 (a) The concentration of atmospheric CO_2 has increased by 18% since continuous measurements began in 1958. (The yearly variations are due to increased intake of CO_2 by plants in spring and summer.) (b) The increase in global average temperature since the beginning of the industrial era is a result of the increase in CO_2 concentration.

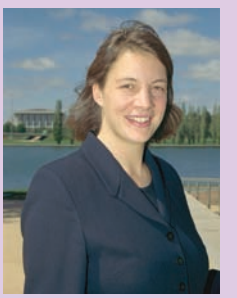
Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

average surface temperature has increased by 0.6°C and the earth has experienced the hottest years ever recorded (Fig. 42.10b). If we continue to consume fossil fuels at the same rate, by 2050 the atmospheric CO_2 concentration will reach 600 parts per million, well off the scale of Fig 42.10a. The resulting temperature increase in the polar regions will cause massive quantities of ice to melt and run from solid land to the sea, thus raising ocean levels worldwide and threatening the homes and lives of hundreds of millions of people who leave near the coast. Coping with this threat is one of the greatest challenges facing 21st century civilisation.

Test Your Understanding of Section 42.2 A rotating diatomic molecule emits a photon when it makes a transition from level l to level $l - 1$. If the value of l increases, does the wavelength of the emitted photon (i) increase, (ii) decrease, or (iii) remain unchanged?

42.3 Structure of Solids

The term *condensed matter* includes both solids and liquids. In both states, the interactions between atoms or molecules are strong enough to give the material a definite volume that changes relatively little with applied stress. In condensed matter, adjacent atoms attract one another until their outer electron charge clouds begin to overlap significantly. Thus the distances between adjacent atoms in condensed matter are about the same as the diameters of the atoms themselves, typically 0.1 to 0.5 nm. Also, when we speak of the distances between atoms, we mean the centre-to-centre (nucleus-to-nucleus) distances.



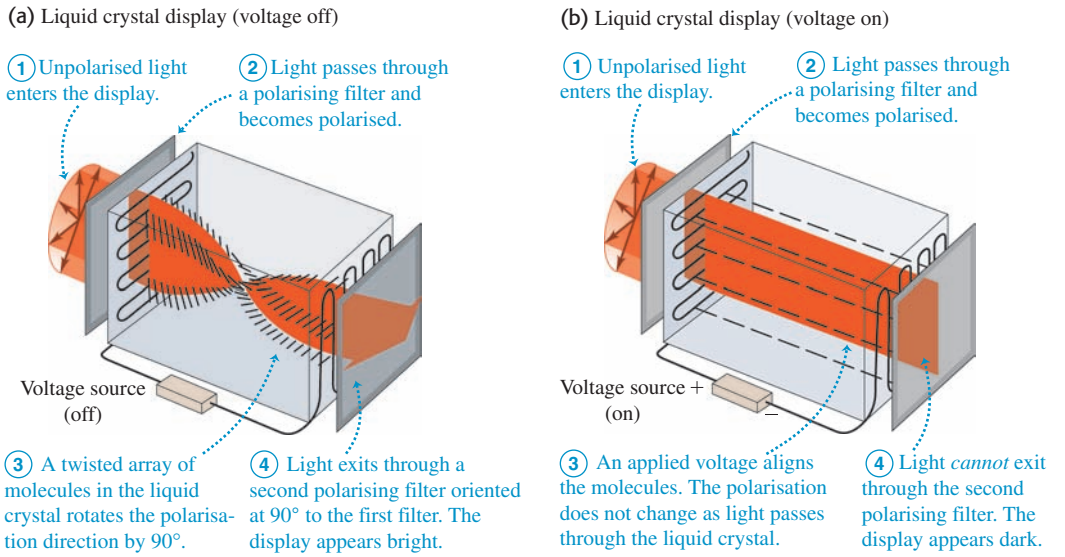
Ordinarily, we think of a liquid as a material that can flow and of a solid as a material with a definite shape. However, if you heat a horizontal glass rod in the flame of a burner, you'll find that the rod begins to sag (flow) more and more easily as its temperature rises. Glass has no definite transition from solid to liquid, and no definite melting point. On this basis, we can consider glass at room temperature as being an extremely viscous liquid. Tar and butter show similar behaviour.

What is the microscopic difference between materials like glass or butter and solids like ice or copper, which do have definite melting points? Ice and copper are examples of *crystalline solids* in which the atoms have *long-range order*, a recurring pattern of atomic positions that extends over many atoms. This pattern is called the *crystal structure*. In contrast, glass at room temperature is an example of an *amorphous* solid, one that has no long-range order, but only *short-range order* (correlations between neighbouring atoms or molecules). Liquids also have only short-range order. The boundaries between crystalline solid, amorphous solid and liquid may be sometimes blurred. Some solids, crystalline when perfect, can form with so many imperfections in their structure that they have almost no long-range order. Conversely, some liquids have a fairly high degree of long-range order; a familiar example is the type of *liquid crystal* illustrated in Fig. 42.11 (next page).

Nearly everything we know about crystal structure has been learned from diffraction experiments, initially with x-rays and later with electrons and neutrons. A typical

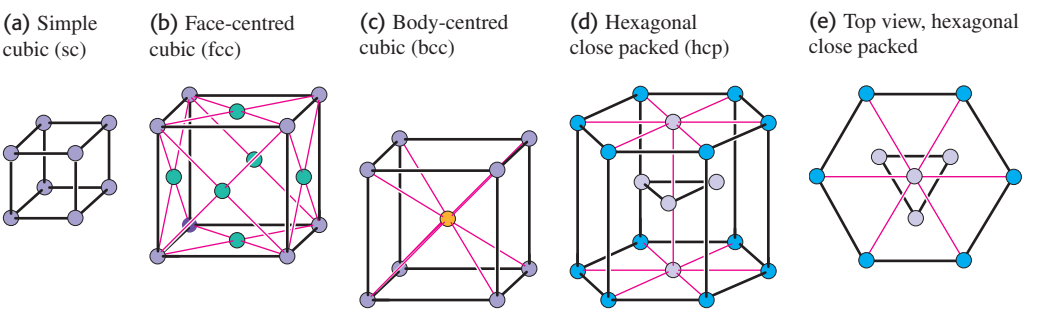
FRONTIERS OF RESEARCH

MICHELLE SIMMONS
University of New South Wales



Professor Simmons is a Federation Fellow, Professor of Physics and Director of the Atomic Fabrication Facility at the UNSW. In the 1990s she spent 6 years as a Research Fellow working with Professor Sir Michael Pepper FRS at the Cavendish Laboratory in Cambridge, UK, in quantum electronics, where she gained an international reputation for her work in the discovery of the '0.7 feature' and the development of 'hole' transistors. In 1999, she was awarded a QEII Fellowship and came to Australia where she was a founding member of the Centre of Excellence for Quantum Computer Technology.

Since 2000 she has established a large research group which has developed the world's thinnest conducting doped wires in silicon and the ability to manipulate and electronically measure devices with atomically precise dopant placement. She has published more than 300 papers in refereed journals, published a book on Nanotechnology, four book chapters on quantum electronics, has filed four patents and has presented over 50 invited and plenary presentations at international conferences. She has been the Chair of the Australian Research Council's Expert Advisory Committee for Physics, Chemistry and Geoscience. In 2005 she was awarded the Pawsey Medal by the Australian Academy of Science and in 2006 became the one of the youngest elected Fellows of this Academy.



She is currently Chair of the Australian Academy's National Committee for Physics, an Associate Editor of *IEEE Journal for Nanotechnology* and has recently been recognised by the *Bulletin* and *Cosmos* magazines as one of Australia's top ten scientific minds under the age of 45. In 2008 she was awarded a second Federation Fellowship by the Australian Government.

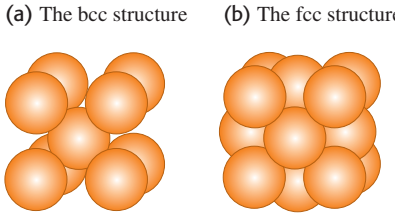
42.11 A simple version of a liquid-crystal display (LCD). A thin layer of liquid crystal—an organic compound whose cylindrical molecules tend to line up parallel to each other—is confined between two parallel glass plates and placed between two crossed polarising filters. (a) The molecules tend to align with fine scratches on the glass plates, twisting them so that the light can pass through the second polarising filter. (b) Each glass plate also has a pattern of fine electrodes. When a voltage is applied between the plates, the molecules align with the electric field and the light does not pass through the second polarising filter. Hence switching the voltage on changes the display from light to dark.

42.12 Portions of some common types of crystal lattices.



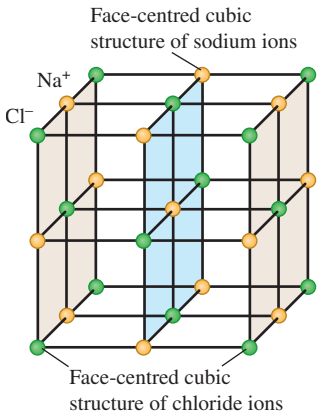
distance between atoms is of the order of 0.1 nm. You can show that 12.4 keV x-rays, 150 eV electrons and 0.0818 eV neutrons all have wavelengths $\lambda = 0.1$ nm.

Crystal Lattices and Structures

A *crystal lattice* is a repeating pattern of mathematical points that extends throughout space. There are 14 general types of such patterns; Fig. 42.12 (next page) shows small portions of some common examples. The *simple cubic lattice* (sc) has a lattice point at each corner of a cubic array (Fig. 42.12a). The *face-centred cubic lattice* (fcc) is like the simple cubic but with an additional lattice point at the centre of each cube face (Fig. 42.12b). The *body-centred cubic lattice* (bcc) is like the simple cubic but with an additional point at the centre of each cube (Fig. 42.12c). The *hexagonal close-packed lattice* has layers of lattice points in hexagonal patterns, each hexagon made up of six equilateral triangles (Figs. 42.12d and 42.12e).

42.13 (a) The bcc *structure* is composed of a bcc *lattice* with a basis of one atom for each lattice point. (b) The fcc *structure* is composed of an fcc *lattice* with a basis of one atom for each lattice point. These structures repeat precisely to make up perfect crystals.

CAUTION **A perfect crystal lattice is infinitely large** Figure 42.12 shows just enough lattice points so you can easily visualise the pattern; the lattice, a mathematical abstraction, extends throughout space. Thus the lattice points shown repeat endlessly in all directions.



Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

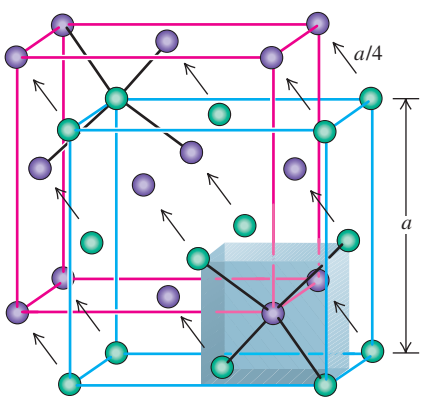
In a crystal structure, a single atom or a group of atoms is associated with *each* lattice point. The group may contain the same or different kinds of atoms. This atom or group of atoms is called a *basis*. Thus a complete description of a crystal structure includes both the lattice and the basis. We initially consider *perfect crystals*, or *ideal single crystals*, in which the crystal structure extends uninterrupted throughout space.

The bcc and fcc structures are two common simple crystal structures. The alkali metals have a bcc structure—that is, a bcc lattice with a basis of one atom at each lattice point. Each atom in a bcc structure has eight nearest neighbours (Fig. 42.13a). The elements Al, Ca, Cu, Ag and Au have an fcc structure—that is, an fcc lattice with a basis of one atom at each lattice point. Each atom in an fcc structure has 12 nearest neighbours (Fig. 42.13b).

Figure 42.14 shows a representation of the structure of sodium chloride (NaCl, ordinary salt). It may look like a simple cubic structure, but it isn't. The sodium and chloride ions each form an fcc structure, so we can think roughly of the sodium chloride structure as being composed of two interpenetrating fcc structures. More correctly, the sodium chloride crystal structure of Fig. 42.14 has an fcc lattice with one chloride ion at each lattice point and one sodium ion half a cube length above it. That is, its basis consists of one chloride and one sodium ion.

42.14 Representation of part of the sodium chloride crystal structure. The distances between ions are exaggerated.

Another example is the *diamond structure*; it's called that because it is the crystal structure of carbon in the diamond form (Fig. 42.15). It's also the crystal structure of silicon, germanium and gray tin (all four are Group IV elements in the periodic table). The diamond lattice is fcc; the basis consists of one atom at each lattice point and a second *identical* atom displaced a quarter of a cube length in each of the three cube-edge directions. Figure 42.16 will help you visualise this. The shaded volume in Fig. 42.16 shows the bottom right front eighth of the basic cube; the four atoms at alternate corners of this cube are at the corners of a regular tetrahedron, and there is an additional atom at the centre. Thus each atom in the diamond structure is at the centre of a regular tetrahedron with four nearest-neighbour atoms at the corners.



42.15 The crystal structure of diamond is similar to that of many other, less highly coveted materials. What makes diamond unique are its beautiful optical properties. A large index of refraction makes diamond sparkle due to total internal reflection, and a large amount of dispersion turns white light into a rainbow of colours.

In the diamond structure, both the purple and green spheres in Fig. 42.16 represent *identical* atoms—for example, both carbon or both silicon. In the cubic zinc sulphide structure, the purple spheres represent one type of atom and the green spheres represent a *different* type. For example, in zinc sulphide (ZnS) each zinc atom (purple in Fig. 42.16) is at the centre of a regular tetrahedron with four sulphur atoms (green in Fig. 42.16) at its corners, and vice versa. Gallium arsenide (GaAs) and similar compounds have this same structure.

Bonding in Solids

The forces that are responsible for the regular arrangement of atoms in a crystal are the same as those involved in molecular bonds, plus one additional type. Not surprisingly, *ionic* and *covalent* molecular bonds are found in ionic and covalent crystals, respectively. The most familiar *ionic crystals* are the alkali halides, such

42.16 The diamond structure, shown as two interpenetrating face-centred cubic structures with distances between atoms exaggerated. Relative to the corresponding green atom, each purple atom is shifted up, back and to the left by a distance $a/4$.

as ordinary salt (NaCl). The positive sodium ions and the negative chloride ions occupy alternate positions in a cubic arrangement (Fig. 42.14). The attractive forces are the familiar Coulomb's-law forces between charged particles. These forces have no preferred direction, and the arrangement in which the material crystallises is partly determined by the relative sizes of the two ions. Such a structure is *stable* in the sense that it has lower total energy than the separated ions (see the following example). The negative potential energies of pairs of opposite charges are greater in absolute value than the positive energies of pairs of like charges because the pairs of unlike charges are closer together, on average.

Example 42.5 Potential energy of an ionic crystal

Consider a fictitious one-dimensional ionic crystal consisting of a very large number of alternating positive and negative ions with charges e and $-e$, with equal spacing a along a line. Prove that the total interaction potential energy is negative.

SOLUTION

IDENTIFY: We can treat each ion as a point charge and then use our result from Section 23.1 for the electric potential energy of a collection of point charges.

SET UP: Equations (23.10) and (23.11) tell us to consider the electric potential energy U of each pair of charges. The total potential energy of the system is the sum of the values of U for every possible pair.

EXECUTE: Let's pick an ion somewhere in the middle of the string and add up the potential energies of its interactions with all the ions to one side of it. We get the series

$$\sum U = -\frac{e^2}{4\pi\epsilon_0}\frac{1}{a} + \frac{e^2}{4\pi\epsilon_0}\frac{1}{2a} - \frac{e^2}{4\pi\epsilon_0}\frac{1}{3a} + \cdots$$
$$= -\frac{e^2}{4\pi\epsilon_0 a}\left(1 - \frac{1}{2} + \frac{1}{3} - \frac{1}{4} + \cdots\right)$$

You may notice the resemblance of the series in parentheses to the Taylor series for $\ln(1 + x)$:

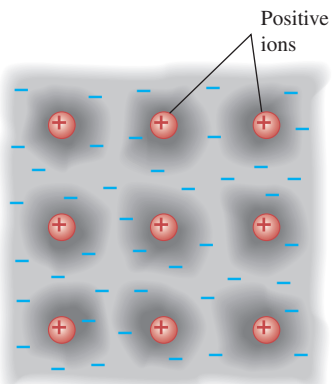
$$\ln(1 + x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4} + \cdots$$

When $x = 1$, we have the series in the parentheses, and

$$\sum U = -\frac{e^2}{4\pi\epsilon_0 a}\ln 2$$

This is certainly a negative quantity. The atoms on the other side of the ion that we're considering make an equal contribution to the potential energy. And if we include the potential energies of all pairs of atoms, the sum is certainly negative.

EVALUATE: We conclude that this structure is stable: It has lower energy than the zero electric potential energy that is obtained when all the ions are infinitely separated from each other.



Types of Crystals

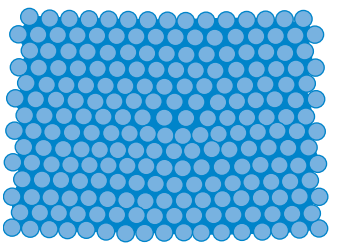
Carbon, silicon, germanium and tin in the diamond structure are simple examples of *covalent crystals*. These elements are in Group IV of the periodic table, meaning that each atom has four electrons in its outermost shell. Each atom forms a covalent bond with each of four adjacent atoms at the corners of a tetrahedron (Fig. 42.16). These bonds are strongly directional because of the asymmetrical electron distributions dictated by the exclusion principle, and the result is the tetrahedral diamond structure.

A third crystal type, less directly related to the chemical bond than are ionic or covalent crystals, is the **metallic crystal**. In this structure, one or more of the outermost electrons in each atom become detached from the parent atom (leaving a positive ion) and are free to move through the crystal. These electrons are not localised near the individual ions. The corresponding electron wave functions extend over many atoms.

Thus we can picture a metallic crystal as an array of positive ions immersed in a sea of freed electrons whose attraction for the positive ions holds the crystal together (Fig. 42.17). These electrons also give metals their high electrical and thermal conductivities. This sea of electrons has many of the properties of a gas, and indeed we speak of the *electron-gas model* of metallic solids. The simplest version of this model is the *free-electron model*, which ignores interactions with the ions completely (except at the surface). We'll return to this model in Section 42.5.

42.17 In a metallic solid, one or more electrons are detached from each atom and are free to wander around the crystal, forming an 'electron gas'. The wave functions for these electrons extend over many atoms. The positive ions vibrate around fixed locations in the crystal.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition



In a metallic crystal the freed electrons are not localised but are shared among *many* atoms. This gives a bonding that is neither localised nor strongly directional. The crystal structure is determined primarily by considerations of *close packing*—that is, the maximum number of atoms that can fit into a given volume. The two most common metallic crystal lattices, the face-centred cubic and the hexagonal close-packed, are shown in Figs. 42.12b, 42.12d and 42.12e. In structures composed of these lattices with a basis of one atom, each atom has 12 nearest neighbours.

As we mentioned in Section 42.1, van der Waals interactions and hydrogen bonding also play a role in the structure of some solids. In polyethylene and similar polymers, covalent bonding of atoms forms long-chain molecules, and hydrogen bonding forms cross-links between adjacent chains. In solid water, both van der Waals forces and hydrogen bonds are significant in determining the crystal structures of ice.

Our discussion has centred on perfect crystals, or ideal single crystals. Real crystals show a variety of departures from this idealised structure. Materials are often *polycrystalline*, composed of many small single crystals bonded together at *grain boundaries*. There may be *point defects* within a single crystal: *interstitial* atoms may occur in places where they do not belong, and there may be *vacancies*, positions that should be occupied by an atom but are not. A point defect of particular interest in semiconductors, which we will discuss in Section 42.6, is the *substitutional impurity*, a foreign atom replacing a regular atom (for example, arsenic in a silicon crystal).

There are several basic types of extended defects called *dislocations*. One type is the *edge dislocation*, shown schematically in Fig. 42.18, in which one plane of atoms slips relative to another. The mechanical properties of metallic crystals are influenced strongly by the presence of dislocations. The ductility and malleability of some metals depend on the presence of dislocations that can move through the crystal during plastic deformations. Solid-state physicists often point out that the biggest extended defect of all, present in *all* real crystals, is the surface of the material with its dangling bonds and abrupt change in potential energy.

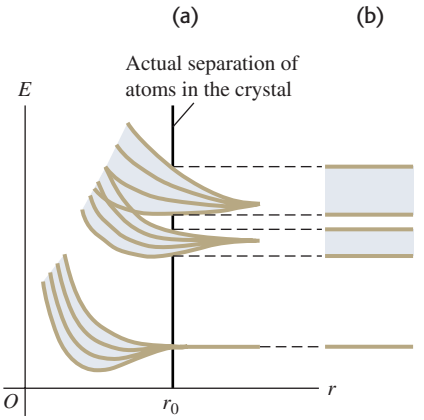
42.18 An edge dislocation in two dimensions. In three dimensions an edge dislocation would look like an extra plane of atoms slipped partway into the crystal.

The irregularity is seen most easily by viewing the figure from various directions at a grazing angle with the page.

Test Your Understanding of Section 42.3 If a is the distance in an NaCl crystal from an Na^+ ion to one of its nearest-neighbour Cl^- ions, what is the distance from an Na^+ ion to one of its *next-to-nearest*-neighbour Cl^- ions? (i) $a\sqrt{2}$; (ii) $a\sqrt{3}$; (iii) $2a$ (iv) none of these.

42.4 Energy Bands

The **energy-band** concept, introduced in 1928 (Fig. 42.19), is a great help in understanding several properties of solids. To introduce the idea, suppose we have a large number N of identical atoms, far enough apart that their interactions are negligible. Every atom has the same energy-level diagram. We can draw an energy-level diagram for the *entire system*. It looks just like the diagram for a single atom, but the exclusion principle, applied to the entire system, permits each state to be occupied by N electrons instead of just one.



Now we begin to push the atoms uniformly closer together. Because of the electrical interactions and the exclusion principle, the wave functions begin to distort, especially those of the outer, or *valence*, electrons. The corresponding energies also shift, some upward and some downward, by varying amounts, as the valence electron wave functions become less localised and extend over more and more atoms. Thus the valence states that formerly gave the *system* a state with a sharp energy level that could accommodate N electrons now give a *band* containing N closely spaced levels (Fig. 42.20, next page). Ordinarily, N is very large, somewhere near the order of Avogadro's number (10^{24}), so we can accurately treat the levels as forming a *continuous* distribution of energies within a

42.19 The concept of energy bands was first developed by the Swiss-American physicist Felix Bloch (1905–1983) in his doctoral thesis. Our modern understanding of electrical conductivity stems from that landmark work. Bloch's work in nuclear physics brought him (along with Edward Purcell) the 1952 Nobel Prize in physics.

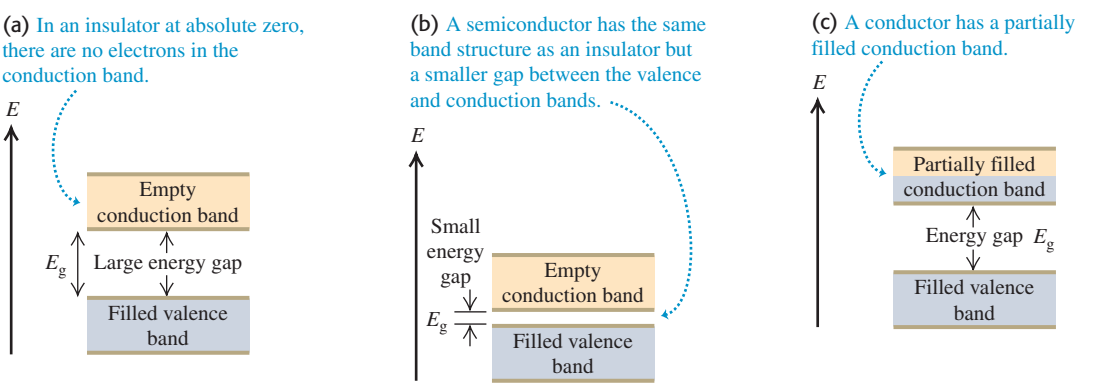
42.20 Origin of energy bands in a solid. (a) As the distance r between atoms decreases, the energy levels spread into bands. The vertical line at r_0 shows the actual atomic spacing in the crystal. (b) Symbolic representation of energy bands.

band. Between adjacent energy bands are gaps or forbidden regions where there are *no* allowed energy levels. The inner electrons in an atom are affected much less by nearby atoms than are the valence electrons, and their energy levels remain relatively sharp.

Insulators, Semiconductors and Conductors



The nature of the energy bands determines whether the material is an electrical insulator, a semiconductor or a conductor. In particular, what matters are the extent to which the states in each band are occupied and the spacing, or *energy gap*, between adjacent bands. A crucial factor is the exclusion principle (see Section 41.4), which states that only one electron can occupy a given quantum-mechanical state.

In an *insulator* at absolute zero temperature, the highest band that is completely filled, called the **valence band**, is also the highest band that has *any* electrons in it. The next higher band, called the **conduction band**, is completely empty; there are no electrons in its states (Fig. 42.21a). Imagine what happens if an electric field is applied to a material of this kind. To move in response to the field, an electron would have to go into a different quantum state with a slightly different energy. It can't do that, however, because all the neighbouring states are already occupied. The only way such an electron can move is to jump across the energy gap into the conduction band, where there are plenty of nearby unoccupied states. At any temperature above absolute zero there is some probability this jump can happen, because an electron can gain energy from thermal motion. In an insulator, however, the energy gap between the valence and conduction bands can be 5 eV or more, and that much thermal energy is not ordinarily available. Hence little or no current flows in response to an applied electric field, and the electric conductivity (Section 25.2) is low. The thermal conductivity (Section 17.7), which also depends on mobile electrons, is likewise low.

We saw in Section 24.4 that an insulator becomes a conductor if it is subjected to a large enough electric field; this is called *dielectric breakdown*. If the electric field is of order 10^{10} V/m, there is a potential difference of a few volts over a distance comparable to atomic sizes. In this case the field can do enough work on a valence electron to boost it across the energy gap and into the conduction band. (In practice, dielectric breakdown occurs for fields much less than 10^{10} V/m, because imperfections in the structure of an insulator provide some more accessible energy states *within* the energy gap.)

As in an insulator, a *semiconductor* at absolute zero has an empty conduction band above the full valence band. The difference is that in a semiconductor the energy gap between these bands is relatively small and electrons can more readily jump into the conduction band (Fig. 42.21b). As the temperature of a semiconductor increases, the population in the conduction band increases very rapidly, as does the electric conductivity. For example, in a semiconductor near

42.21 Three types of energy-band structure.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

room temperature with an energy gap of 1 eV, the number of conduction electrons doubles when the temperature rises by just 10°C. We will use the concept of energy bands to explore semiconductors in more depth in Section 42.6.

In a *conductor* such as a metal, there are electrons in the conduction band even at absolute zero (Fig. 42.21c). The metal sodium is an example. An analysis of the atomic energy-level diagram for sodium (Fig. 38.10a) shows that for an isolated sodium atom, the six lowest excited states (all 3*p* states) are about 2.1 eV above the two 3*s* ground states. In solid sodium, however, the atoms are so close together that the 3*s* and 3*p* *bands* spread out and overlap into a single band. Each sodium atom contributes one electron to the band, leaving an Na^+ ion behind. Each atom also contributes eight *states* to that band (two 3*s*, six 3*p*), so the band is only one-eighth occupied. We call this structure a *conduction* band because it is only partially occupied. Electrons near the top of the filled portion of the band have many adjacent unoccupied states available, and they can easily gain or lose small amounts of energy in response to an applied electric field. Therefore these electrons are mobile, giving solid sodium its high electrical and thermal conductivity. A similar description applies to other conducting materials.

Example 42.6 Photoconductivity in germanium

Even at room temperature, pure germanium has an almost completely filled valence band separated by a gap of 0.67 eV from an almost completely empty conduction band. It is a poor electrical conductor, but its conductivity increases substantially when it is irradiated with electromagnetic waves of a certain maximum wavelength. What maximum wavelength is appropriate?

SOLUTION

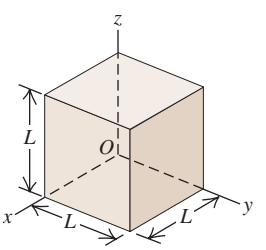
IDENTIFY: The conductivity of a semiconductor increases greatly when electrons are excited from the valence band into the conduction band. In this example, the excitation occurs when an electron absorbs a photon with an energy of at least E_{min}.

SET UP: From the relationship $E = hc/\lambda$ for photons, the *maximum* wavelength corresponds to the *minimum* photon energy.

EXECUTE: An electron at the top of the valence band can absorb a photon with energy of 0.67 eV (no less) and move to the bottom of the conduction band, where it is a mobile charge. Thus the maximum wavelength is

$$\lambda_{\text{max}} = \frac{hc}{E_{\text{min}}} = \frac{(4.136 \times 10^{-15}\ \text{eV} \cdot \text{s})(3.00 \times 10^{8}\ \text{m/s})}{0.67\ \text{eV}}$$
$$= 1.9 \times 10^{-6}\ \text{m} = 1.9\ \mu\text{m} = 1900\ \text{nm}$$

EVALUATE: This wavelength is in the infrared part of the spectrum, so visible-light photons (which have shorter wavelength) will also induce conductivity in germanium. As we will see in Section 42.7, semiconductor crystals are widely used as photocells as well as for many other applications.



Test Your Understanding of Section 42.4 One type of thermometer works by measuring the temperature-dependent electrical resistivity of a sample. Which of the following types of material displays the greatest change in resistivity for a given temperature change? (i) insulator; (ii) semiconductor; (iii) resistor.

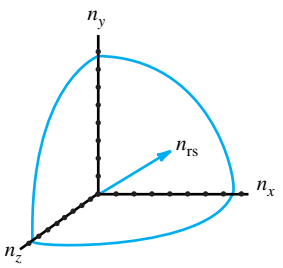
42.5 Free-Electron Model of Metals

Studying the energy states of electrons in metals can give us a lot of insight into their electrical and magnetic properties, the electron contributions to heat capacities, and other behaviour. As we discussed in Section 42.3, one of the distinguishing features of a metal is that one or more valence electrons are detached from their home atom and can move freely within the metal, with wave functions that extend over many atoms.

The **free-electron model** assumes that these electrons are completely free inside the material, that they don't interact at all with the ions or with each other, but that there are infinite potential-energy barriers at the surfaces. The wave functions and energy levels are then the three-dimensional versions of those for the particle in a box that we analysed in Section 40.1 in one dimension. Suppose the box is a cube with side length L (Fig. 42.22). Then the possible wave functions, analogous to Eq. (40.10), are

42.22 A cubical box with rigid walls and side length L. This is the three-dimensional version of the infinite square well discussed in Section 40.1. The energy levels for a particle in this box are given by Eq. (42.11).

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition



$$\psi(x, y, z) = A \sin\frac{n_x \pi x}{L} \sin\frac{n_y \pi y}{L} \sin\frac{n_z \pi z}{L} \tag{42.10}$$

where (n_x, n_y, n_z) is a set of three positive-integer quantum numbers that identify the state. We invite you to verify that these functions are zero at the surfaces of the cube, satisfying the boundary conditions. You can also substitute Eq. (42.10) into the three-dimensional Schrödinger equation, Eq. (40.28), with $U = 0$ to show that the energies of the states are

$$E = \frac{(n_x^2 + n_y^2 + n_z^2)\pi^2\hbar^2}{2mL^2} \tag{42.11}$$

This equation is the three-dimensional analog of Eq. (40.9) for the energy levels of a particle in a box.

42.23 The allowed values of n_x, n_y and n_z are positive integers for the electron states in the free-electron gas model. Including spin, there are two states for each unit volume in n space.

Density of States

Later we'll need to know the *number* dn of quantum states that have energies in a given range dE. The number of states per unit energy range dn/dE is called the **density of states**, denoted by $g(E)$. We'll begin by working out an expression for $g(E)$. Think of a three-dimensional space with coordinates (n_x, n_y, n_z) (Fig. 42.23). The radius n_{rs} of a sphere centred at the origin in that space is given by $n_{rs}^2 = n_x^2 + n_y^2 + n_z^2$. Each point with integer coordinates in that space represents one spatial quantum state. Thus each point corresponds to one unit of volume in the space, and the total number of points with integer coordinates inside a sphere equals the volume of the sphere, $\frac{4}{3}\pi n_{rs}^3$. Because all our n's are positive, we must take only one *octant* of the sphere, with $\frac{1}{8}$ the total volume, or $\left(\frac{1}{8}\right)\left(\frac{4}{3}\pi n_{rs}^3\right) = \frac{1}{6}\pi n_{rs}^3$. The particles are electrons, so each point corresponds to *two* states with opposite spin components $\left(m_s = \pm\frac{1}{2}\right)$, and the total number n of electron states corresponding to points inside the octant is twice $\frac{1}{6}\pi n_{rs}^3$, or

$$n = \frac{\pi n_{rs}^3}{3} \tag{42.12}$$

The energy E of states at the surface of the sphere can be expressed in terms of n_{rs}. Equation (42.11) becomes

$$E = \frac{n_{rs}^2 \pi^2 \hbar^2}{2mL^2} \tag{42.13}$$

We can combine Eqs. (42.12) and (42.13) to get a relationship between E and n that doesn't contain n_{rs}. We'll leave the details as an exercise (Exercise 42.24); the result is

$$n = \frac{(2m)^{3/2} V E^{3/2}}{3\pi^2\hbar^3} \tag{42.14}$$

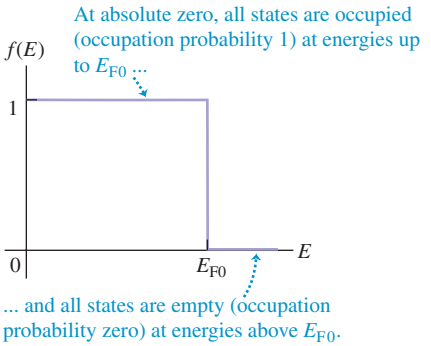
where $V = L^3$ is the volume of the box. Equation (42.14) gives the total number of states with energies of E or less.

To get the number of states dn in an energy interval dE, we treat n and E as continuous variables and take differentials of both sides of Eq. (42.14). We get

$$dn = \frac{(2m)^{3/2} V E^{1/2}}{2\pi^2\hbar^3} dE \tag{42.15}$$

The density of states $g(E)$ is equal to dn/dE, so from Eq. (42.15) we get

$$g(E) = \frac{(2m)^{3/2} V}{2\pi^2\hbar^3} E^{1/2} \qquad \text{(density of states, free-electron model)} \tag{42.16}$$



Fermi-Dirac Distribution

Now we need to know how the electrons are distributed among the various quantum states at any given temperature. The *Maxwell-Boltzmann distribution* states

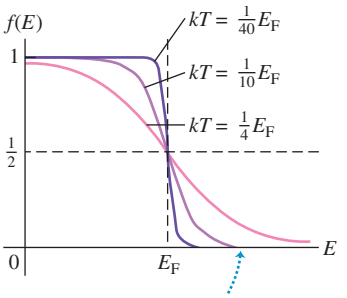
Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

that the average number of particles in a state of energy E is proportional to $e^{-E/kT}$ (see Section 38.6). However, there are two very important reasons why it wouldn't be right to use the Maxwell-Boltzmann distribution. The first reason is the *exclusion principle*. At absolute zero the Maxwell-Boltzmann function predicts that *all* the electrons would go into the two ground states of the system, with $n_x = n_y = n_z = 1$ and $m_s = \pm\frac{1}{2}$. But the exclusion principle allows only one electron in each state. At absolute zero the electrons can fill up the lowest *available* states, but there's not enough room for *all* of them to go into the lowest states. Thus a reasonable guess as to the shape of the distribution would be Fig. 42.24. At absolute zero temperature the states are filled up to some value E_{F0}, and all states above this value are empty.

42.24 The probability distribution for occupation of free-electron energy states at absolute zero.

The second reason we can't use the Maxwell-Boltzmann distribution is more subtle. That distribution assumes that we are dealing with *distinguishable* particles. It might seem that we could put a tag on each electron and know which is which. But overlapping electrons in a system such as a metal are *indistinguishable*. Suppose we have two electrons; a state in which the first is in an energy level E_1 and the second is in level E_2 is not distinguishable from a state in which the two electrons are reversed, because we can't tell which electron is which.

The statistical distribution function that emerges from the exclusion principle and the indistinguishability requirement is called (after its inventors) the **Fermi-Dirac distribution**. Because of the exclusion principle, the probability that a particular state with energy E is occupied by an electron is the same as $f(E)$, the fraction of states with that energy that are occupied:



$$f(E) = \frac{1}{e^{(E-E_F)/kT} + 1} \qquad \text{(Fermi-Dirac distribution)} \qquad (42.17)$$

The energy E_F is called the **Fermi energy** or the *Fermi level*; we'll discuss its significance below. We use E_{F0} for its value at absolute zero $(T = 0)$ and E_F for other temperatures. We can accurately let $E_F = E_{F0}$ for metals because the Fermi energy does not change much with temperature for solid conductors. However, it is not safe to assume that $E_F = E_{F0}$ for semiconductors, in which the Fermi energy usually does change with temperature.

Figure 42.25 shows graphs of Eq. (42.17) for three temperatures. The trend of this function as kT approaches zero confirms our guess. When $E = E_F$, the exponent is zero and $f(E_F) = \frac{1}{2}$. That is, the probability is $\frac{1}{2}$ that a state at the Fermi energy contains an electron. Alternatively, at $E = E_F$, half the states are filled (and half are empty).

For $E < E_F$ the exponent is negative, and $f(E) > \frac{1}{2}$. For $E > E_F$ the exponent is positive, and $f(E) < \frac{1}{2}$. The shape depends on the ratio E_F/kT. At $T \ll E_F/k$ this ratio is very large. Then for $E < E_F$ the curve very quickly approaches 1, and for $E > E_F$ it quickly approaches zero. When T is larger, the changes are more gradual. When T is zero, all the states up to the Fermi level E_{F0} are filled, and all states above that level are empty (Fig. 42.24).

42.25 Graphs of the Fermi-Dirac distribution function for various values of kT, assuming that the Fermi energy E_F is independent of the temperature T.

Example 42.7 Probabilities in the free-electron model

For free electrons in a solid, at what energy is the probability that a particular state is occupied equal to (a) 0.01 and (b) 0.99?

SOLUTION

IDENTIFY: This problem asks us to explore how the Fermi-Dirac distribution depends on temperature.

SET UP: Equation (42.17) tells us the occupation probability $f(E)$ for a given energy E. If we solve this equation for E, we get an expression for the energy that corresponds to a given occupation probability—which is just what we need to solve this problem.

EXECUTE: Solving Eq. (42.17) for E, we get

$$E = E_F + kT \ln\left(\frac{1}{f(E)} - 1\right)$$

Continued

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

(a) When $f(E) = 0.01$,

$$E = E_F + kT\ln\left(\frac{1}{0.01} - 1\right) = E_F + 4.6kT$$

A state $4.6kT$ above the Fermi level is occupied only 1% of the time.

(b) When $f(E) = 0.99$,

$$E = E_F + kT\ln\left(\frac{1}{0.99} - 1\right) = E_F - 4.6kT$$

A state $4.6kT$ below the Fermi level is occupied 99% of the time.

EVALUATE: At very low temperatures, $4.6kT$ becomes very small. Then levels even slightly below E_F are nearly always full, and levels even slightly above E_F are nearly always empty (see Fig. 42.25). In general, if the probability is P that a state with an energy ΔE *above* E_F is occupied, then the probability is $1 - P$ that a state ΔE *below* E_F is occupied. We leave the proof as a problem (Problem 42.48).

Electron Concentration and Fermi Energy

Equation (42.17) gives the probability that any specific state with energy E is occupied at a temperature T. To get the actual number of electrons in any energy range dE, we have to multiply this probability by the number dn of states in that range $g(E)\,dE$. Thus the number dN of electrons with energies in the range dE is

$$dN = g(E)f(E)\,dE = \frac{(2m)^{3/2}VE^{1/2}}{2\pi^2\hbar^3}\frac{1}{e^{(E-E_F)/kT} + 1}\,dE \qquad (42.18)$$

The Fermi energy E_F is determined by the total number N of electrons; at any temperature the electron states are filled up to a point at which all electrons are accommodated. At absolute zero there is a simple relationship between E_{F0} and N. *All* states below E_{F0} are filled; in Eq. (42.14) we set n equal to the total number of electrons N and E to the Fermi energy at absolute zero E_{F0}:

$$N = \frac{(2m)^{3/2}VE_{F0}^{3/2}}{3\pi^2\hbar^3} \qquad (42.19)$$

Solving for E_{F0}, we get

$$E_{F0} = \frac{3^{2/3}\pi^{4/3}\hbar^2}{2m}\left(\frac{N}{V}\right)^{2/3} \qquad (42.20)$$

The quantity N/V is the number of free electrons per unit volume. It is called the *electron concentration* and is usually denoted by n.

If we replace N/V with n, Eq. (42.20) becomes

$$E_{F0} = \frac{3^{2/3}\pi^{4/3}\hbar^2 n^{2/3}}{2m} \qquad (42.21)$$

CAUTION **Electron concentration and number of electrons** Don't confuse the electron concentration n with any quantum number n. Furthermore, the number of states is *not* in general the same as the total number of electrons N.

Example 42.8 The Fermi energy in copper

At low temperatures, copper has a free-electron concentration of $8.45 \times 10^{28}\ \text{m}^{-3}$. Using the free-electron model, find the Fermi energy for solid copper, and find the speed of an electron with a kinetic energy equal to the Fermi energy.

SOLUTION

IDENTIFY: This problem uses the relationship between Fermi energy and free-electron concentration.

SET UP: Because copper is a solid conductor, its Fermi energy changes very little with temperature and we can safely use the expression for the Fermi energy at absolute zero, Eq. (42.21). We determine the speed v_F that corresponds to kinetic energy E_F using the familiar nonrelativistic formula for kinetic energy.

EXECUTE: Using the given value of n,

$$E_F = \frac{3^{2/3}\pi^{4/3}(1.055 \times 10^{-34}\ \text{J}\cdot\text{s})^2(8.45 \times 10^{28}\ \text{m}^{-3})^{2/3}}{2(9.11 \times 10^{-31}\ \text{kg})}$$
$$= 1.126 \times 10^{-18}\ \text{J} = 7.03\ \text{eV}$$

To find the corresponding speed v_F, we use $E_F = \frac{1}{2}mv_F^2$:

$$v_F = \sqrt{\frac{2E_F}{m}} = \sqrt{\frac{2(1.126 \times 10^{-18}\ \text{J})}{9.11 \times 10^{-31}\ \text{kg}}} = 1.57 \times 10^6\ \text{m/s}$$

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

EVALUATE: Typical Fermi energies for metals range from 1.6 to 14 eV; our value is within this range, as it should be.

The quantity v_F is called the *Fermi speed*. The calculated value of v_F is far less than the speed of light $c = 3.00 \times 10^8$ m/s, which justifies our use of nonrelativistic formulas. Typical Fermi speeds for metals range from 0.8 to 2.2×10^6 m/s.

Our results show that the Fermi energy is much *larger* than kT at ordinary temperatures, so it is a good approximation to take almost all the states below E_F as completely full and almost all those above E_F as completely empty (see Fig. 42.24).

We can also use Eq. (42.16) to find $g(E)$ if E and V are known. You can show that if $E = 7$ eV and $V = 1$ cm^3, $g(E)$ is about 2×10^{22} states/eV. This huge number shows why we were justified in treating n and E as continuous variables in our density-of-states derivation.

Average Free-Electron Energy

We can calculate the *average* free-electron energy in a metal at absolute zero by using the same ideas that we used to find E_{F0}. From Eq. (42.18) the number dN of electrons with energies in the range dE is $g(E)f(E)\,dE$. The energy of these electrons is $E\,dN = Eg(E)f(E)\,dE$. At absolute zero we substitute $f(E) = 1$ from $E = 0$ to $E = E_{F0}$ and $f(E) = 0$ for all other energies. Therefore the total energy E_{tot} of all the N electrons is

$$E_{tot} = \int_0^{E_{F0}} Eg(E)(1)\,dE + \int_{E_{F0}}^{\infty} Eg(E)(0)\,dE = \int_0^{E_{F0}} Eg(E)\,dE$$

The simplest way to evaluate this expression is to compare Eqs. (42.16) and (42.20), noting that

$$g(E) = \frac{3NE^{1/2}}{2E_{F0}^{3/2}}$$

Substituting this expression into the integral and using $E_{av} = E_{tot}/N$, we get

$$E_{av} = \frac{3}{2E_{F0}^{3/2}} \int_0^{E_{F0}} E^{3/2}\,dE = \frac{3}{5}E_{F0} \qquad (42.22)$$

That is, at absolute zero the average free-electron energy equals $\frac{3}{5}$ of the corresponding Fermi energy.

Example 42.9 Free-electron gas versus ideal gas

(a) Find the average energy of the free electrons in copper at absolute zero (Example 42.8). (b) If the electrons behaved like an ideal gas (see Section 18.3) at room temperature, what would be their average kinetic energy? What would be the speed of an electron with this kinetic energy?

SOLUTION

IDENTIFY: Free electrons in a metal behave like a type of gas. In this example we're asked to compare this gas to the ideal gas that we examined in Chapter 18.

SET UP: We use Eq. (42.22) to determine the average kinetic energy of free electrons. If the electrons behaved like a classic ideal gas with temperature T, from Eq. (18.16) the average kinetic energy per electron would be $E_{av} = \frac{3}{2}kT$; we use this relationship to determine the energy and the speed asked for in part (b).

EXECUTE: (a) From Example 42.8, the Fermi energy in copper is 1.126×10^{-18} J $= 7.03$ eV. According to Eq. (42.22), the average energy is $\frac{3}{5}$ of this, or 6.76×10^{-19} J $= 4.22$ eV.

(b) If the electrons behaved like an ideal gas at room temperature ($T = 20°C = 293$ K), the average kinetic energy per electron would be

$$E_{av} = \frac{3}{2}kT = \frac{3}{2}(1.381 \times 10^{-23}\ \text{J/K})(293\ \text{K})$$
$$= 6.07 \times 10^{-21}\ \text{J} = 0.0379\ \text{eV}$$

The speed of an electron with this kinetic energy would be

$$v = \sqrt{\frac{2E_{av}}{m}} = \sqrt{\frac{2(6.07 \times 10^{-21}\ \text{J})}{9.11 \times 10^{-31}\ \text{kg}}} = 1.15 \times 10^5\ \text{m/s}$$

EVALUATE: The average energy predicted by the ideal-gas model is less than 1% of the value given (correctly) by the free-electron model, and the corresponding speed in the ideal-gas model is only a small fraction of the characteristic Fermi speed given by the free-electron model (see Example 42.8). Thus temperature plays a *very* small role in determining the properties of electrons in metals; instead, their average energies are determined almost entirely by the exclusion principle.

A similar analysis allows us to determine the contributions of electrons to the heat capacities of a solid metal. If there is one conduction electron per atom, the principle of equipartition of energy (see Section 18.4) would predict that the kinetic energies of these electrons contribute $3R/2$ to the molar heat capacity at constant volume C_V. But when kT is much smaller than E_F, which is usually the situation in metals, only those few electrons near the Fermi level can find empty states and change energy appreciably when the temperature changes. The number of such electrons is proportional to kT/E_F, so we expect that the electron molar heat capacity at constant volume is proportional to $(kT/E_F)(3R/2) = (3kT/2E_F)R$. A more detailed analysis shows that the actual electron contribution to C_V for a solid metal is $(\pi^2 kT/2E_F)\,R$, not far from our prediction. You can verify that if $T = 293$ K and $E_F = 7.03$ eV, the electron contribution to C_V is $0.018R$, which is only 1.2% of the (incorrect) $3R/2$ prediction of the equipartition principle. Because the electronic contribution is so small, the overall heat capacity of most solid metals is due primarily to vibration of the atoms in the crystal structure (see Fig. 18.18 in Section 18.4).

Test Your Understanding of Section 42.5 An ideal gas obeys the relationship $pV = nRT$ (see Section 18.1). That is, for a given volume V and a number of moles n, as the temperature T decreases, the pressure p decreases proportionately and tends to zero as T approaches absolute zero. Is this also true of the free-electron gas in a solid metal?

LORENZO FARAONE
University of Western Australia

Led by Lorenzo Faraone, Professor of Electrical Engineering, the Microelectronics Research Group (MRG) at the University of Western Australia is one of Australia's largest semiconductor electronics research groups. His research has revolutionised sensor technology and has led to the development of the world-leading Quantitative Mobility Spectrum Analysis techniques and tuneable infrared detectors. He is a Fellow of the Australian Academy of Science. His research group is undertaking research on Mercury Cadmium Telluride (MCT) infrared sensor technology and leads the world in the innovative combination of micro-electromechanical systems (MEMS) with infrared sensor technologies for fourth generation IR systems. The MRG is also involved in innovative technologies for the characterisation and processing of new and emerging semiconductor materials including GaN, InAlN and GaInN.

FRONTIERS OF RESEARCH

42.6 Semiconductors

A **semiconductor** has an electrical resistivity that is intermediate between those of good conductors and of good insulators. The tremendous importance of semiconductors in present-day electronics stems in part from the fact that their electrical properties are very sensitive to very small concentrations of impurities. We'll discuss the basic concepts using the semiconductor elements silicon (Si) and germanium (Ge) as examples.

Silicon and germanium are in Group IV of the periodic table. Both have four electrons in the outermost atomic subshells ($3s^2 3p^2$ for silicon, $4s^2 4p^2$ for germanium), and both crystallise in the covalently bonded diamond structure discussed in Section 42.3 (Fig. 42.16). Because all four of the outer electrons are involved in the bonding, at absolute zero the band structure (see Section 42.4) has a completely empty conduction band (Fig. 42.21b). As we discussed in Section 42.4, at very low temperatures electrons cannot jump from the filled valence band into the conduction band. This property makes these materials insulators at very low temperatures; their electrons have no nearby states available into which they can move in response to an applied electric field.

However, the energy gap E_g between the valence and conduction bands is small in comparison to the gap of 5 eV or more for many insulators; room temperature values are 1.12 eV for silicon and only 0.67 eV for germanium. Thus even at room temperature a substantial number of electrons can gain enough energy to jump the gap to the conduction band, where they are dissociated from their parent atoms and are free to move about the crystal. The number of these electrons increases rapidly with temperature.

Example 42.10 Jumping the energy gap

Consider a material with the band structure described above, with its Fermi energy in the middle of the gap (Fig. 42.26). Find the probability that a state at the bottom of the conduction band is occupied at a temperature of 300 K if the band gap is (a) 0.200 eV; (b) 1.00 eV; (c) 5.00 eV. Repeat the calculations for a temperature of 310 K.

SOLUTION

IDENTIFY: Figure 42.25 shows that the higher the temperature, the larger the fraction of electrons that have energies greater than the Fermi energy E_F. We use this idea to carry out the desired calculations.

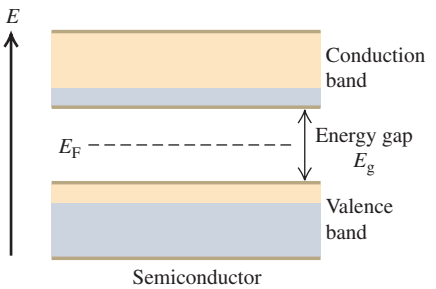
Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

SET UP: The Fermi-Dirac distribution function gives us the probability that a state of energy E is occupied at temperature T. Figure 42.26 shows that the state of interest at the bottom of the conduction band has energy $E = E_F + E_g/2$, so $E - E_F = E_g/2$.

EXECUTE: (a) When $E_g = 0.200$ eV,

$$\frac{E - E_F}{kT} = \frac{0.100\text{ eV}}{(8.617 \times 10^{-5}\text{ eV/K})(300\text{ K})} = 3.87$$

$$f(E) = \frac{1}{e^{3.87} + 1} = 0.0205$$



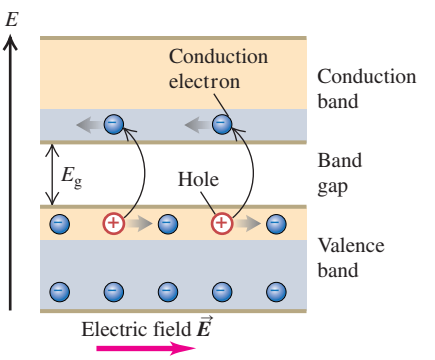
With $E_g = 0.200$ eV and $T = 310$ K, the exponent is 3.74 and $f(E) = 0.0231$, a 13% increase for a temperature rise of only 10K.

(b) When $E_g = 1.00$ eV, both exponents are five times as large as before, 19.3 and 18.7; the values of $f(E)$ are 4.0×10^{-9} and 7.4×10^{-9}. In this case the probability nearly doubles with a temperature rise of 10 K.

(c) When $E_g = 5.0$ eV, the exponents are 96.7 and 93.6; the values of $f(E)$ are 1.0×10^{-42} and 2.3×10^{-41}. The probability increases by a factor of 23 for a 10 K temperature rise, but it is still extremely small. Pure diamond, with a 5.47 eV band gap, has essentially no electrons in the conduction band and is an excellent insulator.

EVALUATE: This example illustrates two important points. First, the probability of finding an electron in a state at the bottom of the conduction band is extremely sensitive to the width of the band gap. When the gap is 0.20 eV, the chance is about 2%, but when it is 1.00 eV, the chance is a few in a thousand million, and for a band gap of 5.0 eV, it is essentially zero. Second, for any given band gap the probability is very temperature dependent, more so for large gaps than for small.

42.26 Band structure of a semiconductor. At absolute zero a completely filled valence band is separated by a narrow energy gap E_g of 1 eV or so from a completely empty conduction band. At ordinary temperatures, a number of electrons are excited to the conduction band.

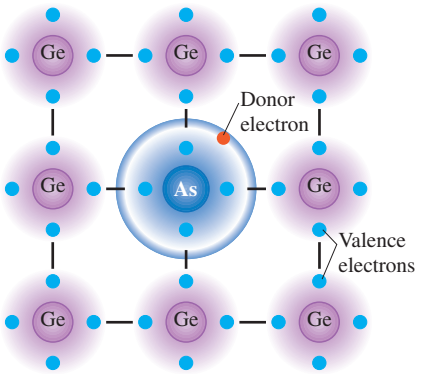


In principle, we could continue the calculation in Example 42.10 to find the actual density $n = N/V$ of electrons in the conduction band at any temperature. To do this, we would have to evaluate the integral $\int g(E)f(E)\,dE$ from the bottom of the conduction band to its top. First we would need to know the density of states function $g(E)$. It wouldn't be correct to use Eq. (42.16) because the energy-level structure and the density of states for real solids are more complex than those for the simple free-electron model. However, there are theoretical methods for predicting what $g(E)$ should be near the bottom of the conduction band, and such calculations have been carried out. Once we know n, we can *begin* to determine the resistivity of the material (and its temperature dependence) using the analysis of Section 25.2, which you may want to review. But next we'll see that the electrons in the conduction band don't tell the whole story about conduction in semiconductors.

Holes

When an electron is removed from a covalent bond, it leaves a vacancy behind. An electron from a neighbouring atom can move into this vacancy, leaving the neighbour with the vacancy. In this way the vacancy, called a **hole**, can travel through the material and serve as an additional current carrier. It's like describing the motion of a bubble in a liquid. In a pure, or *intrinsic*, semiconductor, valence-band holes and conduction-band electrons are always present in equal numbers. When an electric field is applied, they move in opposite directions (Fig. 42.27). Thus a hole in the valence band behaves like a positively charged particle, even though the moving charges in that band are electrons. The conductivity that we just described for a pure semiconductor is called *intrinsic conductivity*. Another kind of conductivity, to be discussed in the next subsection, is due to impurities.

An analogy helps to picture conduction in an intrinsic semiconductor. The valence band at absolute zero is like a floor of a parking garage that's filled bumper to bumper with cars (which represent electrons). No cars can move because there is nowhere for them to go. But if one car is moved to the vacant floor above, it can move freely, just as electrons can move freely in the conduction band. Also, the empty space that it leaves permits cars to move on the nearly filled floor, thereby moving the empty space just as holes move in the normally filled valence band.



42.27 Motion of electrons in the conduction band and of holes in the valence band of a semiconductor under the action of an applied electric field $\vec{E}$.

42.28 An *n*-type semiconductor.

(a) A donor (*n*-type) impurity atom has a fifth valence electron that does not participate in the covalent bonding and is very loosely bound.

(b) Energy-band diagram for an *n*-type semiconductor at a low temperature. One donor electron has been excited from the donor levels into the conduction band.

Impurities

Suppose we mix into melted germanium $(Z = 32)$ a small amount of arsenic $(Z = 33)$, the next element after germanium in the periodic table. This deliberate addition of impurity elements is called *doping*. Arsenic is in Group V; it has *five* valence electrons. When one of these electrons is removed, the remaining electron structure is essentially identical to that of germanium. The only difference is that it is smaller; the arsenic nucleus has a charge of $+33e$ rather than $+32e$, and it pulls the electrons in a little more. An arsenic atom can comfortably take the place of a germanium atom as a substitutional impurity. Four of its five valence electrons form the necessary nearest-neighbour covalent bonds.

The fifth valence electron is very loosely bound (Fig. 42.28a); it doesn't participate in the covalent bonds, and it is screened from the nuclear charge of $+33e$ by the 32 electrons, leaving a net effective charge of about $+e$. We might guess that the binding energy would be of the same order of magnitude as the energy of the $n = 4$ level in hydrogen—that is, $\left(\frac{1}{4}\right)^2(13.6\text{ eV}) = 0.85$ eV. In fact, it is much smaller than this, only about 0.01 eV, because the electron probability distribution actually extends over many atomic diameters and the polarisation of intervening atoms provides additional screening.

The energy level of this fifth electron corresponds in the band picture to an isolated energy level lying in the gap, about 0.01 eV below the bottom of the conduction band (Fig. 42.28b). This level is called a *donor level*, and the impurity atom that is responsible for it is simply called a *donor*. All Group V elements, including N, P, As, Sb and Bi, can serve as donors. At room temperature, kT is about 0.025 eV. This is substantially greater than 0.01 eV, so at ordinary temperatures, most electrons can gain enough energy to jump from donor levels into the conduction band, where they are free to wander through the material. The remaining ionised donor stays at its site in the structure and does not participate in conduction.

Example 42.10 shows that at ordinary temperatures and with a band gap of 1.0 eV, only a very small fraction (of the order of 10^{-9}) of the states at the bottom of the conduction band in a pure semiconductor contain electrons to participate in intrinsic conductivity. Thus we expect the conductivity of such a semiconductor to be about 10^{-9} as great as that of good metallic conductors, and measurements bear out this prediction. However, a concentration of donors as small as one part in 10^8 can increase the conductivity so drastically that conduction due to impurities becomes by far the dominant mechanism. In this case the conductivity is due almost entirely to *negative* charge (electron) motion. We call the material an ***n*-type semiconductor**, with *n*-type impurities.

Adding atoms of an element in Group III (B, Al, Ga, In, Tl), with only *three* valence electrons, has an analogous effect. An example is gallium $(Z = 31)$; as a substitutional impurity in germanium, the gallium atom would like to form four covalent bonds, but it has only three outer electrons. It can, however, steal an electron from a neighbouring germanium atom to complete the required four covalent bonds (Fig. 42.29a). The resulting atom has the same electron configuration as Ge but is somewhat larger because gallium's nuclear charge is smaller, $+31e$ instead of $+32e$.

This theft leaves the neighbouring atom with a *hole*, or missing electron. The hole acts as a positive charge that can move through the crystal just as with intrinsic conductivity. The stolen electron is bound to the gallium atom in a level called an *acceptor level* about 0.01 eV above the top of the valence band (Fig. 42.29b). The gallium atom, called an *acceptor*, thus accepts an electron to complete its desire for four covalent bonds. This extra electron gives the previously neutral gallium atom a net charge of $-e$. The resulting gallium ion is *not* free to move. In a semiconductor that is doped with acceptors, we consider the conductivity to be almost entirely due to *positive* charge (hole) motion. We call the material a ***p*-type semiconductor**, with *p*-type impurities. Some semiconductors are doped with *both* *n*- and *p*-type impurities. Such materials are called *compensated* semiconductors.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

CAUTION **The meaning of '*p*-type' and '*n*-type'** Saying that a material is a *p*-type semiconductor does *not* mean that the material has a positive charge; ordinarily, it would be neutral. Rather, it means that its *majority carriers* of current are positive holes (and therefore its *minority carriers* are negative electrons). The same idea holds for an *n*-type semiconductor; ordinarily, it will *not* have a negative charge, but its majority carriers are negative electrons.

We can verify the assertion that the current in *n*- and *p*-type semiconductors really *is* carried by electrons and holes, respectively, by using the Hall effect (see optional Section 27.9). The sign of the Hall emf is opposite in the two cases. Hall-effect devices constructed from semiconductor materials are used in probes to measure magnetic fields and the currents that cause those fields.

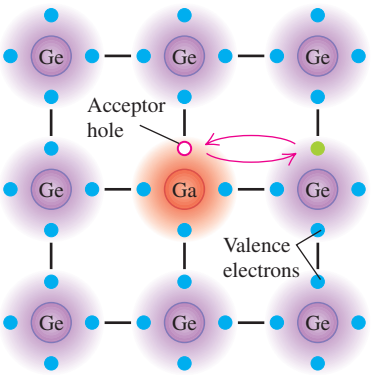
Test Your Understanding of Section 42.6 Would there be any advantage to adding *n*-type or *p*-type impurities to copper?

42.7 Semiconductor Devices

Semiconductor devices play an indispensable role in contemporary electronics. In the early days of radio and television, transmitting and receiving equipment relied on vacuum tubes, but these have been almost completely replaced in the last four decades by solid-state devices, including transistors, diodes, integrated circuits and other semiconductor devices. The only surviving vacuum tubes in consumer electronics are the picture tubes in older TV receivers and computer monitors; these are gradually being replaced by flat-screen displays.

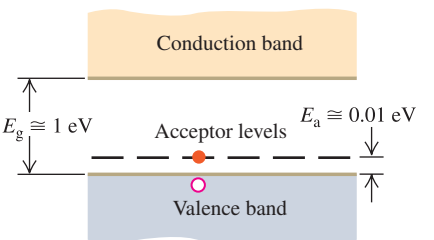
One simple semiconductor device is the *photocell* (Fig. 42.30). When a thin slab of semiconductor is irradiated with an electromagnetic wave whose photons have at least as much energy as the band gap between the valence and conduction bands, an electron in the valence band can absorb a photon and jump to the conduction band, where it and the hole it left behind contribute to the conductivity (see Example 42.6 in Section 42.4). The conductivity therefore increases with wave intensity, thus increasing the current I in the photocell circuit of Fig. 42.30. Hence the ammeter reading indicates the intensity of the light.

Detectors for charged particles operate on the same principle. An external circuit applies a voltage across a semiconductor. An energetic charged particle passing through the semiconductor collides inelastically with valence electrons, exciting them from the valence to the conduction band and creating pairs of holes and conduction electrons. The conductivity increases momentarily, causing a pulse of current in the external circuit. Solid-state detectors are widely used in nuclear and high-energy physics research; without them, many important discoveries could not have been made.



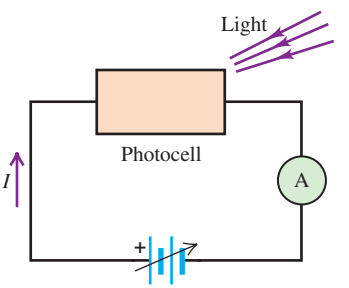
The *p-n* Junction

In many semiconductor devices the essential principle is the fact that the conductivity of the material is controlled by impurity concentrations, which can be varied within wide limits from one region of a device to another. An example is the ***p-n* junction** at the boundary between one region of a semiconductor with *p*-type impurities and another region containing *n*-type impurities. One way of fabricating a *p-n* junction is to deposit some *n*-type material on the *very* clean surface of some *p*-type material. (We can't just stick *p*- and *n*-type pieces together and expect the junction to work properly because of the impossibility of matching their surfaces at the atomic level.)

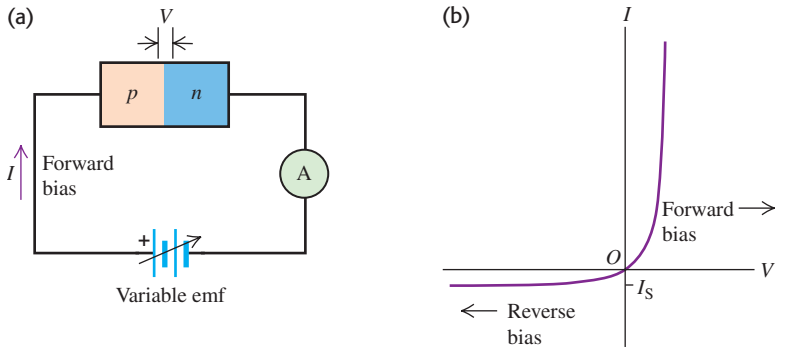


When a *p-n* junction is connected to an external circuit, as in Fig. 42.31a, and the potential difference $V_p - V_n = V$ across the junction is varied, the current I varies as shown in Fig. 42.31b. In striking contrast to the symmetrical behaviour of resistors that obey Ohm's law and give a straight line on an *I-V* graph, a *p-n*

42.29 A *p*-type semiconductor.



(a) An acceptor (*p*-type) impurity atom has only three valence electrons, so it can borrow an electron from a neighbouring atom. The resulting hole is free to move about the crystal.



(b) Energy-band diagram for a *p*-type semiconductor at a low temperature. One acceptor level has accepted an electron from the valence band, leaving a hole behind.

42.30 A semiconductor photocell in a circuit. The more intense the light falling on the photocell, the greater the conductivity of the photocell and the greater the current measured by the ammeter (A).

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

42.31 (a) A semiconductor *p-n* junction in a circuit. (b) Graph showing the asymmetrical current–voltage relationship. The curve is described by Eq. (42.23).

junction conducts much more readily in the direction from *p* to *n* than the reverse. Such a (mostly) one-way device is called a **diode rectifier**. Later we'll discuss a simple model of *p-n* junction behaviour that predicts a current–voltage relationship in the form

$$I = I_S(e^{eV/kT} - 1) \qquad \text{(current through a } p\text{-}n \text{ junction)} \qquad (42.23)$$

In the exponent, $e = 1.602 \times 10^{-19}$ C is the quantum of charge, k is Boltzmann's constant, and T is absolute temperature.

CAUTION **Two different Uses of e** In $e^{eV/kT}$ the base of the exponent also uses the symbol e, standing for the base of the natural logarithms, 2.71828 . . . . This e is quite different from $e = 1.602 \times 10^{-19}$ C in the exponent.

Equation (42.23) is valid for both positive and negative values of V; note that V and I always have the same sign. As V becomes very negative, I approaches the value $-I_S$. The magnitude I_S (always positive) is called the *saturation current*.

Example 42.11 Is a *p-n* junction diode always a one-way device?

At a temperature of 290 K, a certain *p-n* junction diode has a saturation current $I_S = 0.500$ mA. Find the current at this temperature when the voltage is 1.00 mV, −1.00 mV, 100 mV and −100 mV.

SOLUTION

IDENTIFY: This problem uses the relationship among current, saturation current, voltage and temperature for a semiconductor diode.

SET UP: We are given the values of the saturation current I_S and the temperature T, so we can use Eq. (42.23) to determine the current I for various values of the voltage V.

EXECUTE: At $T = 290$ K, $kT = 0.0250$ eV $= 25.0$ meV. When $V = 1.00$ mV, $eV/kT = e(1.00\text{ mV})/(25.0\text{ meV}) = 0.0400$. From Eq. (42.23) the current is

$$I = (0.500\text{ mA})(e^{0.0400} - 1) = 0.0204\text{ mA}$$

When $V = -1.00$ mV,

$$I = (0.500\text{ mA})(e^{-0.0400} - 1) = -0.0196\text{ mA}$$

The values of I for the other two voltages are obtained in the same way; when $V = 100$ mV, $I = 26.8$ mA; and when $V = -100$ mV, $I = -0.491$ mA. We summarise the data in the following table, also calculating the resistance $R = V/I$.

V (mV)	I (mA)	R (Ω)
+1.00	+0.0204	49.0
−1.00	−0.0196	51.0
+100	+26.8	3.73
−100	−0.491	204

EVALUATE: Note that at $|V| = 1.00$ mV the current has nearly the same magnitude for both directions. That is, when $|V| \ll kT/e$ (near the origin of Fig. 42.31b), the curve approaches a straight line, and this junction diode acts more like a 50.0 Ω resistor than like a rectifier. However, as the voltage increases, the directional asymmetry becomes more and more pronounced. At $|V| = 100$ V the negative current is nearly equal to the saturation value and has a magnitude that is less than 2% of the positive current.

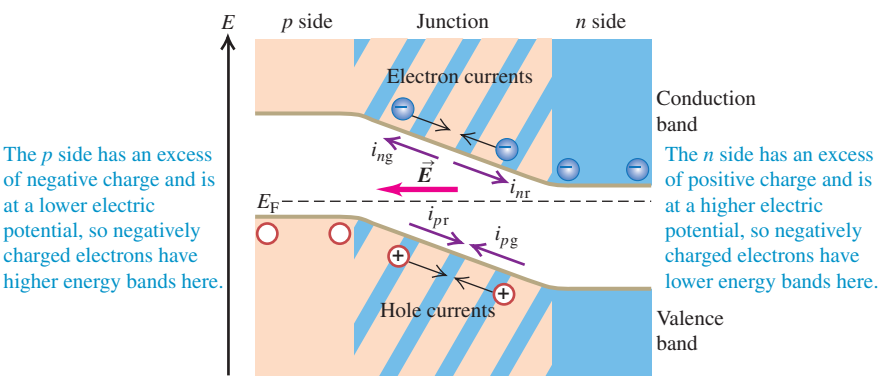
Currents Through a *p-n* Junction

We can understand the behaviour of a *p-n* junction diode qualitatively on the basis of the mechanisms for conductivity in the two regions. Suppose, as in Fig. 42.31a, you connect the positive terminal of the battery to the *p* region and

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

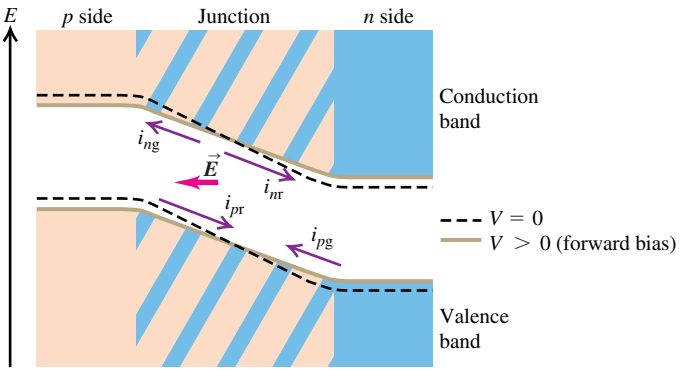
the negative terminal to the *n* region. Then the *p* region is at higher potential than the *n* region, corresponding to positive V in Eq. (42.23), and the resulting electric field is in the direction *p* to *n*. This is called the *forward* direction, and the positive potential difference is called *forward bias*. Holes, plentiful in the *p* region, flow easily across the junction into the *n* region, and free electrons, plentiful in the *n* region, easily flow into the *p* region; these movements of charge constitute a *forward* current. Connecting the battery with the opposite polarity gives *reverse bias*, and the field tends to push electrons from *p* to *n* and holes from *n* to *p*. But there are very few free electrons in the *p* region and very few holes in the *n* region. As a result, the current in the *reverse* direction is much smaller than that with the same potential difference in the forward direction.

Suppose you have a box with a barrier separating the left and right sides: You fill the left side with oxygen gas and the right side with nitrogen gas. What happens if the barrier leaks? Oxygen diffuses to the right, and nitrogen diffuses to the left. A similar diffusion occurs across a *p*-*n* junction. First consider the equilibrium situation with no applied voltage (Fig. 42.32). The many holes in the *p* region act like a hole gas that diffuses across the junction into the *n* region. Once there, the holes recombine with some of the many free electrons. Similarly, electrons diffuse from the *n* region to the *p* region and fall into some of the many holes there. The hole and electron diffusion currents lead to a net positive charge in the *n* region and a net negative charge in the *p* region, causing an electric field in the direction from *n* to *p* at the junction. The potential energy associated with this field raises the electron energy levels in the *p* region relative to the same levels in the *n* region.



There are four currents across the junction, as shown. The diffusion processes lead to *recombination currents* of holes and electrons, labelled i_{pr} and i_{nr} in Fig. 42.32. At the same time, electron–hole pairs are generated in the junction region by thermal excitation. The electric field described above sweeps these electrons and holes out of the junction; electrons are swept opposite the field to the *n* side, and holes are swept in the same direction as the field to the *p* side. The corresponding currents, called *generation currents*, are labelled i_{pg} and i_{ng}. At equilibrium the magnitudes of the generation and recombination currents are equal:

$$|i_{pg}| = |i_{pr}| \quad \text{and} \quad |i_{ng}| = |i_{nr}| \tag{42.24}$$



At thermal equilibrium the Fermi energy is the same at each point across the junction.

Now we apply a forward bias—that is, a positive potential difference V across the junction. A forward bias *decreases* the electric field in the junction region. It also decreases the difference between the energy levels on the *p* and *n* sides (Fig. 42.33, next page) by an amount $\Delta E = -eV$. It becomes easier for the electrons in the *n* region to climb the potential-energy hill and diffuse into the *p* region and for the holes in the *p* region to diffuse into the *n* region. This effect increases both recombination currents by the Maxwell-Boltzmann factor $e^{-\Delta E/kT} = e^{eV/kT}$. (We don't have

42.32 A *p*-*n* junction in equilibrium, with no externally applied field or potential difference. The generation and recombination currents exactly balance. The Fermi energy E_F is the same on both sides of the junction. The excess positive and negative charges on the *n* and *p* sides produce an electric field $\vec{E}$ in the direction shown.

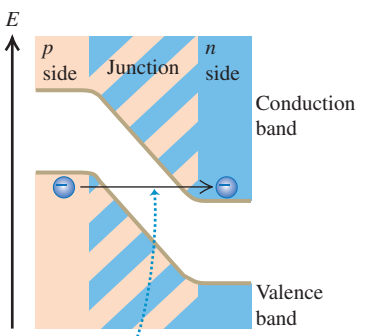
Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

42.33 A *p-n* junction under forward-bias conditions. The potential difference between *p* and *n* regions is reduced, as is the electric field within the junction. The recombination currents increase but the generation currents are nearly constant, causing a net current from left to right. (Compare Fig. 42.32.)

to use the Fermi-Dirac distribution because most of the available states for the diffusing electrons and holes are empty, so the exclusion principle has little effect.) The generation currents don't change appreciably, so the net hole current is

$$\begin{aligned} i_{p\text{tot}} &= i_{pr} - |i_{pg}| \\ &= |i_{pg}|e^{eV/kT} - |i_{pg}| \\ &= |i_{pg}|(e^{eV/kT} - 1) \end{aligned} \tag{42.25}$$

The net electron current $i_{n\text{tot}}$ is given by a similar expression, so the total current $I = i_{p\text{tot}} + i_{n\text{tot}}$ is



$$I = I_S(e^{eV/kT} - 1) \tag{42.26}$$

in agreement with Eq. (42.23). This entire discussion can be repeated for reverse bias (negative V and I) with the same result. Therefore Eq. (42.23) is valid for both positive and negative values.

Several effects make the behaviour of practical *p-n* junction diodes more complex than this simple analysis predicts. One effect, *avalanche breakdown*, occurs under large reverse bias. The electric field in the junction is so great that the carriers can gain enough energy between collisions to create electron–hole pairs during inelastic collisions. The electrons and holes then gain energy and collide to form more pairs, and so on. (A similar effect occurs in dielectric breakdown in insulators, discussed in Section 42.4.)

A second type of breakdown begins when the reverse bias becomes large enough that the top of the valence band in the *p* region is just higher in energy than the bottom of the conduction band in the *n* region (Fig. 42.34). If the junction region is thin enough, the probability becomes large that electrons can *tunnel* from the valence band of the *p* region to the conduction band of the *n* region. This process is called *Zener breakdown*. It occurs in Zener diodes, which are widely used for voltage regulation and protection against voltage surges.

42.34 Under reverse-bias conditions the potential-energy difference between the *p* and *n* sides of a junction is greater than at equilibrium. If this difference is great enough, the bottom of the conduction band on the *n* side may actually be below the top of the valence band on the *p* side.

If a *p-n* junction under reverse bias is thin enough, electrons can tunnel from the valence band to the conduction band (a process called Zener breakdown).

Semiconductor Devices and Light

A *light-emitting diode (LED)* is a *p-n* junction diode that emits light. When the junction is forward biased, many holes are pushed from their *p* region to the junction region, and many electrons are pushed from their *n* region to the junction region. In the junction region the electrons fall into holes (recombine). In recombining, the electron can emit a photon with energy approximately equal to the band gap. This energy (and therefore the photon wavelength and the colour of the light) can be varied by using materials with different band gaps. Light-emitting diodes are widely used for digital displays in clocks, electronic equipment, car instrument panels and many other applications.

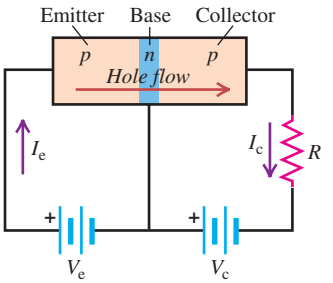
The reverse process is called the *photovoltaic effect*. Here the material absorbs photons, and electron–hole pairs are created. Pairs that are created in the *p-n* junction, or close enough to migrate to it without recombining, are separated

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

by the electric field we described above that sweeps the electrons to the *n* side and the holes to the *p* side. We can connect this device to an external circuit, where it becomes a source of emf and power. Such a device is often called a *solar cell*, although sunlight isn't required. *Any* light with photon energies greater than the band gap will do. You might have a calculator powered by such cells. Production of low-cost photovoltaic cells for large-scale solar energy conversion is a very active field of research. The same basic physics is used in charge-coupled device (CCD) image detectors, digital cameras and camcorders.

Transistors

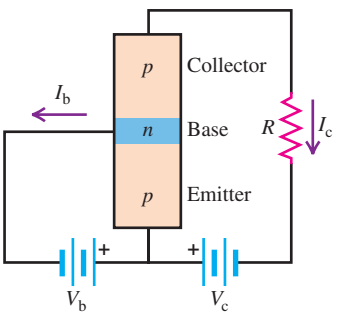
A *bipolar junction transistor* includes two *p*-*n* junctions in a 'sandwich' configuration, which may be either *p*-*n*-*p* or *n*-*p*-*n*. Such a *p*-*n*-*p* transistor is shown in Fig. 42.35. The three regions are called the emitter, base and collector, as shown. When there is no current in the left loop of the circuit, there is only a very small current through the resistor R because the voltage across the base–collector junction is in the reverse direction. But when a forward bias is applied between emitter and base, as shown, most of the holes travelling from emitter to base travel *through* the base (which is typically both narrow and lightly doped) to the second junction, where they come under the influence of the collector-to-base potential difference and flow on through the collector to give an increased current to the resistor.



In this way the current in the collector circuit is *controlled* by the current in the emitter circuit. Furthermore, V_c may be considerably larger than V_e, so the *power* dissipated in R may be much larger than the power supplied to the emitter circuit by the battery V_e. Thus the device functions as a *power amplifier*. If the potential drop across R is greater than V_e, it may also be a voltage amplifier.

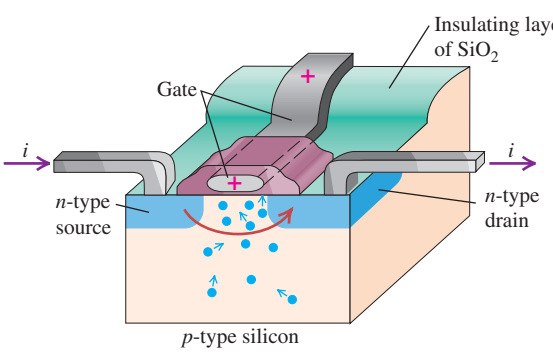
In this configuration the *base* is the common element between the 'input' and 'output' sides of the circuit. Another widely used arrangement is the *common-emitter* circuit, shown in Fig. 42.36. In this circuit the current in the collector side of the circuit is much larger than that in the base side, and the result is current amplification.

The *field-effect transistor* (Fig. 42.37) is an important type. In one variation a slab of *p*-type silicon is made with two *n*-type regions on the top, called the *source* and the *drain*; a metallic conductor is fastened to each. A third electrode called the *gate* is separated from the slab, source and drain by an insulating layer of SiO_2. When there is no charge on the gate and a potential difference of either polarity is applied between the source and the drain, there is very little current because one of the *p*-*n* junctions is reverse biased.



Now we place a positive charge on the gate. With dimensions of the order of 10^{-6} m, it takes little charge to provide a substantial electric field. Thus there is very little current into or out of the gate. There aren't many free electrons in the *p*-type material, but there are some, and the effect of the field is to attract them towards the positive gate. The resulting greatly enhanced concentration of electrons near the gate (and between the two junctions) permits current to flow between the source and the drain. The current is very sensitive to the gate charge and potential, and the

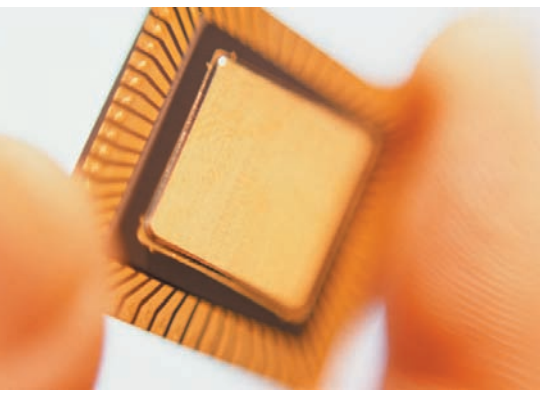
42.35 Schematic diagram of a *p*-*n*-*p* transistor and circuit.



- When $V_e = 0$, the current is very small.
- When a potential V_e is applied between emitter and base, holes travel from the emitter to the base.
- When V_c is sufficiently large, most of the holes continue into the collector.

42.36 A common-emitter circuit.

- When $V_b = 0$, I_c is very small, and most of the voltage V_c appears across the base–collector junction.
- As V_b increases, the base–collector potential decreases, and more holes can diffuse into the collector; thus, I_c increases. Ordinarily, I_c is much larger than I_b.



42.37 A field-effect transistor. The current from source to drain is controlled by the potential difference between the source and the drain and by the charge on the gate; no current flows through the gate.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

device functions as an amplifier. The device just described is called an *enhancement-type MOSFET* (metal-oxide-semiconductor field-effect transistor).

Integrated Circuits

42.38 An integrated circuit chip the size of your thumb can contain millions of transistors.

A further refinement in semiconductor technology is the *integrated circuit*. By successively depositing layers of material and etching patterns to define current paths, we can combine the functions of several MOSFETs, capacitors and resistors on a single square of semiconductor material that may be only a few millimetres on a side. An elaboration of this idea leads to *large-scale integrated circuits* and *very-large-scale integration* (VLSI). The resulting integrated circuit chips are the heart of all pocket calculators and present-day computers, large and small. An example is shown in Fig. 42.38.

The first semiconductor devices were invented in 1947. Since then, they have completely revolutionised the electronics industry through miniaturisation, reliability, speed, energy usage and cost. They have found applications in communications, computer systems, control systems and many other areas. In transforming these areas, they have changed, and continue to change, human civilisation itself.

Test Your Understanding of Section 42.7 Suppose a negative charge is placed on the gate of the MOSFET shown in Fig. 42.37. Will a substantial current flow between the source and the drain?

42.8 Superconductivity

Superconductivity is the complete disappearance of all electrical resistance at low temperatures. We described this property at the end of Section 25.2 and the magnetic properties of type-I and type-II superconductors in Section 29.8. In this section we'll relate superconductivity to the structure and energy-band model of a solid.

Although superconductivity was discovered in 1911, it was not well understood on a theoretical basis until 1957. In that year, the American physicists John Bardeen, Leon Cooper and Robert Schrieffer published the theory of superconductivity, now called the BCS theory, that was to earn them the Nobel Prize in physics in 1972. (It was Bardeen's second Nobel Prize; he shared his first for his work on the development of the transistor.) The key to the BCS theory is an interaction between *pairs* of conduction electrons, called *Cooper pairs*, caused by an interaction with the positive ions of the crystal. Here's a rough qualitative picture of what happens. A free electron exerts attractive forces on nearby positive ions, pulling them slightly closer together. The resulting slight concentration of positive charge then exerts an attractive force on another free electron with momentum opposite to the first. At ordinary temperatures this electron-pair interaction is very small in comparison to energies of thermal motion, but at very low temperatures it becomes significant.

Bound together this way, the pairs of electrons cannot *individually* gain or lose very small amounts of energy, as they would ordinarily be able to do in a partly filled conduction band. Their pairing gives an energy gap in the allowed electron quantum levels, and at low temperatures there is not enough collision energy to jump this gap. Therefore the electrons can move freely through the crystal without any energy exchange through collisions—that is, with zero resistance.

Researchers have not yet reached a consensus on whether some modification of the BCS theory can explain the properties of the high-T_C superconductors that have been discovered since 1986. There *is* evidence for pairing, but possibly of holes rather than electrons. Furthermore, the original pairing mechanism of the BCS theory seems too weak to explain the high transition temperatures and critical fields of these new superconductors.

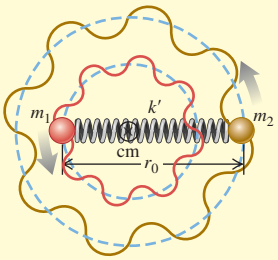
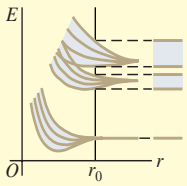
CHAPTER 42 SUMMARY



Molecular bonds and molecular spectra: The principal types of molecular bonds are ionic, covalent, van der Waals and hydrogen bonds. In a diatomic molecule the rotational energy levels are given by Eq. (42.3), where I is the moment of inertia of the molecule, m_r is its reduced mass, and r_0 is the distance between the two atoms. The vibrational energy levels are given by Eq. (42.7), where k' is the effective force constant of the interatomic force. (See Examples 42.1–42.4.)

$$E_l = l(l+1)\frac{\hbar^2}{2I} \quad (l = 0, 1, 2, \ldots) \tag{42.3}$$

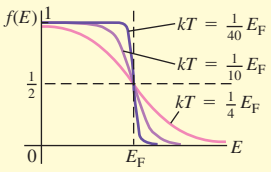
$$I = m_r r_0^2 \tag{42.6}$$



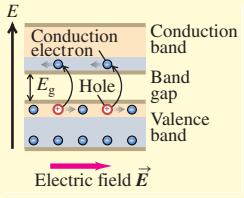
$$m_r = \frac{m_1 m_2}{m_1 + m_2} \tag{42.4}$$

$$E_n = \left(n + \frac{1}{2}\right)\hbar\omega = \left(n + \frac{1}{2}\right)\hbar\sqrt{\frac{k'}{m_r}} \quad (n = 0, 1, 2, \ldots) \tag{42.7}$$

Solids and energy bands: Interatomic bonds in solids are of the same types as in molecules plus one additional type, the metallic bond. Associating the basis with each lattice point gives the crystal structure. (See Example 42.5.)



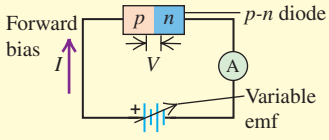
When atoms are bound together in condensed matter, their outer energy levels spread out into bands. At absolute zero, insulators and conductors have a completely filled valence band separated by an energy gap from an empty conduction band. Conductors, including metals, have partially filled conduction bands. (See Example 42.6.)



Free-electron model of metals: In the free-electron model of the behaviour of conductors, the electrons are treated as completely free particles within the conductor. In this model the density of states is given by Eq. (42.16). The probability that an energy state of energy E is occupied is given by the Fermi-Dirac distribution, Eq. (42.17), which is a consequence of the exclusion principle. In Eq. (42.17), E_F is the Fermi energy. (See Examples 42.7–42.9.)

$$g(E) = \frac{(2m)^{3/2}V}{2\pi^2\hbar^3}E^{1/2} \tag{42.16}$$

$$f(E) = \frac{1}{e^{(E-E_F)/kT} + 1} \tag{42.17}$$



Semiconductors: A semiconductor has an energy gap of about 1 eV between its valence and conduction bands. Its electrical properties may be drastically changed by the addition of small concentrations of donor impurities, giving an n-type semiconductor, or acceptor impurities, giving a p-type semiconductor. (See Example 42.10.)

Semiconductor devices: Many semiconductor devices, including diodes, transistors and integrated circuits, use one or more p-n junctions. The current–voltage relationship for an ideal p-n junction diode is given by Eq. (42.23). (See Example 42.11.)

$$I = I_S(e^{eV/kT} - 1) \tag{42.23}$$

Answer to Chapter Opening Question ?

The earth must radiate energy into space at the same rate that it receives energy in the form of sunlight. However, carbon dioxide (CO_2) molecules in the atmosphere absorb infrared radiation emitted by the earth's surface and re-emit it towards the ground. To compensate for this and to maintain the balance between emitted and received energy, the earth's surface temperature and hence the rate of blackbody radiation from the surface both increase.

Answers to Test Your Understanding Questions

42.1 Answer: (i) The exclusion principle states that only one electron can be in a given state. Real electrons have spin, so two electrons (one spin-up, one spin-down) can be in a given *spatial* state and hence two can participate in a given covalent bond between two atoms. If electrons obeyed the exclusion principle but did not have spin, that state of an electron would be completely described by its spatial distribution and only *one* electron could participate in a covalent bond. (We will learn in Chapter 44 that this situation is wholly imaginary: There are subatomic particles without spin, but they do *not* obey the exclusion principle.)

42.2 Answer: (ii) Figure 42.5 shows that the difference in energy between adjacent rotational levels increases with increasing l. Hence, as l increases, the energy E of the emitted photon increases and the wavelength $\lambda = hc/E$ decreases.

42.3 Answer (ii) In Fig. 42.14 let a be the distance between adjacent Na^+ and Cl^- ions. This figure shows that the Cl^- ion that is the next nearest neighbour to a Na^+ ion is on the opposite corner of a cube of side a. The distance between these two ions is $\sqrt{a^2 + a^2 + a^2} = \sqrt{3a^2} = a\sqrt{3}$.

42.4 Answer (ii) A small temperature change causes a substantial increase in the population of electrons in a semiconductor's conduction band and a comparably substantial increase in conductivity. The conductivity of conductors and insulators varies more gradually with temperature.

42.5 Answer: no The kinetic-molecular model of an ideal gas (see Section 18.3) shows that the gas pressure is proportional to the average translational kinetic energy E_{av} of the particles that make up the gas. In a classical ideal gas, E_{av} is directly proportional to the average temperature T, so the pressure decreases as T decreases. In a free-electron gas, the average kinetic energy per electron is *not* related simply to T; as Example 42.9 shows, for the free-electron gas in a metal, E_{av} is almost completely a consequence of the exclusion principle at room temperature and colder. Hence the pressure of a free-electron gas in a solid metal does *not* change appreciably between room temperature and absolute zero.

42.6 Answer: no Pure copper is already an excellent conductor since it has a partially filled conduction band (Fig. 42.21c). Furthermore, copper forms a metallic crystal (Fig. 42.17) as opposed to the covalent crystals of silicon or germanium, so the scheme of using an impurity to donate or accept an electron does not work for copper. In fact, adding impurities to copper *decreases* the conductivity because an impurity tends to scatter electrons, impeding the flow of current.

42.7 Answer: no A negative charge on the gate will repel, not attract, electrons in the *p*-type silicon. Hence the electron concentration in the region between the two *p-n* junctions will be made even smaller. With so few charge carriers present in this region, very little current will flow between the source and the drain.

PROBLEMS

For instructor-assigned homework, go to **www.pearson.com.au/masteringphysics** MP

Exercises

Section 42.1 Types of Molecular Bonds

42.1. We know from Chapter 18 that the average kinetic energy of an ideal gas atom or molecule at Kelvin temperature T is $\frac{3}{2}kT$. For what value of T does this energy correspond to (a) the bond energy of the van der Waals bond in He_2 (7.9×10^{-4} eV) and (b) the bond energy of the covalent bond in H_2 (4.48 eV)? (c) The kinetic energy in a collision between molecules can go into dissociating one or both molecules, provided the kinetic energy is higher than the bond energy. At room temperature (300 K), is it likely that He_2molecules will remain intact after a collision? What about H_2 molecules? Explain.

42.2. (a) Calculate the electric potential energy for a K^+ ion and a Br^- ion separated by a distance of 0.29 nm, the equilibrium separation in the KBr molecule. Treat the ions as point charges. (b) The ionisation energy of the potassium atom is 4.3 eV. Atomic bromine has an electron affinity of 3.5 eV. Use these data and the results of part (a) to estimate the binding energy of the KBr molecule. Do you expect the actual binding energy to be higher or lower than your estimate? Explain your reasoning.

Section 42.2 Molecular Spectra

42.3. A hypothetical NH molecule makes a rotational-level transition from $l = 3$ to $l = 1$ and gives off a photon of wavelength 1.780 nm in doing so. What is the separation between the two atoms in this molecule if we model them as point masses? The mass of hydrogen is 1.67×10^{-27} kg, and the mass of nitrogen is 2.33×10^{-26} kg.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

42.4. The water molecule has an $l = 1$ rotational level 1.01×10^{-5} eV above the $l = 0$ ground level. Calculate the wavelength and frequency of the photon absorbed by water when it undergoes a rotational-level transition from $l = 0$ to $l = 1$. The magnetron oscillator in a microwave oven generates microwaves with a frequency of 2450 MHz. Does this make sense, in view of the frequency you calculated in this problem? Explain.

42.5. In Example 42.2 the moment of inertia for CO was calculated using Eq. (42.6). (a) In CO, how far is each atom from the centre of mass of the molecule? (b) Use $I = m_1 r_1^2 + m_2 r_2^2$ to calculate the moment of inertia of CO about an axis through the centre of mass and perpendicular to the line joining the centres of the two atoms. Does your result agree with the value obtained in Example 42.2?

42.6. Two atoms of cesium (Cs) can form a Cs_2 molecule. The equilibrium distance between the nuclei in a Cs_2 molecule is 0.447 nm. Calculate the moment of inertia about an axis through the centre of mass of the two nuclei and perpendicular to the line joining them. The mass of a cesium atom is 2.21×10^{-25} kg.

42.7. The rotational energy levels of CO are calculated in Example 42.2. If the energy of the rotating molecule is described by the classical expression $K = \frac{1}{2} I\omega^2$, for the $l = 1$ level what are (a) the angular speed of the rotating molecule; (b) the linear speed of each atom (use the result of Exercise 42.5); (c) the rotational period (the time for one rotation)?

42.8. If a sodium chloride (NaCl) molecule could undergo an $n \to n - 1$ vibrational transition with no change in rotational quantum number, a photon with wavelength 20.0 μm would be emitted. The mass of a sodium atom is 3.82×10^{-26} kg, and the mass of a chlorine atom is 5.81×10^{-26} kg. Calculate the force constant k' for the interatomic force in NaCl.

42.9. A lithium atom has mass 1.17×10^{-26} kg, and a hydrogen atom has mass 1.67×10^{-27} kg. The equilibrium separation between the two nuclei in the LiH molecule is 0.159 nm. (a) What is the difference in energy between the $l = 3$ and $l = 4$ rotational levels? (b) What is the wavelength of the photon emitted in a transition from the $l = 4$ to the $l = 3$ level?

42.10. When a hypothetical diatomic molecule having atoms 0.8860 nm apart undergoes a rotational transition from the $l = 2$ state to the next lower state, it gives up a photon having energy 8.841×10^{-4} eV. When the molecule undergoes a vibrational transition from one energy state to the next lower energy state, it gives up 0.2560 eV. Find the force constant of this molecule.

42.11. (a) Show that the energy difference between rotational levels with angular-momentum quantum numbers l and $l - 1$ is $l\hbar^2/I$.(b) In terms of l, $\hbar$, and I, what is the frequency of the photon emitted in the pure rotation transition $l \to l - 1$?

42.12. The rotational energy levels of the CO molecule are calculated in Example 42.2 and the vibrational-level energy differences are given in Example 42.3. The vibrational and rotational energies are given by Eq. (42.9). Calculate the wavelength of the photon absorbed by CO in each of the following vibration–rotation transitions: (a) $n = 0$, $l = 1 \to n = 1$, $l = 2$; (b) $n = 0$, $l = 2 \to n = 1$, $l = 1$; (c) $n = 0$, $l = 3 \to n = 1$, $l = 2$.

42.13. The vibration frequency for the molecule HF is 1.24×10^{14} Hz. The mass of a hydrogen atom is 1.67×10^{-27} kg, and the mass of a fluorine atom is 3.15×10^{-26} kg. (a) What is the force constant k' for the interatomic force? (b) What is the spacing between adjacent vibrational energy levels in joules and in electron volts? (c) What is the wavelength of a photon of energy equal to the energy difference between two adjacent vibrational levels? In what region of the spectrum does it lie?

Section 42.3 Structure of Solids

42.14. Potassium bromide (KBr) has a density of 2.75×10^3 kg/m^3 and the same crystal structure as NaCl. The mass of a potassium atom is 6.49×10^{-26} kg, and the mass of a bromine atom is 1.33×10^{-25} kg. (a) Calculate the average spacing between adjacent atoms in a KBr crystal. (b) How does the value calculated in part (a) compare with the spacing in NaCl (see Exercise 42.15)? Is the relationship between the two values qualitatively what you would expect? Explain.

42.15. The spacing of adjacent atoms in a crystal of sodium chloride is 0.282 nm. The mass of a sodium atom is 3.82×10^{-26} kg, and the mass of a chlorine atom is 5.89×10^{-26} kg. Calculate the density of sodium chloride.

42.16. Calculate the wavelengths of (a) a 6.20 keV x-ray; (b) a 37.6 eV electron; (c) a 0.0205 eV neutron.

Section 42.4 Energy Bands

42.17. The maximum wavelength of light that a certain silicon photocell can detect is 1.11 μm. (a) What is the energy gap (in electron volts) between the valence and conduction bands for this photocell? (b) Explain why pure silicon is opaque.

42.18. The gap between valence and conduction bands in diamond is 5.47 eV. (a) What is the maximum wavelength of a photon that can excite an electron from the top of the valence band into the conduction band? In what region of the electromagnetic spectrum does this photon lie? (b) Explain why pure diamond is transparent and colourless. (c) Most gem diamonds have a yellow colour. Explain how impurities in the diamond can cause this colour.

42.19. The gap between valence and conduction bands in silicon is 1.12 eV. A nickel nucleus in an excited state emits a gamma-ray photon with wavelength 9.31×10^{-4} nm. How many electrons can be excited from the top of the valence band to the bottom of the conduction band by the absorption of this gamma ray?

Section 42.5 Free-Electron Model of Metals

42.20. What is the value of the constant A in Eq. (42.10) that makes $\psi(x, y, z)$ normalised?

42.21. Calculate the density of states $g(E)$ for the free-electron model of a metal if $E = 7.0$ eV and $V = 1.0$ cm^3. Express your answer in units of states per electron volt.

42.22. Calculate v_{rms} for free electrons with average kinetic energy $\frac{3}{2}kT$ at a temperature of 300 K. How does your result compare to the speed of an electron with a kinetic energy equal to the Fermi energy of copper, calculated in Example 42.9? Why is there such a difference between these speeds?

42.23. (a) Show that the wave function ψ given in Eq. (42.10) is a solution of the three-dimensional Schrödinger equation, Eq. (40.29), with the energy as given by Eq. (42.11). (b) What are the energies of the ground level and the lowest two excited levels? What is the degeneracy of each of these levels? (Include the factor of 2 in the degeneracy that is due to the two possible spin states.)

42.24. Supply the details in the derivation of Eq. (42.14) from Eqs. (42.13) and (42.12).

42.25. Silver has a Fermi energy of 5.48 eV. Calculate the electron contribution to the molar heat capacity at constant volume of silver, C_V, at 300 K. Express your result (a) as a multiple of R and (b) as a fraction of the actual value for silver, $C_V = 25.3$ J/mol · K.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

(c) Is the value of C_V due principally to the electrons? If not, to what is it due? (*Hint:* See Section 18.4.)

42.26. The Fermi energy of sodium is 3.23 eV. (a) Find the average energy E_{av} of the electrons at absolute zero. (b) What is the speed of an electron that has energy E_{av}? (c) At what Kelvin temperature T is kT equal to E_F? (This is called the *Fermi temperature* for the metal. It is approximately the temperature at which molecules in a classical ideal gas would have the same kinetic energy as the fastest-moving electron in the metal.)

42.27. For a solid metal having a Fermi energy of 8.500 eV, what is the probability, at room temperature, that a state having an energy of 8.520 eV is occupied by an electron?

Section 42.6 Semiconductors

42.28. Pure germanium has a band gap of 0.67 eV. The Fermi energy is in the middle of the gap. (a) For temperatures of 250 K, 300 K and 350 K, calculate the probability $f(E)$ that a state at the bottom of the conduction band is occupied. (b) For each temperature in part (a), calculate the probability that a state at the top of the valence band is empty.

42.29. Germanium has a band gap of 0.67 eV. Doping with arsenic adds donor levels in the gap 0.01 eV below the bottom of the conduction band. At a temperature of 300 K, the probability is 4.4×10^{-4} that an electron state is occupied at the bottom of the conduction band. Where is the Fermi level relative to the conduction band in this case?

Section 42.7 Semiconductor Devices

42.30. For a certain *p-n* junction diode, the saturation current at room temperature (20°C) is 0.750 mA. What is the resistance of this diode when the voltage across it is (a) 85.0 mV (b) −50.0 mV?

42.31. (a) A forward-bias voltage of 15.0 mV produces a positive current of 9.25 mA through a *p-n* junction at 300 K. What does the positive current become if the forward-bias voltage is reduced to 10.0 mV? (b) For reverse-bias voltages of −15.0 mV and −10.0 mV, what is the reverse-bias negative current?

42.32. A *p-n* junction has a saturation current of 3.60 mA. (a) At a temperature of 300 K, what voltage is needed to produce a positive current of 40.0 mA? (b) For a voltage equal to the negative of the value calculated in part (a), what is the negative current?

Problems

42.33. A hypothetical diatomic molecule of oxygen (mass = 2.656×10^{-26} kg) and hydrogen (mass = 1.67×10^{-27} kg) emits a photon of wavelength 2.39 μm when it makes a transition from one vibrational state to the next lower state. If we model this molecule as two point masses at opposite ends of a massless spring, (a) what is the force constant of this spring, and (b) how many vibrations per second is the molecule making?

42.34. When a diatomic molecule undergoes a transition from the $l = 2$ to the $l = 1$ rotational state, a photon with wavelength 63.8 μm is emitted. What is the moment of inertia of the molecule for an axis through its centre of mass and perpendicular to the line connecting the nuclei?

42.35. (a) The equilibrium separation of the two nuclei in an NaCl molecule is 0.24 nm If the molecule is modelled as charges $+e$ and $-e$ separated by 0.24 nm, what is the electric dipole moment of the molecule (see Section 21.7)? (b) The measured electric dipole moment of an NaCl molecule is 3.0×10^{-29} C · m. If this dipole moment arises from point charges $+q$ and $-q$ separated by 0.24 nm, what is q? (c) A definition of the *fractional ionic character* of the bond is q/e. If the sodium atom has charge $+e$ and the chlorine atom has charge $-e$, the fractional ionic character would be equal to 1. What is the actual fractional ionic character for the bond in NaCl? (d) The equilibrium distance between nuclei in the hydrogen iodide (HI) molecule is 0.16 nm, and the measured electric dipole moment of the molecule is 1.5×10^{-30} C · m. What is the fractional ionic character for the bond in HI? How does your answer compare to that for NaCl calculated in part (c)? Discuss reasons for the difference in these results.

42.36. The binding energy of a potassium chloride molecule (KCl) is 4.43 eV. The ionisation energy of a potassium atom is 4.3 eV, and the electron affinity of chlorine is 3.6 eV. Use these data to estimate the equilibrium separation between the two atoms in the KCl molecule. Explain why your result is only an estimate and not a precise value.

42.37. (a) For the sodium chloride molecule (NaCl) discussed at the beginning of Section 42.1, what is the maximum separation of the ions for stability if they may be regarded as point charges? That is, what is the largest separation for which the energy of an Na^+ ion and a Cl^- ion, calculated in this model, is lower than the energy of the two separate atoms Na and Cl? (b) Calculate this distance for the potassium bromide molecule, described in Exercise 42.2.

42.38. The rotational spectrum of HCl contains the following wavelengths (among others): 60.4 μm, 69.0 μm, 80.4 μm, 96.4 μm and 120.4 μm. Use this spectrum to find the moment of inertia of the HCl molecule about an axis through the centre of mass and perpendicular to the line joining the two nuclei.

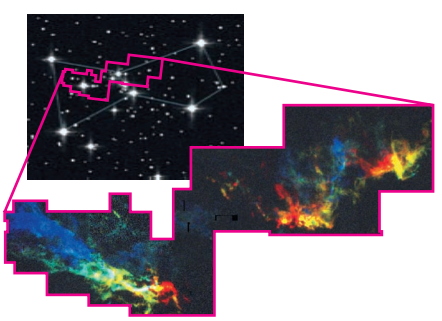
42.39. (a) Use the result of Problem 42.38 to calculate the equilibrium separation of the atoms in HCl molecule. The mass of a chlorine atom is 5.81×10^{-26} kg, and the mass of a hydrogen atom is 1.67×10^{-27} kg. (b) The value of l changes by ± 1 in rotational transitions. What is the value of l for the upper level of the transition that gives rise to each of the wavelengths listed in Problem 42.38? (c) What is the longest-wavelength line in the rotational spectrum of HCl? (d) Calculate the wavelengths of the emitted light for the corresponding transitions in the deuterium chloride (DCl) molecule. In this molecule the hydrogen atom in HCl is replaced by an atom of deuterium, an isotope of hydrogen with a mass of 3.34×10^{-27} kg. Assume that the equilibrium separation between the atoms is the same as for HCl.

42.40. When a NaF molecule makes a transition from the $l = 3$ to the $l = 2$ rotational level with no change in vibrational quantum number or electronic state, a photon with wavelength 3.83 mm is emitted. A sodium atom has mass 3.82×10^{-26} kg, and a fluorine atom has mass 3.15×10^{-26} kg. Calculate the equilibrium separation between the nuclei in a NaF molecule. How does your answer compare with the value for NaCl given in Section 42.1? Is this result reasonable? Explain.

42.41. Consider a gas of diatomic molecules (moment of inertia I) at an absolute temperature T. If E_g is a ground-state energy and E_{ex} is the energy of an excited state, then the Maxwell-Boltzmann distribution (see Section 38.6) predicts that the ratio of the numbers of molecules in the two states is

$$\frac{n_{ex}}{n_g} = e^{-(E_{ex}-E_g)/kT}$$

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition



(a) Explain why the ratio of the number of molecules in the lth rotational energy *level* to the number of molecules in the ground $(l = 0)$ rotational level is

$$\frac{n_l}{n_0} = (2l + 1)e^{-[l(l+1)\hbar^2]/2IkT}$$

(*Hint:* For each value of l, how many states are there with different values of m_l?) (b) Determine the ratio n_l/n_0 for a gas of CO molecules at 300 K for the cases (i) $l = 1$; (ii) $l = 2$; (iii) $l = 10$; (iv) $l = 20$; (v) $l = 50$. The moment of inertia of the CO molecule is given in Example 42.2 (Section 42.2). (c) Your results in part (b) show that as l is increased, the ratio n_l/n_0 first increases and then decreases. Explain why.

42.42. Our galaxy contains numerous *molecular clouds*, regions many light-years in extent in which the density is high enough and the temperature low enough for atoms to form into molecules. Most of the molecules are H_2, but a small fraction of the molecules are carbon monoxide (CO). Such a molecular cloud in the constellation Orion is shown in Fig. 42.39. The left-hand image was made with an ordinary visible-light telescope; the right-hand image shows the molecular cloud in Orion as imaged with a radio telescope tuned to a wavelength emitted by CO in a rotational transition. The different colours in the radio image indicate regions of the cloud that are moving either towards us (blue) or away from us (red) relative to the motion of the cloud as a whole, as determined by the Doppler shift of the radiation. (Since a molecular cloud has about 10 000 hydrogen molecules for each CO molecule, it might seem more reasonable to tune a radio telescope to emissions from H_2 than to emissions from CO. Unfortunately, it turns out that the H_2 molecules in molecular clouds do not radiate in either the radio or visible portions of the electromagnetic spectrum.) (a) Using the data in Example 42.2 (Section 42.2), calculate the energy and wavelength of the photon emitted by a CO molecule in an $l = 1 \rightarrow l = 0$ rotational transition. (b) As a rule, molecules in a gas at temperature T will be found in a certain excited rotational energy level provided the energy of that level is no higher than kT (see Problem 42.41). Use this rule to explain why astronomers can detect radiation from CO in molecular clouds even though the typical temperature of a molecular cloud is a very low 20 K.

Figure 42.39 Problem 42.42.

42.43. The equilibrium separation for NaCl is 0.2361 nm. The mass of a sodium atom is 3.8176×10^{-26} kg. Chlorine has two stable isotopes, ^{35}Cl and ^{37}Cl, that have different masses but identical chemical properties. The atomic mass of ^{35}Cl is 5.8068×10^{-26} kg, and the atomic mass of ^{37}Cl is 6.1384×10^{-26} kg. (a) Calculate the wavelength of the photon emitted in the $l = 2 \rightarrow l = 1$ and $l = 1 \rightarrow l = 0$ transitions for $Na^{35}Cl$. (b) Repeat part (a) for $Na^{37}Cl$. What are the differences in the wavelengths for the two isotopes?

42.44. When an OH molecule undergoes a transition from the $n = 0$ to the $n = 1$ vibrational level, its internal vibrational energy increases by 0.463 eV. Calculate the frequency of vibration and the force constant for the interatomic force. (The mass of an oxygen atom is 2.66×10^{-26} kg, and the mass of a hydrogen atom is 1.67×10^{-27} kg.)

42.45. The force constant for the internuclear force in a hydrogen molecule (H_2) is $k' = 576$ N/m. A hydrogen atom has mass 1.67×10^{-27} kg. Calculate the zero-point vibrational energy for H_2 (that is, the vibrational energy the molecule has in the $n = 0$ ground vibrational level). How does this energy compare in magnitude with the H_2 bond energy of -4.48 eV?

42.46. Suppose the hydrogen atom in HF (see Exercise 42.13) is replaced by an atom of deuterium, an isotope of hydrogen with a mass of 3.34×10^{-27} kg. The force constant is determined by the electron configuration, so it is the same as for the normal HF molecule. (a) What is the vibrational frequency of this molecule? (b) What wavelength of light corresponds to the energy difference between the $n = 1$ and $n = 0$ levels? In what region of the spectrum does this wavelength lie?

42.47. The hydrogen iodide (HI) molecule has equilibrium separation 0.160 nm and vibrational frequency 6.93×10^{13} Hz. The mass of a hydrogen atom is 1.67×10^{-27} kg, and the mass of an iodine atom is 2.11×10^{-25} kg. (a) Calculate the moment of inertia of HI about a perpendicular axis through its centre of mass. (b) Calculate the wavelength of the photon emitted in each of the following vibration–rotation transitions: (i) $n = 1$, $l = 1 \rightarrow n = 0$, $l = 0$; (ii) $n = 1$, $l = 2 \rightarrow n = 0$, $l = 1$; (iii) $n = 2$, $l = 2 \rightarrow n = 1$, $l = 3$.

42.48. Prove this statement: For free electrons in a solid, if a state that is at an energy ΔE above E_F has probability P of being occupied, then the probability is $1 - P$ that a state at an energy ΔE below E_F is occupied.

42.49. Compute the Fermi energy of potassium by making the simple approximation that each atom contributes one free electron. The density of potassium is 851 kg/m^3, and the mass of a single potassium atom is 6.49×10^{-26} kg.

42.50. Hydrogen is found in two naturally occurring isotopes; normal hydrogen (containing a single proton in its nucleus) and deuterium (having a proton and a neutron). Assuming that both molecules are the same size and that the proton and neutron have the same mass (which is almost the case), find the ratio of (a) the energy of any given rotational state in a diatomic hydrogen molecule to the energy of the same state in a diatomic deuterium molecule and (b) the energy of any given vibrational state in hydrogen to the same state in deuterium (assuming that the force constant is the same for both molecules). Why is it physically reasonable that the force constant would be the same for hydrogen and deuterium molecules?

42.51. Metallic lithium has a bcc crystal structure. Each unit cell is a cube of side length $a = 0.35$ nm. (a) For a bcc lattice, what is the number of atoms per unit volume? Give your answer in terms of a. (*Hint:* How many atoms are there per unit cell?) (b) Use the result of part (a) to calculate the zero-temperature Fermi energy E_{F0} for metallic lithium. Assume there is one free electron per atom.

42.52. The one-dimensional calculation of Example 42.5 (Section 42.3) can be extended to three dimensions. For the

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

three-dimensional fcc NaCl lattice, the result for the potential energy of a pair of Na^+ and Cl^- ions due to the electrostatic interaction with all of the ions in the crystal is $U = -\alpha e^2/4\pi\epsilon_0 r$, where $\alpha = 1.75$ is the *Madelung constant*. Another contribution to the potential energy is a repulsive interaction at small ionic separation r due to overlap of the electron clouds. This contribution can be represented by A/r^8, where A is a positive constant, so the expression for the total potential energy is

$$U_{\text{tot}} = -\frac{\alpha e^2}{4\pi\epsilon_0 r} + \frac{A}{r^8}$$

(a) Let r_0 be the value of the ionic separation r for which U_{tot} is a minimum. Use this definition to find an equation that relates r_0 and A, and use this to write U_{tot} in terms of r_0. For NaCl, $r_0 = 0.281$ nm. Obtain a numerical value (in electron volts) of U_{tot} for NaCl. (b) The quantity $-U_{\text{tot}}$ is the energy required to remove a Na^+ ion and a Cl^- ion from the crystal. Forming a pair of neutral atoms from this pair of ions involves the release of 5.14 eV (the ionisation energy of Na) and the expenditure of 3.61 eV (the electron affinity of Cl). Use the result of part (a) to calculate the energy required to remove a pair of neutral Na and Cl atoms from the crystal. The experimental value for this quantity is 6.39 eV; how well does your calculation agree?

42.53. Consider a system of N free electrons within a volume V. Even at absolute zero, such a system exerts a pressure p on its surroundings due to the motion of the electrons. To calculate this pressure, imagine that the volume increases by a small amount dV. The electrons will do an amount of work pdV on their surroundings, which means that the total energy E_{tot} of the electrons will change by an amount $dE_{\text{tot}} = -pdV$. Hence $p = -dE_{\text{tot}}/dV$. (a) Show that the pressure of the electrons at absolute zero is

$$p = \frac{3^{2/3}\pi^{4/3}\hbar^2}{5m}\left(\frac{N}{V}\right)^{5/3}$$

(b) Evaluate this pressure for copper, which has a free-electron concentration of $8.45 \times 10^{28}\ \text{m}^{-3}$. Express your result in pascals and in atmospheres. (c) The pressure you found in part (b) is extremely high. Why, then, don't the electrons in a piece of copper simply explode out of the metal?

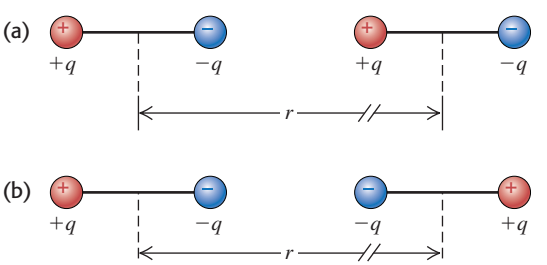
42.54. When the pressure p on a material increases by an amount Δp, the volume of the material will change from V to $V + \Delta V$, where ΔV is negative. The *bulk modulus* B of the material is defined to be the ratio of the pressure change Δp to the absolute value $|\Delta V/V|$ of the fractional volume change. The greater the bulk modulus, the greater the pressure increase required for a given fractional volume change, and the more incompressible the material (see Section 11.4). Since $\Delta V < 0$, the bulk modulus can be written as $B = -\Delta p/(\Delta V/V_0)$. In the limit that the pressure and volume changes are very small, this becomes

$$B = -V\frac{dp}{dV}$$

(a) Use the result of Problem 42.53 to show that the bulk modulus for a system of N free electrons in a volume V at low temperatures is $B = \frac{5}{3}p$. (*Hint:* The quantity p in the expression $B = -V(dp/dV)$ is the *external* pressure on the system. Can you explain why this is equal to the *internal* pressure of the system itself, as found in Problem 42.53?) (b) Evaluate the bulk modulus for the electrons in copper, which has a free-electron concentration of $8.45 \times 10^{28}\ \text{m}^{-3}$. Express your result in pascals. (c) The actual bulk modulus of copper is 1.4×10^{11} Pa. Based on your result in part (b), what fraction of this is due to the free electrons in copper? (This result shows that the free electrons in a metal play a major role in making the metal resistant to compression.) What do you think is responsible for the remaining fraction of the bulk modulus?

42.55. In the discussion of free electrons in Section 42.5, we assumed that we could ignore the effects of relativity. This is not a safe assumption if the Fermi energy is greater than about $\frac{1}{100}mc^2$ (that is, more than about 1% of the rest energy of an electron). (a) Assume that the Fermi energy at absolute zero, as given by Eq. (42.20), is equal to $\frac{1}{100}mc^2$. Show that the electron concentration is

$$\frac{N}{V} = \frac{2^{3/2}m^3c^3}{3000\pi^2\hbar^3}$$



and determine the numerical value of N/V. (b) Is it a good approximation to ignore relativistic effects for electrons in a metal such as copper, for which the electron concentration is $8.45 \times 10^{28}\ \text{m}^{-3}$? Explain. (c) A *white dwarf star* is what is left behind by a star like the sun after it has ceased to produce energy by nuclear reactions. (Our own sun will become a white dwarf star in another 6×10^9 years or so.) A typical white dwarf has mass 2×10^{30} kg (comparable to the sun) and radius 6000 km (comparable to that of the earth). The gravitational attraction of different parts of the white dwarf for each other tends to compress the star; what prevents it from compressing is the pressure of free electrons within the star (see Problem 42.53). Estimate the electron concentration within a typical white dwarf star using the following assumptions: (i) the white dwarf star is made of carbon, which has a mass per atom of 1.99×10^{-26} kg; and (ii) all six of the electrons from each carbon atom are able to move freely throughout the star. (d) Is it a good approximation to ignore relativistic effects in the structure of a white dwarf star? Explain.

42.56. A variable DC battery is connected in series with a 125-Ω resistor and a *p-n* junction diode that has a saturation current of 0.625 mA at room temperature (20°C). When a voltmeter across the 125-Ω resistor reads 35.0 V, what are (a) the voltage across the diode and (b) the resistance of the diode?

Challenge Problems

42.57. Van der Waals bonds arise from the interaction between two permanent or induced electric dipole moments in a pair of atoms or molecules. (a) Consider two identical dipoles, each consisting of charges $+q$ and $-q$ separated by a distance d and oriented as shown in Fig. 42.40a. Calculate the electric potential energy, expressed in terms of the electric dipole moment $p = qd$, for the situation where $r \gg d$. Is the interaction attractive or repulsive, and how does this potential energy vary with r, the separation

Figure **42.40** Challenge Problem 42.57.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

between the centres of the two dipoles? (b) Repeat part (a) for the orientation of the dipoles shown in Fig. 42.40b. The dipole interaction is more complicated when we have to average over the relative orientations of the two dipoles due to thermal motion or when the dipoles are induced rather than permanent.

42.58. (a) Consider the hydrogen molecule (H_2) to be a simple harmonic oscillator with an equilibrium spacing of 0.074 nm, and estimate the vibrational energy-level spacing for H_2. The mass of a hydrogen atom is 1.67×10^{-27} kg. (*Hint:* Estimate the force constant by equating the change in Coulomb repulsion of the protons, when the atoms move slightly closer together than r_0, to the 'spring' force. That is, assume that the chemical binding force remains approximately constant as r is decreased slightly from r_0.) (b) Use the results of part (a) to calculate the vibrational energy-level spacing for the deuterium molecule, D_2. Assume that the spring constant is the same for D_2 as for H_2. The mass of a deuterium atom is 3.34×10^{-27} kg.

43 NUCLEAR PHYSICS

LEARNING GOALS

By studying this chapter, you will be able to explain:

- Some key properties of atomic nuclei, including radii, densities, spins and magnetic moments.
- How the binding energy of a nucleus depends on the numbers of protons and neutrons that it contains.
- The most important ways in which unstable nuclei undergo radioactive decay.
- How the decay rate of a radioactive substance depends on time.
- Some of the biological hazards and medical uses of radiation.
- How to analyse some important types of nuclear reactions.
- What happens in a nuclear fission chain reaction, and how it can be controlled.
- The sequence of nuclear reactions that allow the sun and stars to shine.

? Oetzi, the Italian Iceman, is the world's oldest mummy and had been freeze-dried in the Alps about 3000 metres above sea level. What physical principles make it possible to date biological specimens such as these?

During the past century, applications of nuclear physics have had enormous effects on humankind, some beneficial, some catastrophic. Many people have strong opinions about applications such as bombs and reactors. Ideally, those opinions should be based on understanding, not on prejudice or emotion, and we hope this chapter will help you to reach that ideal.

Every atom contains at its centre an extremely dense, positively charged *nucleus*, which is much smaller than the overall size of the atom but contains most of its total mass. We will look at several important general properties of nuclei and of the nuclear force that holds them together. The stability or instability of a particular nucleus is determined by the competition between the attractive nuclear force among the protons and neutrons and the repulsive electrical interactions among the protons. Unstable nuclei *decay*, transforming themselves spontaneously into other structures by a variety of decay processes. Structure-altering nuclear reactions can also be induced by impact on a nucleus of a particle or another nucleus. Two classes of reactions of special interest are *fission* and *fusion*. We could not survive without the 3.90×10^{26} watt output of one nearby fusion reactor, our sun.

43.1 Properties of Nuclei

As we described in Section 38.4, Rutherford found that the nucleus is tens of thousands of times smaller in radius than the atom itself. Since Rutherford's initial experiments, many additional scattering experiments have been performed, using high-energy protons, electrons and neutrons as well as alpha particles (helium-4 nuclei). These experiments show that we can model a nucleus as a sphere with a radius R that depends on the total number of *nucleons* (neutrons

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

and protons) in the nucleus. This number is called the **nucleon number** A. The radii of most nuclei are represented quite well by the equation

$$R = R_0 A^{1/3} \qquad \text{(radius of a nucleus)} \qquad (43.1)$$

where R_0 is an experimentally determined constant:

$$R_0 = 1.2 \times 10^{-15}\ \text{m} = 1.2\ \text{fm}$$

The nucleon number A in Eq. (43.1) is also called the **mass number** because it is the nearest whole number to the mass of the nucleus measured in unified atomic mass units (u). (The proton mass and the neutron mass are both approximately 1 u.) The best current conversion factor is

$$1\ \text{u} = 1.66053886(28) \times 10^{-27}\ \text{kg}$$

In Section 43.2 we'll discuss the masses of nuclei in more detail. Note that when we speak of the masses of nuclei and particles, we mean their *rest* masses.

Nuclear Density

The volume V of a sphere is equal to $4\pi R^3/3$, so Eq. (43.1) shows that the *volume* of a nucleus is proportional to A. Dividing A (the approximate mass in u) by the volume gives us the approximate density and cancels out A. Thus *all nuclei have approximately the same density*. This fact is of crucial importance in understanding nuclear structure.

Example 43.1 Calculating nuclear properties

The most common kind of iron nucleus has a mass number of 56. Find the radius, approximate mass and approximate density of the nucleus.

SOLUTION

IDENTIFY: We use two key ideas: The radius and mass of a nucleus depend on the mass number A and density is mass divided by volume.

SET UP: We use Eq. (43.1) to determine the radius of the nucleus. The mass of the nucleus in atomic mass units is approximately equal to the mass number.

EXECUTE: The radius is

$$R = R_0 A^{1/3} = (1.2 \times 10^{-15}\ \text{m})(56)^{1/3}$$
$$= 4.6 \times 10^{-15}\ \text{m} = 4.6\ \text{fm}$$

Since $A = 56$, the mass of the nucleus is approximately 56 u, or

$$m \approx (56)(1.66 \times 10^{-27}\ \text{kg}) = 9.3 \times 10^{-26}\ \text{kg}$$

The volume is

$$V = \frac{4}{3}\pi R^3 = \frac{4}{3}\pi(4.6 \times 10^{-15}\ \text{m})^3 = 4.1 \times 10^{-43}\ \text{m}^3$$

and the density ρ is approximately

$$\rho = \frac{m}{V} \approx \frac{9.3 \times 10^{-26}\ \text{kg}}{4.1 \times 10^{-43}\ \text{m}^3} = 2.3 \times 10^{17}\ \text{kg/m}^3$$

EVALUATE: The density of solid iron is about $7000\ \text{kg/m}^3$, so we see that the iron nucleus is more than 10^{13} times as dense as the bulk material. Densities of this magnitude are also found in *neutron stars*, which are similar to gigantic nuclei made almost entirely of neutrons. A 1 cm cube of material with this density would have a mass of 2.3×10^{11} kg, or 230 million metric tons!

Nuclides and Isotopes

The basic building blocks of the nucleus are the proton and the neutron. In a neutral atom, the nucleus is surrounded by one electron for every proton in the nucleus. We introduced these particles in Section 21.1; we will recount the discovery of the neutron in Chapter 44. The masses of these particles are

Proton:	$m_p = 1.007276\ \text{u} = 1.672622 \times 10^{-27}\ \text{kg}$
Neutron:	$m_n = 1.008665\ \text{u} = 1.674927 \times 10^{-27}\ \text{kg}$
Electron:	$m_e = 0.000548580\ \text{u} = 9.10938 \times 10^{-31}\ \text{kg}$

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

The number of protons in a nucleus is the **atomic number** Z. The number of neutrons is the **neutron number** N. The nucleon number or mass number A is the sum of the number of protons Z and the number of neutrons N:

$$A = Z + N \tag{43.2}$$

A single nuclear species having specific values of both Z and N is called a **nuclide**. Table 43.1 lists values of A, Z and N for a few nuclides. The electron structure of an atom, which is responsible for its chemical properties, is determined by the charge Ze of the nucleus. The table shows some nuclides that have the same Z but different N. These nuclides are called **isotopes** of that element; they have different masses because they have different numbers of neutrons in their nuclei. A familiar example is chlorine (Cl, $Z = 17$). About 76% of chlorine nuclei have $N = 18$; the other 24% have $N = 20$. Different isotopes of an element usually have slightly different physical properties such as melting and boiling temperatures and diffusion rates. The two common isotopes of uranium with $A = 235$ and 238 are usually separated industrially by taking advantage of the different diffusion rates of gaseous uranium hexafluoride (UF_6) containing the two isotopes.

Table 43.1 also shows the usual notation for individual nuclides: the symbol of the element, with a pre-subscript equal to Z and a pre-superscript equal to the mass number A. The general format for an element El is ${}^{A}_{Z}\mathrm{El}$. The isotopes of chlorine mentioned above, with $A = 35$ and 37, are written ${}^{35}_{17}\mathrm{Cl}$ and ${}^{37}_{17}\mathrm{Cl}$ and pronounced 'chlorine-35' and 'chlorine-37,' respectively. This name of the element determines the atomic number Z, so the pre-subscript Z is sometimes omitted, as in ${}^{35}\mathrm{Cl}$.

Table 43.2 gives the masses of some common atoms, including their electrons. Note that this table gives masses of *neutral* atoms (with Z electrons) rather than masses of *bare* nuclei, because it is much more difficult to measure masses of bare nuclei with high precision. The mass of a neutral carbon-12 atom is exactly 12 u; that's how the unified atomic mass unit is defined. The masses of other atoms are *approximately* equal to A atomic mass units, as we stated earlier. In fact, the atomic masses are *less* than the sum of the masses of their parts (the Z protons, the Z electrons and the N neutrons). We'll explain this very important mass difference in the next section.

Table 43.1 Compositions of Some Common Nuclides

Nucleus	Mass Number (Total Number of Nucleons), A	Atomic Number (Number of Protons), Z	Neutron Number, $N = A - Z$
${}^{1}_{1}\mathrm{H}$	1	1	0
${}^{2}_{1}\mathrm{D}$	2	1	1

Nuclear Spins and Magnetic Moments

Like electrons, protons and neutrons are also spin-$\frac{1}{2}$ particles with spin angular momentum given by the same equations as in Section 41.3. The magnitude of the spin angular momentum $\vec{\boldsymbol{S}}$ of a nucleon is

$$S = \sqrt{\frac{1}{2}\left(\frac{1}{2}+1\right)}\hbar = \sqrt{\frac{3}{4}}\hbar \tag{43.3}$$

and the z-component is

$$S_z = \pm\frac{1}{2}\hbar \tag{43.4}$$

In addition to the spin angular momentum of the nucleons, there may be *orbital* angular momentum associated with their motions within the nucleus. The orbital angular momentum of the nucleons is quantised in the same way as that of electrons in atoms.

The *total* angular momentum $\vec{\boldsymbol{J}}$ of the nucleus is the vector sum of the individual spin and orbital angular momenta of all the nucleons. It has magnitude

$$J = \sqrt{j(j+1)}\hbar \tag{43.5}$$

and z-component

$$J_z = m_j\hbar \qquad (m_j = -j, -j+1, \ldots, j-1, j) \tag{43.6}$$

When the total number of nucleons A is *even*, j is an integer; when it is *odd*, j is a half-integer. All nuclides for which both Z and N are even have $J = 0$, which suggests that pairing of particles with opposite spin components may be an important consideration in nuclear structure. The total nuclear angular momentum quantum number j is usually called the *nuclear spin*, even though in general it refers to a combination of the orbital and spin angular momenta of the nucleons that make up the nucleus.

Associated with nuclear angular momentum is a *magnetic moment*. When we discussed *electron* magnetic moments in Section 41.2, we introduced the Bohr magneton $\mu_B = e\hbar/2m_e$ as a natural unit of magnetic moment. We found that the

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

magnitude of the z-component of the electron-spin magnetic moment is almost exactly equal to μ_B; that is, $|\mu_{sz}|_{\text{electron}} \approx \mu_B$. In discussing *nuclear* magnetic moments, we can define an analogous quantity, the **nuclear magneton** μ_n:

$$\mu_n = \frac{e\hbar}{2m_p} = 5.05078 \times 10^{-27}\,\text{J/T} = 3.15245 \times 10^{-8}\,\text{eV/T} \quad \text{(nuclear magneton)} \tag{43.7}$$

where m_p is the proton mass. Because the proton mass m_p is 1836 times larger than the electron mass m_e, the nuclear magneton μ_n is 1836 times smaller than the Bohr magneton μ_B.

We might expect the magnitude of the z-component of the spin magnetic moment of the proton to be approximately μ_n. Instead, it turns out to be

$$|\mu_{sz}|_{\text{proton}} = 2.7928\mu_n \tag{43.8}$$

Even more surprising, the neutron, which has no charge, has a corresponding magnitude of

$$|\mu_{sz}|_{\text{neutron}} = 1.9130\mu_n \tag{43.9}$$

The proton has a positive charge; as expected, its spin magnetic moment $\vec{\boldsymbol{\mu}}$ is parallel to its spin angular momentum $\vec{\boldsymbol{S}}$. However, $\vec{\boldsymbol{\mu}}$ and $\vec{\boldsymbol{S}}$ are opposite for a neutron, as would be expected for a negative charge distribution. These *anomalous* magnetic moments arise because the proton and neutron aren't really fundamental particles but are made of simpler particles called *quarks*. We'll discuss quarks in some detail in Chapter 44.

The magnetic moment of an entire nucleus is typically a few nuclear magnetons. When a nucleus is placed in an external magnetic field $\vec{\boldsymbol{B}}$, there is an interaction energy $U = -\vec{\boldsymbol{\mu}} \cdot \vec{\boldsymbol{B}} = -\mu_z B$ just as with atomic magnetic moments. The components of the magnetic moment in the direction of the field μ_z are quantised, so a series of energy levels results from this interaction.

Example 43.2 Proton spin flips

Protons are placed in a magnetic field in the z-direction with magnitude 2.30 T. (a) What is the energy difference between a state with the z-component of proton spin angular momentum parallel to the field and one with the component antiparallel to the field? (b) A proton can make a transition from one of these states to the other by emitting or absorbing a photon with energy equal to the energy difference of the two states. Find the frequency and wavelength of such a photon.

SOLUTION

IDENTIFY: The proton is a spin-$\frac{1}{2}$ particle with a magnetic moment, so its energy depends on the orientation of its spin relative to an applied magnetic field.

SET UP: The magnetic field $\vec{\boldsymbol{B}}$ is assumed to be in the positive z-direction, and the magnetic moment $\vec{\boldsymbol{\mu}}$ of the proton is in the same direction as its spin. If the z-component of spin is aligned with $\vec{\boldsymbol{B}}$, then μ_z is equal to the positive value given in Eq. (43.8); if the z-component of spin is opposite $\vec{\boldsymbol{B}}$, then μ_z is the negative of this value. The interaction energy in either case is $U = -\mu_z B$, and the energy difference [our target variable in part (a)] is the difference between the values of U for the two spin orientations. We find the photon frequency and wavelength using the relationships $E = hf = hc/\lambda$.

EXECUTE: (a) When the z-component of $\vec{\boldsymbol{S}}$ (and $\vec{\boldsymbol{\mu}}$) is parallel to the field, the interaction energy is

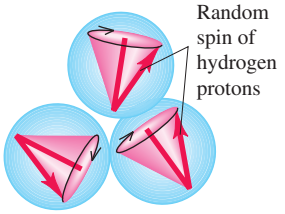
$$U = -|\mu_z|B = -(2.7928)(3.152 \times 10^{-8}\,\text{eV/T})(2.30\,\text{T}) = -2.025 \times 10^{-7}\,\text{eV}$$

When the components are antiparallel to the field, the energy is $+2.025 \times 10^{-7}$ eV, and the energy *difference* between the two states is

$$\Delta E = 2(2.025 \times 10^{-7}\,\text{eV}) = 4.05 \times 10^{-7}\,\text{eV}$$

(b) The corresponding photon frequency and wavelength are

$$f = \frac{\Delta E}{h} = \frac{4.05 \times 10^{-7}\,\text{eV}}{4.136 \times 10^{-15}\,\text{eV} \cdot \text{s}} = 9.79 \times 10^{7}\,\text{Hz} = 97.9\,\text{MHz}$$



$$\lambda = \frac{c}{f} = \frac{3.00 \times 10^{8}\,\text{m/s}}{9.79 \times 10^{7}\,\text{s}^{-1}} = 3.06\,\text{m}$$

EVALUATE: This frequency is in the middle of the FM radio band. When a hydrogen specimen is placed in a 2.30 T magnetic field and then irradiated with radiation of this frequency, the proton *spin flips* can be detected by the absorption of energy from the radiation.

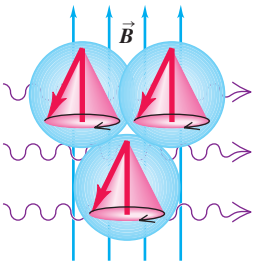
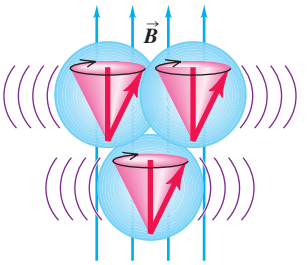
43.1 Magnetic resonance imaging (MRI).

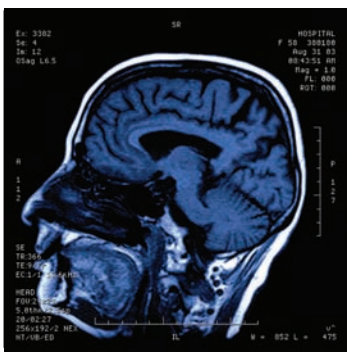


(a)

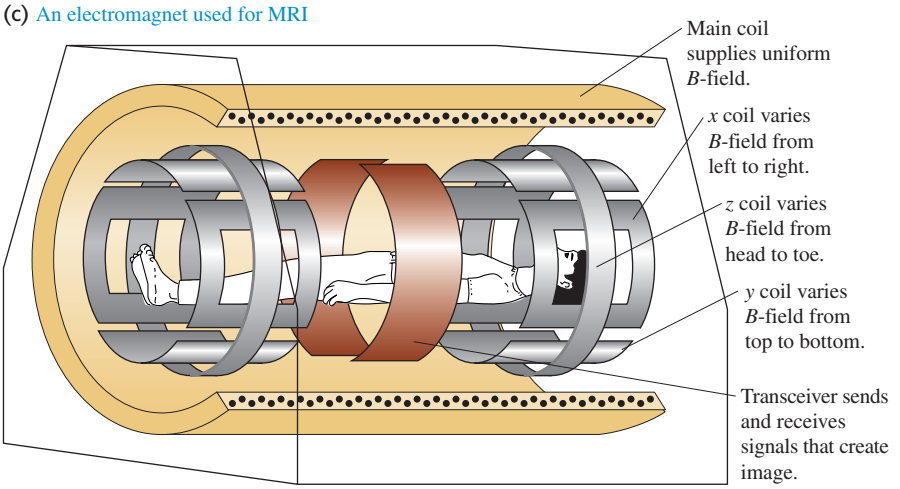


Protons, the nuclei of hydrogen atoms in the tissue under study, normally have random spin orientations.

In the presence of a strong magnetic field, the spins become aligned with a component parallel to $\vec{B}$.



A brief radio signal causes the spins to flip orientation.



As the protons realign with the $\vec{B}$-field, they emit radio waves that are picked up by sensitive detectors.

(b) Since $\vec{B}$ has a different value at different locations in the tissue, the radio waves from different locations have different frequencies. This makes it possible to construct an image.

(c) An electromagnet used for MRI

Nuclear Magnetic Resonance and MRI

Spin-flip experiments of the sort referred to in Example 43.2 are called *nuclear magnetic resonance* (NMR). They have been carried out with many different nuclides. Frequencies and magnetic fields can be measured very precisely, so this technique permits precise measurements of nuclear magnetic moments. An elaboration of this basic idea leads to *magnetic resonance imaging* (MRI), a noninvasive imaging technique that discriminates among various body tissues on the basis of the differing environments of protons in the tissues. The principles of MRI are shown in Fig. 43.1.

The magnetic moment of a nucleus is also the *source* of a magnetic field. In an atom the interaction of an electron's magnetic moment with the field of the nucleus's magnetic moment causes additional splittings in atomic energy levels and spectra. We called this effect *hyperfine structure* in Section 41.3. Measurements of the hyperfine structure may be used to directly determine the nuclear spin.

Australian Research

Headed by Professor William Price, the NMR facility at the University of Western Sydney is used for nanotechnology research.

(b) By what factor must the mass number increase to double the radius of the nucleus? (i) $\sqrt[3]{2}$; (ii) $\sqrt{2}$; (iii) 2; (iv) 4; (v) 8.

MP

43.2 Nuclear Binding and Nuclear Structure

Because energy must be added to a nucleus to separate it into its individual protons and neutrons, the total rest energy E_0 of the separated nucleons is greater than the rest energy of the nucleus. The energy that must be added to separate the

Activ ONLINE Physics
19.2 Nuclear Binding Energy

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

nucleons is called the **binding energy** E_B; it is the magnitude of the energy by which the nucleons are bound together. Thus the rest energy of the nucleus is $E_0 - E_B$. Using the equivalence of rest mass and energy (see Section 37.8), we see that the total mass of the nucleons is always greater than the mass of the nucleus by an amount E_B/c^2 called the *mass defect*. The binding energy for a nucleus containing Z protons and N neutrons is defined as

$$E_B = (ZM_H + Nm_n - {}^A_Z M)c^2 \qquad \text{(nuclear binding energy)} \qquad (43.10)$$

where ${}^A_Z M$ is the mass of the *neutral* atom containing the nucleus, the quantity in the parentheses is the mass defect, and $c^2 = 931.5\ \text{MeV/u}$. Note that Eq. (43.10) does not include Zm_p, the mass of Z protons. Rather, it contains ZM_H, the mass of Z protons and Z electrons combined as Z neutral ${}^1_1\text{H}$ atoms, to balance the Z electrons included in ${}^A_Z M$, the mass of the neutral atom.

The simplest nucleus is that of hydrogen, a single proton. Next comes the nucleus of ${}^2_1\text{H}$, the isotope of hydrogen with mass number 2, usually called *deuterium*. Its nucleus consists of a proton and a neutron bound together to form a particle called the *deuteron*. By using values from Table 43.2 in Eq. (43.10), the binding energy of the deuteron is

$$\begin{aligned} E_B &= (1.007825\ \text{u} + 1.008665\ \text{u} - 2.014102\ \text{u})(931.5\ \text{MeV/u}) \\ &= 2.224\ \text{MeV} \end{aligned}$$

This much energy would be required to pull the deuteron apart into a proton and a neutron. An important measure of how tightly a nucleus is bound is the *binding energy per nucleon*, E_B/A. At $(2.224\ \text{MeV})(2\ \text{nucleons}) = 1.112\ \text{MeV}$ per nucleon, ${}^2_1\text{H}$ has the lowest binding energy per nucleon of all nuclides.

Problem-Solving Strategy 43.1 Nuclear Properties

IDENTIFY *the relevant concepts*: The key properties of any nucleus include the mass, radius, binding energy, mass defect, binding energy per nucleon and angular momentum.

SET UP *the problem*: Once you have identified your target variables, collect the equations you need to solve the problem. A relatively small number of equations from this section and Section 43.1 are all you need, but make sure that you understand their meanings.

EXECUTE *the solution*: Solve the equations for the target variables. When doing energy calculations involving the binding energy and binding energy per nucleon, note that mass tables almost always list the masses of *neutral* atoms, including their full complement of electrons. To compensate for this, use the mass M_H of a ${}^1_1\text{H}$ atom in Eq. (43.10) rather than the mass of a bare proton. The binding energies of the electrons in the neutral atoms are much smaller and tend to cancel in the subtraction in Eq. (43.10), so we won't worry about them. As Eq. (43.10) shows, binding-energy calculations often involve subtracting two nearly equal quantities. To get enough precision in the difference, you often have to carry seven, eight or nine significant figures, if that many are available. If not, you may have to be content with an approximate result.

EVALUATE *your answer*: Familiarity with some typical numerical magnitudes is very useful when checking your results. Many of these magnitudes are quite different in nuclear physics than in atomic physics. Protons and neutrons are about 1840 times as massive as electrons. The radius of a nucleus is of the order 10^{-15} m; the electric potential energy of two protons in a nucleus is of the order 10^{-13} J or 1 MeV. Thus typical nuclear interaction energies are of the order of a few MeV, rather than a few eV as with atoms. The typical binding energy per nucleon is about 1% of the rest energy of a nucleon. For comparison, the ionisation energy of the hydrogen atom is only 0.003% of the electron's rest energy.

Angular momentum is of the same order of magnitude in both nuclei and atoms because it is determined by the value of $\hbar$. Magnetic moments of nuclei, however, are about 1000 times *smaller* than those of electrons in atoms because the nuclei are so much more massive than electrons.

Example 43.3 The most strongly bound nuclide

Because it has the highest binding energy per nucleon of all nuclides, ${}^{62}_{28}\text{Ni}$ may be described as the most strongly bound. Its neutral atomic mass is 61.928349 u. Find its mass defect, its total binding energy, and its binding energy per nucleon.

SOLUTION

IDENTIFY: The mass defect is the difference between the mass of the nucleus and the combined mass of its constituent nucleons. The

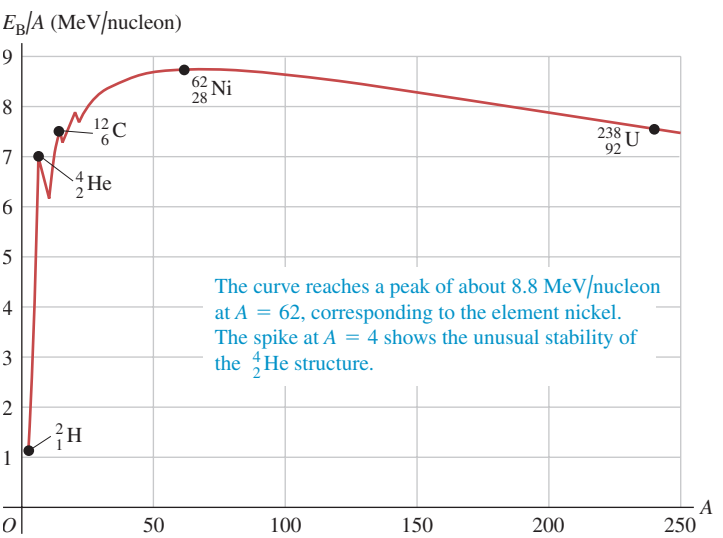
Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

binding energy E_B is this quantity multiplied by c^2, and the binding energy per nucleon is E_B divided by the mass number A.

SET UP: We use Eq. (43.10) to determine the binding energy.

EXECUTE: We use $Z = 28$, $M_H = 1.007825$ u, $N = A - Z = 62 - 28 = 34$, $m_n = 1.008665$ u, and ${}^A_Z M = 61.928349$ u in the parentheses of Eq. (43.10) to find a mass defect of 0.585361 u. Then

$$E_B = (0.585361\ \text{u})(931.5\ \text{MeV/u}) = 545.3\ \text{MeV}$$



It would require a minimum of 545.3 MeV to pull a ${}^{62}_{28}$Ni nucleus completely apart into 62 separate nucleons. The binding energy *per nucleon* is $\frac{1}{62}$ of this, or 8.795 MeV per nucleon.

EVALUATE: The mass defect of ${}^{62}_{28}$Ni is about 1% of the mass of the atom: $(0.585361\ \text{u})/(61.928349\ \text{u}) = 0.00945223 = 0.945223\%$ Since the mass of the atom is almost the same as the mass of the nucleus, this means that the binding energy (mass defect times c^2) is about 1% of the rest energy of the nucleus, and the binding energy per nucleon is about 1% of the rest energy of a nucleon. This result is as expected. Note that the mass defect is more than half the mass of a neutron or a proton, which suggests how tightly bound nuclei are.

Nearly all stable nuclides, from the lightest to the most massive, have binding energies in the range of 7–9 MeV per nucleon. Figure 43.2 is a graph of binding energy per nucleon as a function of the mass number A. Note the spike at $A = 4$, showing the unusually large binding energy per nucleon of the ${}^4_2$He nucleus (alpha particle) relative to its neighbours. To explain this curve, we must consider the interactions among the nucleons.

The Nuclear Force

The force that binds protons and neutrons together in the nucleus, despite the electrical repulsion of the protons, is an example of the *strong interaction* that we mentioned in Section 5.5. In the context of nuclear structure, this interaction is called the *nuclear force*. Here are some of its characteristics. First, it does not depend on charge; neutrons as well as protons are bound, and the binding is the same for both. Second, it has short range, of the order of nuclear dimensions—that is, 10^{-15} m. (Otherwise, the nucleus would grow by pulling in additional protons and neutrons.) But within its range, the nuclear force is much stronger than electrical forces; otherwise, the nucleus could never be stable. It would be nice if we could write a simple equation like Newton's law of gravitation or Coulomb's law for this force, but physicists have yet to fully determine its dependence on the separation r. Third, the nearly constant density of nuclear matter and the nearly constant binding energy per nucleon of larger nuclides show that a particular nucleon cannot interact simultaneously with *all* the other nucleons in a nucleus, but only with those few in its immediate vicinity. This is different from electrical forces; *every* proton in the nucleus repels every other one. This limited number of

43.2 Approximate binding energy per nucleon as a function of mass number A (the total number of nucleons) for stable nuclides.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

interactions is called *saturation*; it is analogous to covalent bonding in molecules and solids. Finally, the nuclear force favours binding of *pairs* of protons or neutrons with opposite spins and of *pairs of pairs*—that is, a pair of protons and a pair of neutrons, each pair having opposite spins. Hence the alpha particle (two protons and two neutrons) is an exceptionally stable nucleus for its mass number. We'll see other evidence for pairing effects in nuclei in the next subsection. (In Section 42.8 we described an analogous pairing that binds opposite-spin electrons in Cooper pairs in the BCS theory of superconductivity.)

The analysis of nuclear structure is more complex than the analysis of many-electron atoms. Two different kinds of interactions are involved (electrical and nuclear), and the nuclear force is not yet completely understood. Even so, we can gain some insight into nuclear structure by the use of simple models. We'll discuss briefly two rather different but successful models, the *liquid-drop model* and the *shell model*.

The Liquid-Drop Model

The **liquid-drop model**, first proposed in 1928 by the Russian physicist George Gamow and later expanded on by Niels Bohr, is suggested by the observation that all nuclei have nearly the same density. The individual nucleons are analogous to molecules of a liquid, held together by short-range interactions and surface-tension effects. We can use this simple picture to derive a formula for the estimated total binding energy of a nucleus. We'll include five contributions:

1. We've remarked that nuclear forces show *saturation*; an individual nucleon interacts only with a few of its nearest neighbours. This effect gives a binding-energy term that is proportional to the number of nucleons. We write this term as C_1A, where C_1 is an experimentally determined constant.
2. The nucleons on the surface of the nucleus are less tightly bound than those in the interior because they have no neighbours outside the surface. This decrease in the binding energy gives a *negative* energy term proportional to the surface area $4\pi R^2$. Because R is proportional to $A^{1/3}$, this term is proportional to $A^{2/3}$; we write it as $-C_2A^{2/3}$, where C_2 is another constant.
3. Every one of the Z protons repels every one of the $(Z-1)$ other protons. The total repulsive electric potential energy is proportional to $Z(Z-1)$ and inversely proportional to the radius R and thus to $A^{1/3}$. This energy term is negative because the nucleons are less tightly bound than they would be without the electrical repulsion. We write this correction as $-C_3Z(Z-1)/A^{1/3}$.
4. To be in a stable, low-energy state, the nucleus must have a balance between the energies associated with the neutrons and with the protons. This means that N is close to Z for small A and N is greater than Z (but not too much greater) for larger A. We need a negative energy term corresponding to the difference $|N-Z|$. The best agreement with observed binding energies is obtained if this term is proportional to $(N-Z)^2/A$. If we use $N = A - Z$ to express this energy in terms of A and Z, this correction is $-C_4(A-2Z)^2/A$.
5. Finally, the nuclear force favours *pairing* of protons and of neutrons. This energy term is positive (more binding) if both Z and N are even, negative (less binding) if both Z and N are odd, and zero otherwise. The best fit to the data occurs with the form $\pm C_5A^{-4/3}$ for this term.

The total estimated binding energy E_B is the sum of these five terms:

$$E_B = C_1A - C_2A^{2/3} - C_3\frac{Z(Z-1)}{A^{1/3}} - C_4\frac{(A-2Z)^2}{A} \pm C_5A^{-4/3} \qquad (43.11)$$

(nuclear binding energy)

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

The constants C_1, C_2, C_3, C_4, and C_5, chosen to make this formula best fit the observed binding energies of nuclides, are

$$C_1 = 15.75 \text{ MeV}$$
$$C_2 = 17.80 \text{ MeV}$$
$$C_3 = 0.7100 \text{ MeV}$$
$$C_4 = 23.69 \text{ MeV}$$
$$C_5 = 39 \text{ MeV}$$

The constant C_1 is the binding energy per nucleon due to the saturated nuclear force. This energy is almost 16 MeV per nucleon, about double the *total* binding energy per nucleon in most nuclides.

If we estimate the binding energy E_B using Eq. (43.11), we can solve Eq. (43.10) to use it to estimate the mass of any neutral atom:

$$^A_ZM = ZM_H + Nm_n - \frac{E_B}{c^2} \qquad \text{(semiempirical mass formula)} \quad (43.12)$$

Equation (43.12) is called the *semiempirical mass formula*. The name is apt; it is *empirical* in the sense that the C's have to be determined empirically (experimentally), yet it does have a sound theoretical basis.

Example 43.4 Estimating the binding energy and mass

Consider the nuclide $^{62}_{28}$Ni of Example 43.3. (a) Calculate the five terms in the binding energy and the total estimated binding energy. (b) Find its neutral atomic mass using the semiempirical mass formula.

SOLUTION

IDENTIFY: We use the liquid-drop model of the nucleus and its five contributions to the binding energy.

SET UP: We use Eq. (43.11) to calculate the individual terms in the binding energy as well as the total binding energy, and we use Eq. (43.12) to find the neutral atomic mass.

EXECUTE: (a) If we substitute $Z = 28$, $A = 62$, and $N = 34$ into Eq. (43.11), the individual terms are

1. $C_1A = (15.75 \text{ MeV})(62) = 976.5 \text{ MeV}$

2. $-C_2A^{2/3} = -(17.80 \text{ MeV})(62)^{2/3} = -278.8 \text{ MeV}$

3. $$-C_3\frac{Z(Z-1)}{A^{1/3}} = -(0.7100 \text{ MeV})\frac{(28)(27)}{(62)^{1/3}} = -135.6 \text{ MeV}$$

4. $$-C_4\frac{(A-2Z)^2}{A} = -(23.69 \text{ MeV})\frac{(62-56)^2}{62} = -13.8 \text{ MeV}$$

5. $+C_5A^{-4/3} = (39 \text{ MeV})(62)^{-4/3} = 0.2 \text{ MeV}$

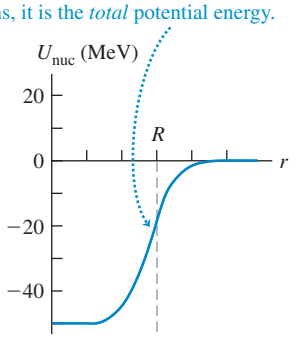
The pairing correction (term 5) is positive because both Z and N are even. Note that this is by far the smallest of all the terms. The total estimated binding energy is the sum of these five terms, or 548.5 MeV.

(b) Now we use the $E_B = 548.5$ MeV value in Eq. (43.12) to find

$$M = 28(1.007825 \text{ u}) + 34(1.008665 \text{ u}) - \frac{548.5 \text{ MeV}}{931.5 \text{ MeV/u}}$$
$$= 61.925 \text{ u}$$

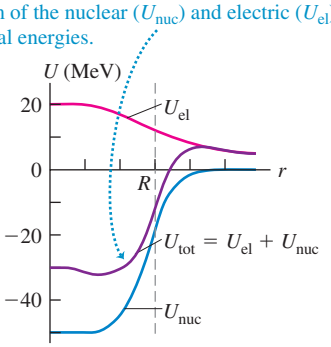
EVALUATE: The binding energy of $^{62}_{28}$Ni calculated in part (a) is only about 0.6% larger than the true value of 545.3 MeV found in Example 43.3, and the mass calculated in part (b) is only about 0.005% smaller than the measured value of 61.928349 u. These results show how accurate the semiempirical mass formula can be.

The liquid-drop model and the mass formula derived from it are quite successful in correlating nuclear masses, and we will see later that they are a great help in understanding decay processes of unstable nuclides. Some other aspects of nuclei, such as angular momentum and excited states, are better approached with different models.



The Shell Model

The **shell model** of nuclear structure is analogous to the central-field approximation in atomic physics (see Section 41.4). We picture each nucleon as moving in a potential that represents the averaged-out effect of all the other nucleons. This



Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

43.3 Approximate potential-energy functions for a nucleon in a nucleus. The approximate nuclear radius is R.

(a) The potential energy U_{nuc} due to the nuclear force is the same for protons and neutrons. For neutrons, it is the *total* potential energy.

(b) For protons, the total potential energy U_{tot} is the sum of the nuclear (U_{nuc}) and electric (U_{el}) potential energies.

may not seem to be a very promising approach; the nuclear force is very strong, very short range, and therefore strongly distance dependent. However, in some respects, this model turns out to work fairly well.

The potential-energy function for the nuclear force is the same for protons as for neutrons. A reasonable assumption for the shape of this function is shown in Fig. 43.3a. This function is a three-dimensional version of the square well we discussed in Section 40.2. The corners are somewhat rounded because the nucleus doesn't have a sharply defined surface. For protons there is an additional potential energy associated with electrical repulsion. We consider each proton to interact with a sphere of uniform charge density, with radius R and total charge $(Z-1)e$. Figure 43.3b shows the nuclear, electric and total potential energies for a proton as functions of the distance r from the centre of the nucleus.

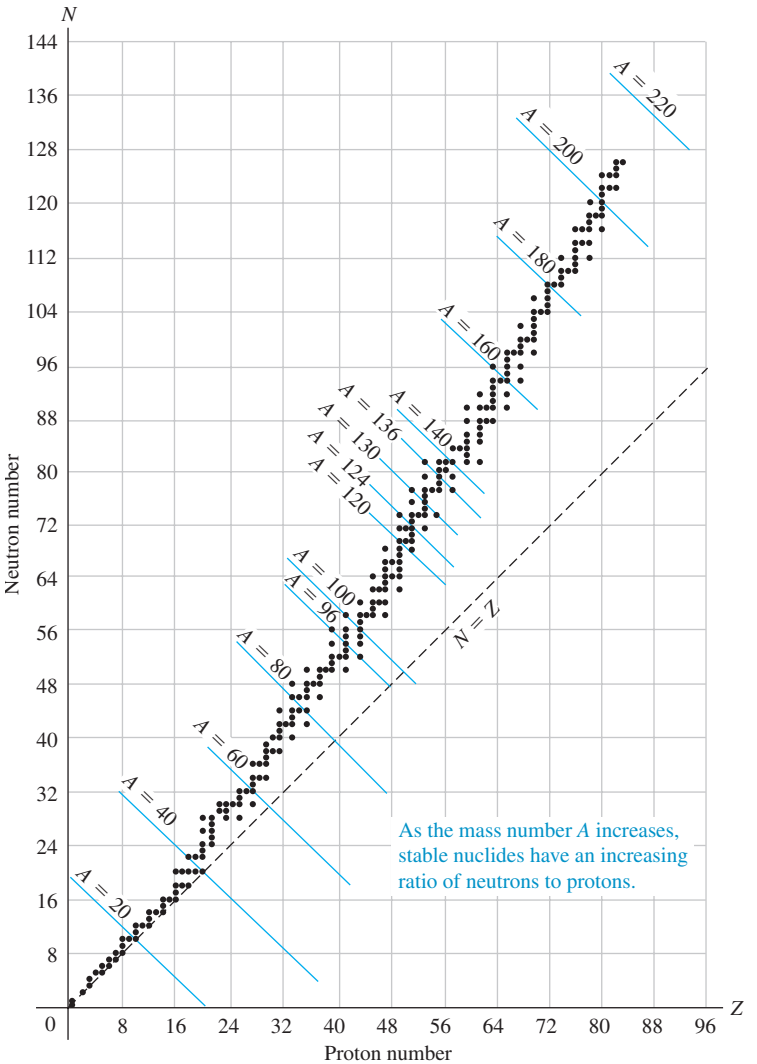
In principle, we could solve the Schrödinger equation for a proton or neutron moving in such a potential. For any spherically symmetric potential energy, the angular-momentum states are the same as for the electrons in the central-field approximation in atomic physics. In particular, we can use the concept of *filled shells and subshells* and their relationship to stability. In atomic structure we found that the values $Z = 2$, 10, 18, 36, 54 and 86 (the atomic numbers of the noble gases) correspond to particularly stable electron arrangements.

A comparable effect occurs in nuclear structure. The numbers are different because the potential-energy function is different and the nuclear spin–orbit interaction is much stronger and of opposite sign than in atoms, so the subshells fill up in a different order from those for electrons in an atom. It is found that when the number of neutrons *or* the number of protons is 2, 8, 20, 28, 50, 82 or 126, the resulting structure is unusually stable—that is, has an unusually great binding energy. (Nuclides with $Z = 126$ have not been observed in nature.) These numbers are called *magic numbers*. Nuclides in which Z is a magic number tend to have an above-average number of stable isotopes. There are several *doubly magic* nuclides for which both Z and N are magic, including

$$^{4}_{2}\mathrm{He} \qquad ^{16}_{8}\mathrm{O} \qquad ^{40}_{20}\mathrm{Ca} \qquad ^{48}_{20}\mathrm{Ca} \qquad ^{208}_{82}\mathrm{Pb}$$

All these nuclides have substantially higher binding energy per nucleon than do nuclides with neighbouring values of N or Z. They also all have zero nuclear spin. The magic numbers correspond to filled-shell or -subshell configurations of nucleon energy levels with a relatively large jump in energy to the next allowed level.

Test Your Understanding of Section 43.2 Rank the following nuclei in order from largest to smallest value of the binding energy per nucleon. (i) $^{4}_{2}$He; (ii) $^{52}_{24}$Cr; (iii) $^{152}_{62}$Sm; (iv) $^{200}_{80}$Hg; (v) $^{252}_{92}$Cf.



43.3 Nuclear Stability and Radioactivity

Among about 2500 known nuclides, fewer than 300 are stable. The others are unstable structures that decay to form other nuclides by emitting particles and electromagnetic radiation, a process called **radioactivity**. The time scale of these decay processes ranges from a small fraction of a microsecond to billions of years. The *stable* nuclides are shown by dots on the graph in Fig. 43.4, where the neutron number N and proton number (or atomic number) Z for each nuclide are plotted. Such a chart is called a *Segrè chart*, after its inventor, the Italian-American physicist Emilio Segrè (1905–1989).

Each blue line perpendicular to the line $N = Z$ represents a specific value of the mass number $A = Z + N$. Most lines of constant A pass through only one or two stable nuclides; that is, there is usually a very narrow range of stability for a given mass number. The lines at $A = 20$, $A = 40$, $A = 60$ and $A = 80$ are exam-

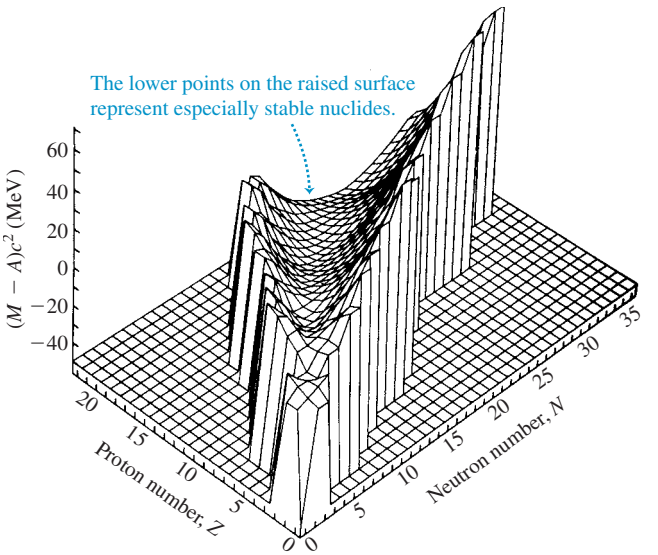
43.4 Segrè chart showing neutron number and proton number for stable nuclides.

ples. In four cases these lines pass through *three* stable nuclides—namely, at $A = 96$, 124, 130 and 136.

Four stable nuclides have both odd Z and odd N:



$$^{2}_{1}\mathrm{H} \qquad ^{6}_{3}\mathrm{Li} \qquad ^{10}_{5}\mathrm{B} \qquad ^{14}_{7}\mathrm{N}$$

These are called *odd-odd nuclides*. The absence of other odd-odd nuclides shows the influence of pairing. Also, there is *no* stable nuclide with $A = 5$ or $A = 8$. The doubly magic $^{4}_{2}$He nucleus, with a pair of protons and a pair of neutrons, has no interest in accepting a fifth particle into its structure. Collections of eight nucleons decay to smaller nuclides, with a $^{8}_{4}$Be nucleus immediately splitting into two $^{4}_{2}$He nuclei.

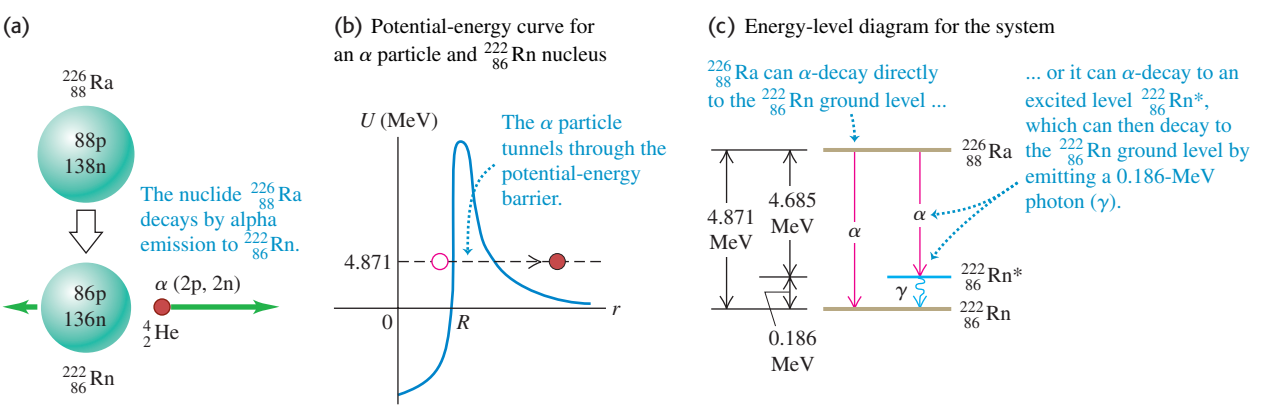
The points on the Segrè chart representing stable nuclides define a rather narrow stability region. For low mass numbers, the numbers of protons and neutrons are approximately equal, $N \approx Z$. The ratio N/Z increases gradually with A, up to about 1.6 at large mass numbers, because of the increasing influence of the electrical repulsion of the protons. Points to the right of the stability region represent nuclides that have too many protons relative to neutrons to be stable. In these cases, repulsion wins, and the nucleus comes apart. To the left are nuclides with too many neutrons relative to protons. In these cases the energy associated with the neutrons is out of balance with that associated with the protons, and the nuclides decay in a process that converts neutrons to protons. The graph also shows that no nuclide with $A > 209$ or $Z > 83$ is stable. A nucleus is unstable if

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

43.5 A three-dimensional Segrè chart for light nuclides up to $Z = 22$ (titanium). The quantity plotted on the third axis is $(M - A)c^2$, where M is the nuclide mass expressed in u. This quantity is related to the binding energy by a different constant for each nuclide.

it is too big. We also note that there is no stable nuclide with $Z = 43$ (technetium) or 61 (promethium). Figure 43.5, a three-dimensional version of the Segrè chart, shows the 'valley of stability' for light nuclides (up to $Z = 22$).

Alpha Decay



Nearly 90% of the 2500 known nuclides are *radioactive*; they are not stable but decay into other nuclides. When unstable nuclides decay into different nuclides, they usually emit alpha (α) or beta (β) particles. An **alpha particle** is a ^{4}He nucleus, two protons and two neutrons bound together, with total spin zero. Alpha emission occurs principally with nuclei that are too large to be stable. When a nucleus emits an alpha particle, its N and Z values each decrease by 2 and A decreases by 4, moving it closer to stable territory on the Segrè chart.

A familiar example of an alpha emitter is radium, $^{226}_{88}$Ra (Fig. 43.6a). The speed of the emitted alpha particle, determined from the curvature of its path in a transverse magnetic field, is about 1.52×10^7 m/s. This speed, although large, is only 5% of the speed of light, so we can use the nonrelativistic kinetic-energy expression $K = \frac{1}{2}mv^2$:

$$K = \frac{1}{2}(6.64 \times 10^{-27}\ \text{kg})(1.52 \times 10^7\ \text{m/s})^2 = 7.7 \times 10^{-13}\ \text{J} = 4.8\ \text{MeV}$$

Alpha particles are always emitted with definite kinetic energies, determined by conservation of momentum and energy. Because of their charge and mass, alpha

43.6 Alpha decay of the unstable radium nuclide $^{226}_{88}$Ra.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

particles can travel only several centimetres in air, or a few tenths or hundredths of a millimetre through solids, before they are brought to rest by collisions.

Some nuclei can spontaneously decay by emission of α particles because energy is released in their alpha decay. You can use conservation of mass-energy to show that

alpha decay is possible whenever the mass of the original neutral atom is greater than the sum of the masses of the final neutral atom and the neutral helium-4 atom.

In alpha decay, the α particle tunnels through a potential-energy barrier, as shown in Fig. 43.6b. You may want to review the discussion of tunnelling in Section 40.3.

Example 43.5 Alpha decay of radium

You are given the following neutral atomic masses:

$^{226}_{88}$Ra: 226.025403 u

$^{222}_{86}$Rn: 222.017571 u

Show that alpha emission is energetically possible and that the calculated kinetic energy of the emitted α particle agrees with the experimentally measured value of 4.78 MeV.

SOLUTION

IDENTIFY: Alpha emission is possible if the mass of the $^{226}_{88}$Ra atom is greater than the sum of the atomic masses of $^{222}_{86}$Rn and $^{4}_{2}$He.

SET UP: The mass difference between the initial radium atom and the final radon and helium atoms corresponds (through $E = mc^2$) to the energy E released in the decay. Because momentum is conserved as well as energy, *both* the alpha particle and the $^{222}_{86}$Rn atom are in motion after the decay; we will have to account for this fact in determining the kinetic energy of the alpha particle.

EXECUTE: From Table 43.2, the mass of the $^{4}_{2}$He atom is 4.002603 u. The difference in mass between the original nucleus and the decay products is

$$226.025403\ \text{u} - (222.017571\ \text{u} + 4.002603\ \text{u}) = +0.005229\ \text{u}$$

Since this is positive, alpha decay is energetically possible.

The energy equivalent of 0.005229 u is

$$E = (0.005229\ \text{u})(931.5\ \text{MeV/u}) = 4.871\ \text{MeV}$$

Thus we expect the decay products to emerge with total kinetic energy 4.871 MeV. Momentum is also conserved; if the parent nucleus is at rest, the daughter and the α particle have momenta of equal magnitude p but opposite direction. Kinetic energy is $K = p^2/2m$: Since p is the same for the two particles, the kinetic energy divides inversely as their masses. The α particle gets $222/(222 + 4)$ of the total, or 4.78 MeV, equal to the observed α-particle energy.

EVALUATE: An excellent way to check your results is to verify that the alpha particle and the $^{222}_{86}$Rn nucleus produced in the decay have the same magnitude of momentum $p = mv$. You can calculate the speed v of each of the decay products from its respective kinetic energy. You'll find that the alpha particle moves at a sprightly $0.0506c = 1.52 \times 10^7$ m/s; if momentum is conserved, you should find that the $^{222}_{86}$Rn nucleus moves 4/222 as fast. Does it?

Beta Decay

There are three different simple types of *beta decay*: *beta-minus*, *beta-plus* and *electron capture*. A **beta-minus particle** (β^-) is an electron. It's not obvious how a nucleus can emit an electron if there aren't any electrons in the nucleus. Emission of a β^- involves *transformation* of a neutron into a proton, an electron, and a third particle called an *antineutrino*. In fact, if you freed a neutron from a nucleus, it would decay into a proton, an electron and an antineutrino in an average time of about 15 minutes.

Beta particles can be identified and their speeds can be measured with techniques that are similar to the Thomson experiments we described in Section 27.5. The speeds of beta particles range up to 0.9995 of the speed of light, so their motion is highly relativistic. They are emitted with a continuous spectrum of energies. This would not be possible if the only two particles were the β^- and the recoiling nucleus, since energy and momentum conservation would then require a definite speed for the β^-. Thus there must be a *third* particle involved. From conservation of charge, it must be neutral, and from conservation of angular momentum, it must be a spin-$\frac{1}{2}$ particle.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

This third particle is an antineutrino, the *antiparticle* of a **neutrino**. The symbol for a neutrino is ν_e (the Greek letter nu). Both the neutrino and the antineutrino have zero charge and zero (or very small) mass and therefore produce very little observable effect when passing through matter. Both evaded detection until 1953, when Frederick Reines and Clyde Cowan succeeded in observing the antineutrino directly. We now know that there are at least three varieties of neutrinos, each with its corresponding antineutrino; one is associated with beta decay and the other two are associated with the decay of two unstable particles, the muon and the tau particle. We'll discuss these particles in more detail in Chapter 44. The antineutrino that is emitted in β^- decay is denoted as $\bar{\nu}_e$. The basic process of β^- decay is

$$n \rightarrow p + \beta^- + \bar{\nu}_e \tag{43.13}$$

Beta-minus decay usually occurs with nuclides for which the neutron-to-proton ratio N/Z is too large for stability. In β^- decay, N decreases by 1, Z increases by 1 and A doesn't change. You can use conservation of mass-energy to show that

beta-minus decay can occur whenever the mass of the original neutral atom is larger than that of the final atom.

Example 43.6 Why cobalt-60 is a beta-minus emitter

The nuclide $^{60}_{27}$Co, an odd-odd unstable nucleus, is used in medical applications of radiation. Show that it is unstable relative to β^- decay. The following masses are given:

$^{60}_{27}$Co: 59.933822 u

$^{60}_{28}$Ni: 59.930791 u

SOLUTION

IDENTIFY: Beta-minus decay is possible if the mass of the original neutral atom is greater than that of the final atom.

SET UP: We must first decide which nuclide will result if $^{60}_{27}$Co undergoes β^- decay and then compare its neutral atomic mass to that of $^{60}_{27}$Co.

EXECUTE: The original nuclide is $^{60}_{27}$Co. In β^- decay, Z increases by 1 from 27 to 28 and A remains at 60, so the final nuclide is $^{60}_{28}$Ni. Its mass is less than that of $^{60}_{27}$Co by 0.003031 u, so β^- decay *can* occur.

EVALUATE: As with alpha decay, this beta-minus decay obeys the conservation laws for both momentum and energy. But with three decay products in β^- decay—the $^{60}_{28}$Ni nucleus, the electron and the antineutrino—the energy can be shared in many different ways that are consistent with the conservation laws. It's impossible to predict precisely how the energy will be shared for the decay of a particular $^{60}_{27}$Co nucleus. By contrast, in alpha decay there are just two decay products, and their energies and momenta are determined uniquely (see Example 43.5).

We have noted that β^- decay occurs with nuclides that have too large a neutron-to-proton ratio N/Z. Nuclides for which N/Z is too *small* for stability can emit a *positron*, the electron's antiparticle, which is identical to the electron but with positive charge. (We mentioned the positron in connection with positronium in Section 38.5, and we will discuss it in more detail in Chapter 44.) The basic process, called *beta-plus decay* (β^+), is

$$p \rightarrow n + \beta^+ + \nu_e \tag{43.14}$$

where β^+ is a positron and ν_e is the electron neutrino.

Beta-plus decay can occur whenever the mass of the original neutral atom is at least two electron masses larger than that of the final atom;

you can show this using conservation of mass-energy.

The third type of beta decay is *electron capture*. There are a few nuclides for which β^+ emission is not energetically possible but in which an orbital electron (usually in the K shell) can combine with a proton in the nucleus to form a neutron and a neutrino. The neutron remains in the nucleus and the neutrino is emitted. The basic process is

$$p + \beta^- \rightarrow n + \nu_e \tag{43.15}$$

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

You can use conservation of mass-energy to show that

electron capture can occur whenever the mass of the original neutral atom is larger than that of the final atom.

In all types of beta decay, A remains constant. However, in beta-plus decay and electron capture, N increases by 1 and Z decreases by 1 as the neutron–proton ratio increases towards a more stable value. The reaction of Eq. (43.15) also helps to explain the formation of a neutron star, mentioned in Example 43.1.

CAUTION **Beta decay inside and outside nuclei** The beta decay reactions given by Eqs. (43.13) (43.14) and (43.15) occur *within* a nucleus. Although the decay of a neutron outside the nucleus proceeds through the reaction of Eq. (43.13), the reaction of Eq. (43.14) is forbidden by conservation of mass-energy for a proton outside the nucleus. The reaction of Eq. (43.15) can occur outside the nucleus only with the addition of some extra energy, as in a collision.

Example 43.7 Why cobalt-57 is not a beta-plus emitter

The nuclide $^{57}_{27}$Co, an odd-even unstable nucleus, is often used as a source of radiation in a nuclear process called the *Mössbauer effect*. Show that this nuclide is stable relative to β^+ decay but can decay by electron capture. The following masses are given:

$^{57}_{27}$Co: 56.936296 u

$^{57}_{26}$Fe: 56.935399 u

SOLUTION

IDENTIFY: Beta-plus decay is possible if the mass of the original neutral atom is greater than that of the final atom plus two electron masses.

SET UP: We must first decide which nuclide will result if $^{57}_{27}$Co undergoes β^+ decay and then compare its neutral atomic mass to that of $^{57}_{27}$Co.

EXECUTE: The original nuclide is $^{57}_{27}$Co. In β^+ decay and electron capture, Z decreases by 1 from 27 to 26, and A remains at 57. Thus the final nuclide is $^{57}_{26}$Fe. Its mass is less than that of $^{57}_{27}$Co by 0.000897 u, a value smaller than 0.001097 u (two electron masses), so β^+ decay *cannot* occur. However, the mass of the original atom is greater than the mass of the final atom, so electron capture *can* occur. In Section 43.4 we'll see how to relate the probability that electron capture will occur to the *half-life* of this nuclide.

EVALUATE: In electron capture there are just two decay products: the final nucleus and the emitted neutrino. Unlike in β^- decay (Example 43.6) but like in alpha decay (Example 43.5), the decay products of electron capture have unique energies and momenta.

Gamma Decay

The energy of internal motion of a nucleus is quantised. A typical nucleus has a set of allowed energy levels, including a *ground state* (state of lowest energy) and several *excited states*. Because of the great strength of nuclear interactions, excitation energies of nuclei are typically of the order of 1 MeV, compared with a few eV for atomic energy levels. In ordinary physical and chemical transformations the nucleus always remains in its ground state. When a nucleus is placed in an excited state, either by bombardment with high-energy particles or by a radioactive transformation, it can decay to the ground state by emission of one or more photons called **gamma rays** or *gamma-ray photons*, with typical energies of 10 keV to 5 MeV. This process is called *gamma* (γ) *decay*. For example, alpha particles emitted from ^{226}Ra have two possible kinetic energies, either 4.784 MeV or 4.602 MeV. Including the recoil energy of the resulting ^{222}Rn nucleus, these correspond to a total released energy of 4.871 MeV or 4.685 MeV, respectively. When an alpha particle with the smaller energy is emitted, the ^{222}Rn nucleus is left in an excited state. It then decays to its ground state by emitting a gamma-ray photon with energy

$$(4.871 - 4.685)\ \text{MeV} = 0.186\ \text{MeV}$$

A photon with this energy is observed during this decay (Fig. 43.6c).

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

CAUTION **γ decay vs α and β decay** In both α and β decay, the Z value of a nucleus changes and the nucleus of one element becomes the nucleus of a different element. In γ decay, the element does *not* change; the nucleus merely goes from an excited state to a less excited state.

Natural Radioactivity

Many radioactive elements occur in nature. For example, you are very slightly radioactive because of unstable nuclides such as carbon-14 and potassium-40 that are present throughout your body. The study of natural radioactivity began in 1896, one year after Röntgen discovered x-rays. Henri Becquerel discovered a radiation from uranium salts that seemed similar to x rays. Intensive investigation in the following two decades by Marie and Pierre Curie, Ernest Rutherford and many others revealed that the emissions consist of positively and negatively charged particles and neutral rays; they were given the names *alpha*, *beta* and *gamma* because of their differing penetration characteristics.

43.7 Earthquakes are caused in part by the radioactive decay of ^{238}U in the earth's interior. These decays release energy that helps to produce convection currents in the earth's interior. Such currents drive the motions of the earth's crust, including the sudden sharp motions that we call earthquakes (like the one that caused this damage).

The decaying nucleus is usually called the *parent nucleus*; the resulting nucleus is the *daughter nucleus*. When a radioactive nucleus decays, the daughter nucleus may also be unstable. In this case a *series* of successive decays occurs until a stable configuration is reached. Several such series are found in nature. The most abundant radioactive nuclide found on earth is the uranium isotope ^{238}U, which undergoes a series of 14 decays, including eight α emissions and six β^- emissions, terminating at a stable isotope of lead, ^{206}Pb (Fig. 43.7).

Radioactive decay series can be represented on a Segrè chart, as in Fig. 43.8. The neutron number N is plotted vertically, and the atomic number Z is plotted horizontally. In alpha emission, both N and Z decrease by 2. In β^- emission, N decreases by 1 and Z increases by 1. The decays can also be represented in equation form; the first two decays in the series are written as

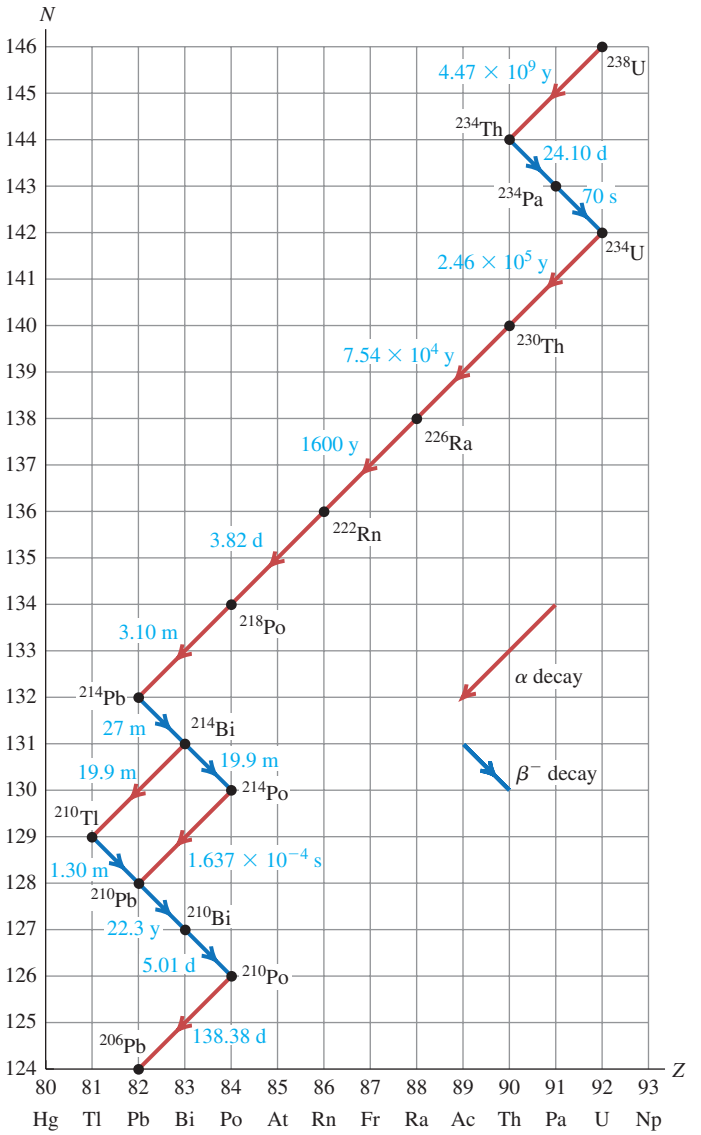
$$^{238}\text{U} \rightarrow {}^{234}\text{Th} + \alpha$$
$$^{234}\text{Th} \rightarrow {}^{234}\text{Pa} + \beta^- + \bar{\nu}_e$$

or more briefly as

$$^{238}\text{U} \xrightarrow{\alpha} {}^{234}\text{Th}$$
$$^{234}\text{Th} \xrightarrow{\beta^-} {}^{234}\text{Pa}$$

In the second process, the beta decay leaves the daughter nucleus ^{234}Pa in an excited state, from which it decays to the ground state by emitting a gamma-ray photon. An excited state is denoted by an asterisk, so we can represent the γ emission as

$$^{234}\text{Pa}^* \rightarrow {}^{234}\text{Pa} + \gamma$$



or

$$^{234}\text{Pa}^* \xrightarrow{\gamma} {}^{234}\text{Pa}$$

An interesting feature of the ^{238}U decay series is the branching that occurs at ^{214}Bi. This nuclide decays to ^{210}Pb by emission of an α and a β^-, which can occur in either order. We also note that the series includes unstable isotopes of several elements that also have stable isotopes, including thallium (Tl), lead (Pb) and bismuth (Bi). The unstable isotopes of these elements that occur in the ^{238}U series all have too many neutrons to be stable.

Many other decay series are known. Two of these occur in nature, one starting with the uncommon isotope ^{235}U and ending with ^{207}Pb, the other starting with thorium (^{232}Th) and ending with ^{208}Pb.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

43.8 Segrè chart showing the uranium ^{238}U decay series, terminating with the stable nuclide ^{206}Pb. The times are half-lives (discussed in the next section), given in years (y), days (d), hours (h), minutes (m) or seconds (s).

Test Your Understanding of Section 43.3 A nucleus with atomic number Z and neutron number N undergoes two decay processes. The result is a nucleus with atomic number $Z - 3$ and neutron number $N - 1$. Which decay processes took place? (i) two β^- decays; (ii) two β^+ decays; (iii) two α decays; (iv) an α decay and a β^- decay; (v) an α decay and a β^+ decay.

MP

43.4 Activities and Half-Lives

Suppose you need to dispose of some radioactive waste that contains a certain number of nuclei a particular radioactive nuclide. If no more are produced, that number decreases in a simple manner as the nuclei decay. This decrease is a statistical process; there is no way to predict when any individual nucleus will decay. No change in physical or chemical environment, such as chemical reactions or heating or cooling, greatly affects most decay rates. The rate varies over an extremely wide range for different nuclides.

Radioactive Decay Rates

Let $N(t)$ be the (very large) number of radioactive nuclei in a sample at time t, and let $dN(t)$ be the (negative) change in that number during a short time interval

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

dt. (We'll use $N(t)$ to minimise confusion with the neutron number N.) The number of decays during the interval dt is $-dN(t)$. The rate of change of $N(t)$ is the negative quantity $dN(t)/dt$; thus $-dN(t)/dt$ is called the *decay rate* or the **activity** of the specimen. The larger the number of nuclei in the specimen, the more nuclei decay during any time interval. That is, the activity is directly proportional to $N(t)$; it equals a constant λ multiplied by $N(t)$:

$$-\frac{dN(t)}{dt} = \lambda N(t) \tag{43.16}$$

The constant λ is called the **decay constant**, and it has different values for different nuclides. A large value of λ corresponds to rapid decay; a small value corresponds to slower decay. Solving Eq. (43.16) for λ shows us that λ is the ratio of the number of decays per time to the number of remaining radioactive nuclei; λ can then be interpreted as the *probability per unit time* that any individual nucleus will decay.

The situation is reminiscent of a discharging capacitor, which we studied in Section 26.4. Equation (43.16) has the same form as the negative of Eq. (26.15), with q and $1/RC$ replaced by $N(t)$ and λ. Then we can make the same substitutions in Eq. (26.16), with the initial number of nuclei $N(0) = N_0$, to find the exponential function:

$$N(t) = N_0 e^{-\lambda t} \qquad \text{(number of remaining nuclei)} \tag{43.17}$$

43.9 The number of nuclei in a sample of a radioactive element as a function of time. The sample's activity has an exponential decay curve with the same shape.

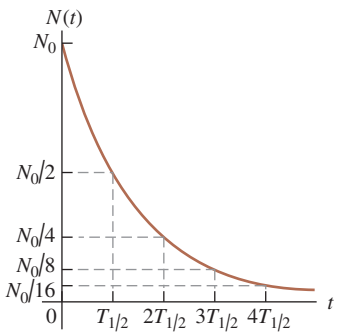


Figure 43.9 is a graph of this function, showing the number of remaining nuclei $N(t)$ as a function of time.

The **half-life** $T_{1/2}$ is the time required for the number of radioactive nuclei to decrease to one-half the original number N_0. Then half of the remaining radioactive nuclei decay during a second interval $T_{1/2}$, and so on. The numbers remaining after successive half-lives are $N_0/2$, $N_0/4$, $N_0/8$, ...

To get the relationship between the half-life $T_{1/2}$ and the decay constant λ, we set $N(t)/N_0 = \frac{1}{2}$ and $t = T_{1/2}$ in Eq. (43.17), obtaining

$$\frac{1}{2} = e^{-\lambda T_{1/2}}$$

We take logarithms of both sides and solve for $T_{1/2}$:

$$T_{1/2} = \frac{\ln 2}{\lambda} = \frac{0.693}{\lambda} \tag{43.18}$$

The mean lifetime T_{mean}, generally called the *lifetime*, of a nucleus or unstable particle is proportional to the half-life $T_{1/2}$:

$$T_{\text{mean}} = \frac{1}{\lambda} = \frac{T_{1/2}}{\ln 2} = \frac{T_{1/2}}{0.693} \qquad \begin{array}{l}\text{(lifetime } T_{\text{mean}}\text{, decay}\\ \text{constant } \lambda\text{, and half-life } T_{1/2}\text{)}\end{array} \tag{43.19}$$

In particle physics the life of an unstable particle is usually described by the lifetime, not the half-life.

Because the activity $-dN(t)/dt$ at any time equals $\lambda N(t)$, Eq. (43.17) tells us that the activity also depends on time as $e^{-\lambda t}$. Thus the graph of activity versus time has the same shape as Fig. 43.9. Also, after successive half-lives, the activity is one-half, one-fourth, one-eighth, and so on of the original activity.

CAUTION **A half-life may not be enough** It is sometimes implied that any radioactive sample will be safe after a half-life has passed. That's wrong. If your radioactive waste initially has ten times too much activity for safety, it is not safe after one half-life, when it still has five times too much. Even after three half-lives it still has 25% more

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

activity than is safe. The number of radioactive nuclei and the activity approach zero only as t approaches infinity.

A common unit of activity is the **curie**, abbreviated Ci, which is defined to be 3.70×10^{10} decays per second. This is approximately equal to the activity of one gram of radium. The SI unit of activity is the *becquerel*, abbreviated Bq. One becquerel is one decay per second, so

$$1\ \text{Ci} = 3.70 \times 10^{10}\ \text{Bq} = 3.70 \times 10^{10}\ \text{decays/s}$$

Example 43.8 Activity of ^{57}Co

The radioactive isotope ^{57}Co decays by electron capture with a half-life of 272 days. (a) Find the decay constant and the lifetime. (b) If you have a radiation source containing ^{57}Co, with activity 2.00 μCi, how many radioactive nuclei does it contain? (c) What will be the activity of your source after one year?

SOLUTION

IDENTIFY: This problem uses the relationships among decay constant λ, lifetime T_{mean}, and activity $-dN(t)/dt$.

SET UP: We determine the decay constant λ and lifetime T_{mean} from the half-life $T_{1/2}$ using Eq. (43.19). Once we have found λ, we calculate the number of nuclei $N(t)$ from the activity (which is the same as the decay rate $-dN(t)/dt$) using Eq. (43.16). We then use Eq. (43.17) to find the number of nuclei remaining after one year, and from this value find the activity after one year by using Eq. (43.16) once again.

EXECUTE: (a) To simplify the units, we convert the half-life to seconds:

$$T_{1/2} = (272\ \text{days})(86{,}400\ \text{s/day}) = 2.35 \times 10^7\ \text{s}.$$

From Eq. (43.19) the lifetime is

$$T_{\text{mean}} = \frac{T_{1/2}}{\ln 2} = \frac{2.35 \times 10^7\ \text{s}}{0.693} = 3.39 \times 10^7\ \text{s}$$

The decay constant is

$$\lambda = \frac{1}{T_{\text{mean}}} = 2.95 \times 10^{-8}\ \text{s}^{-1}$$

(b) The activity $-dN(t)/dt$ is given as 2.00 μCi, so

$$-\frac{dN(t)}{dt} = 2.00\ \mu\text{Ci} = (2.00 \times 10^{-6})(3.70 \times 10^{10}\ \text{s}^{-1}) = 7.40 \times 10^4\ \text{decays/s}$$

From Eq. (43.16) this is equal to $\lambda N(t)$, so we find

$$N(t) = -\frac{dN(t)/dt}{\lambda} = \frac{7.40 \times 10^4\ \text{s}^{-1}}{2.95 \times 10^{-8}\ \text{s}^{-1}} = 2.51 \times 10^{12}\ \text{nuclei}$$

If you feel we're being too cavalier about the 'units' decays and nuclei, you can use decays/(nucleus · s) as the unit for λ.

(c) From Eq. (43.17) the number $N(t)$ of nuclei remaining after one year $(3.156 \times 10^7\ \text{s})$ is

$$N(t) = N_0 e^{-\lambda t} = N_0 e^{-(2.95\times10^{-8}\ \text{s}^{-1})(3.156\times10^7\ \text{s})} = 0.394 N_0$$

The number of nuclei has decreased to 0.394 of the original number. Equation (43.16) says that the activity is proportional to the number of nuclei, so the activity has decreased by this same factor to $(0.394)(2.00\ \mu\text{Ci}) = 0.788\ \mu\text{Ci}$.

EVALUATE: The number of nuclei found in part (b) is equivalent to 4.17×10^{-12} mol, with a mass of 2.38×10^{-10} g. This is a far smaller mass than even the most sensitive balance can measure.

After one 272 day half-life, the number of ^{57}Co nuclei has decreased to $N_0/2$; after $2(272\ \text{d}) = 544\ \text{d}$, it has decreased to $N_0/2^2 = N_0/4$. This result agrees with our answer to part (c), which says that after 365 d the number of nuclei is between $N_0/2$ and $N_0/4$.

Radioactive Dating

An interesting application of radioactivity is the dating of archaeological and anthropological geological specimens by measuring the concentration of radioactive isotopes. The most familiar example is *carbon dating*. The unstable isotope ^{14}C, produced during nuclear reactions in the atmosphere that result from cosmic-ray bombardment, gives a small proportion of ^{14}C in the CO_2 in the atmosphere. Plants that obtain their carbon from this source contain the same proportion of ^{14}C as the atmosphere. When a plant dies, it stops taking in carbon, and its ^{14}C β^- decays to ^{14}N with a half-life of 5730 years. By measuring the proportion of ^{14}C in the remains, we can determine how long ago the organism died.

One difficulty with radiocarbon dating is that the ^{14}C concentration in the atmosphere changes over long time intervals. Corrections can be made on the basis of other data such as measurements of tree rings that show annual growth cycles. Similar radioactive techniques are used with other isotopes for dating geological specimens. Some rocks, for example, contain the unstable potassium

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

isotope ^{40}K, a beta emitter that decays to the stable nuclide ^{40}Ar with a half-life of 2.4×10^8 y. The age of the rock can be determined by comparing the concentrations of ^{40}K and ^{40}Ar.

Example 43.9 Radiocarbon dating

Before 1900 the activity per unit mass of atmospheric carbon due to the presence of ^{14}C averaged about 0.255 Bq per gram of carbon. (a) What fraction of carbon atoms were ^{14}C? (b) In analysing an archaeological specimen containing 500 mg of carbon, you observe 174 decays in one hour. What is the age of the specimen, assuming that its activity per unit mass of carbon when it died was that average value of the air?

SOLUTION

IDENTIFY: The key idea is that the present-day activity of a biological sample containing ^{14}C is related to both the elapsed time since it stopped taking in atmospheric carbon and its activity at that time.

SET UP: In part (a) we determine the number of ^{14}C atoms $N(t)$ from the activity $-dN(t)/dt$ using Eq. (43.16). We find the total number of carbon atoms in 500 mg by using the molar mass of carbon (12.011 g/mol, given in Appendix D), and we use the result to calculate the fraction of carbon atoms that are ^{14}C. The activity decays at the same rate as the number of ^{14}C nuclei; we use this fact in conjunction with Eq. (43.17) to solve for the age t of the specimen.

EXECUTE: (a) To use Eq. (43.16), we must first find λ from Eq. (43.18):

$$T_{1/2} = 5730 \text{ y} = (5730 \text{ y})(3.156 \times 10^7 \text{ s/y}) = 1.808 \times 10^{11} \text{ s}$$

$$\lambda = \frac{\ln 2}{T_{1/2}} = \frac{0.693}{1.808 \times 10^{11} \text{ s}} = 3.83 \times 10^{-12} \text{ s}^{-1}$$

Alternatively,

$$\lambda = \frac{0.693}{5730 \text{ y}} = 1.209 \times 10^{-4} \text{ y}^{-1}$$

Then, from Eq. (43.16),

$$N(t) = \frac{-dN/dt}{\lambda} = \frac{0.255 \text{ s}^{-1}}{3.83 \times 10^{-12} \text{ s}^{-1}} = 6.66 \times 10^{10} \text{ atoms}$$

The *total* number of C atoms in one gram $(1/12.011 \text{ mol})$ is $(1/12.011)(6.022 \times 10^{23}) = 5.01 \times 10^{22}$. The ratio of ^{14}C atoms to all C atoms is

$$\frac{6.66 \times 10^{10}}{5.01 \times 10^{22}} = 1.33 \times 10^{-12}$$

Only four carbon atoms in every 3 million million are ^{14}C.

(b) Assuming that the activity per gram of carbon in the specimen when it died was $0.255 \text{ Bq/g} = (0.255 \text{ s}^{-1} \cdot \text{g}^{-1})(3600 \text{ s/h}) = 918 \text{ h}^{-1} \cdot \text{g}^{-1}$, the activity of 500 mg of carbon then was $(0.500 \text{ g}) \times (918 \text{ h}^{-1} \cdot \text{g}^{-1}) = 459 \text{ h}^{-1}$. The observed activity now, at time t later, is 174 h^{-1}. Since the activity is proportional to the number of radioactive nuclei, the activity ratio $174/459 = 0.379$ equals the number ratio $N(t)/N_0$.

Now we solve Eq. (43.17) for t and insert values for $N(t)/N_0$ and λ:

$$t = \frac{\ln (N(t)/N_0)}{-\lambda} = \frac{\ln 0.379}{-1.209 \times 10^{-4} \text{ y}^{-1}} = 8020 \text{ y}$$

EVALUATE: After 8020 y the ^{14}C activity has decreased from 459 to 174 decays per hour. The specimen died and stopped taking CO_2 out of the air about 8000 years ago.

Radiation in the Home

A serious health hazard in some areas is the accumulation in houses of ^{222}Rn, an inert, colourless, odourless radioactive gas. Looking at the ^{238}U decay chain (Fig. 43.8), we see that the half-life of ^{222}Rn is 3.82 days. If so, why not just move out of the house for a while and let it decay away? The answer is that ^{222}Rn is continuously being *produced* by the decay of ^{226}Ra, which is found in minute quantities in the rocks and soil on which some houses are built. It's a dynamic equilibrium situation, in which the rate of production equals the rate of decay. The reason ^{222}Rn is a bigger hazard than the other elements in the ^{238}U decay series is that it's a gas. During its short half-life of 3.82 days it can migrate from the soil into your house. If a ^{222}Rn nucleus decays in your lungs, it emits a damaging α particle and its daughter nucleus ^{218}Po, which is *not* chemically inert and is likely to stay in your lungs until it decays, emits another damaging α particle and so on down the ^{238}U decay series.

How much of a hazard is radon? Although reports indicate values as high as 3500 pCi/L, the average activity per volume in the air inside homes due to ^{222}Rn is about 1.5 pCi/L (over a thousand decays each second in an average-sized

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

room). *If* your environment has this level of activity, it has been estimated that a lifetime exposure would reduce your life expectancy by about 40 days. For comparison, smoking one pack of cigarettes per day reduces life expectancy by 6 years, and it is estimated that the average emission from all the nuclear power plants in the world reduces life expectancy by anywhere from 0.01 day to 5 days. These figures include catastrophes such as the 1986 nuclear reactor disaster at Chernobyl, for which the *local* effect on life expectancy is much greater.

Test Your Understanding of Section 43.4 Which sample contains a greater number of nuclei: a 5.00-μCi sample of ^{240}Pu (half-life 6560 y) or a 4.45-μCi sample of ^{243}Am (half-life 7370 y)? (i) the ^{240}Pu sample; (ii) the ^{243}Am sample; (iii) both have the same number of nuclei.

43.5 Biological Effects of Radiation

The above discussion of radon introduced the interaction of radiation with living organisms, a topic of vital interest and importance. Under *radiation* we include radioactivity (alpha, beta, gamma and neutrons) and electromagnetic radiation such as x-rays. As these particles pass through matter, they lose energy, breaking molecular bonds and creating ions—hence the term *ionising radiation*. Charged particles interact directly with the electrons in the material. X-rays and γ-rays interact by the photoelectric effect, in which an electron absorbs a photon and breaks loose from its site, or by Compton scattering (see Section 38.7). Neutrons cause ionisation indirectly through collisions with nuclei or absorption by nuclei with subsequent radioactive decay of the resulting nuclei.

These interactions are extremely complex. It is well known that excessive exposure to radiation, including sunlight, x-rays and all the nuclear radiations, can destroy tissues. In mild cases it results in a burn, as with common sunburn. Greater exposure can cause very severe illness or death by a variety of mechanisms, including massive destruction of tissue cells, alterations of genetic material and destruction of the components in bone marrow that produce red blood cells.

Calculating Radiation Doses

Radiation dosimetry is the quantitative description of the effect of radiation on living tissue. The *absorbed dose* of radiation is defined as the energy delivered to the tissue per unit mass. The SI unit of absorbed dose, the joule per kilogram, is called the *gray* (Gy); 1 Gy = 1 J/kg. Another unit, in more common use at present, is the *rad*, defined as 0.01 J/kg:

$$1 \text{ rad} = 0.01 \text{ J/kg} = 0.01 \text{ Gy}$$

Absorbed dose by itself is not an adequate measure of biological effect because equal energies of different kinds of radiation cause different extents of biological effect. This variation is described by a numerical factor called the **relative biological effectiveness (RBE)**, also called the *quality factor* (QF), of each specific radiation. X-rays with 200 keV of energy are defined to have an RBE of unity, and the effects of other radiations can be compared experimentally. Table 43.3 shows approximate values of RBE for several radiations. All these values depend somewhat on the kind of tissue in which the radiation is absorbed and on the energy of the radiation.

The biological effect is described by the product of the absorbed dose and the RBE of the radiation; this quantity is called the *biologically equivalent dose*, or simply the equivalent dose. The SI unit of equivalent dose for humans is the sievert (Sv):

$$\text{Equivalent dose (Sv)} = \text{RBE} \times \text{Absorbed dose (Gy)} \qquad (43.20)$$

Table 43.3 Relative Biological Effectiveness (RBE) for Several Types of Radiation

Radiation	RBE (Sv/Gy or rem/rad)
X-rays and γ-rays	1
Electrons	1.0–1.5
Slow neutrons	3–5
Protons	10
α particles	20
Heavy ions	20

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

A more common unit, corresponding to the rad, is the rem (an abbreviation of *röntgen equivalent for man*):

$$\text{Equivalent dose (rem)} = \text{RBE} \times \text{Absorbed dose (rad)} \qquad (43.21)$$

Thus the unit of the RBE is 1 Sv/Gy or 1 rem/rad, and 1 rem = 0.01 Sv.

Example 43.10 A medical x-ray exam

During a diagnostic x-ray examination a 1.2 kg portion of a broken leg receives an equivalent dose of 0.40 mSv. (a) What is the equivalent dose in mrem? (b) What is the absorbed dose in mrad and mGy? (c) If the x-ray energy is 50 keV, how many x-ray photons are absorbed?

SOLUTION

IDENTIFY: We are asked to relate the equivalent dose (the biological effect of the radiation, measured in sieverts or rems) to the absorbed dose (the energy absorbed per mass, measured in grays or rads).

SET UP: In part (a) we use the conversion factor 1 rem = 0.01 Sv for equivalent dose. Table 43.3 gives the RBE for x-rays; we use this value in part (b) to determine the absorbed dose using Eqs. (43.20) and (43.21). Finally, in part (c) we use the mass and the definition of absorbed dose to find the total energy absorbed and the total number of photons absorbed.

EXECUTE: (a) The equivalent dose in mrem is

$$\frac{0.40\ \text{mSv}}{0.01\ \text{Sv/rem}} = 40\ \text{mrem}$$

(b) For x-rays, RBE = 1 rem/rad or 1 Sv/Gy, so the absorbed dose is

$$\frac{40\ \text{mrem}}{1\ \text{rem/rad}} = 40\ \text{mrad}$$

$$\frac{0.40\ \text{mSv}}{1\ \text{Sv/Gy}} = 0.40\ \text{mGy} = 4.0 \times 10^{-4}\ \text{J/kg}$$

(c) The total energy absorbed is

$$(4.0 \times 10^{-4}\ \text{J/kg})(1.2\ \text{kg}) = 4.8 \times 10^{-4}\ \text{J} = 3.0 \times 10^{15}\ \text{eV}$$

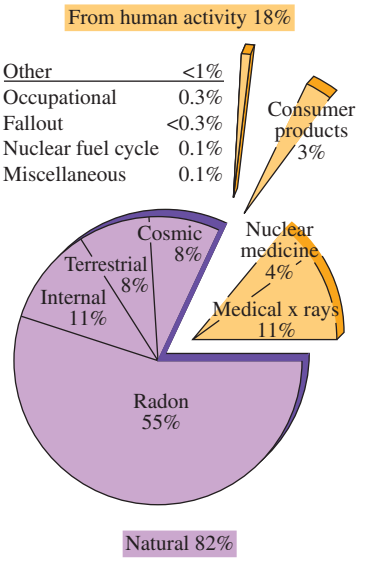
The number of x-ray photons is

$$\frac{3.0 \times 10^{15}\ \text{eV}}{5.0 \times 10^{4}\ \text{eV/photon}} = 6.0 \times 10^{10}\ \text{photons}$$

EVALUATE: The absorbed dose is relatively large because x-rays have a low RBE. If the ionising radiation had been a beam of α particles, for which RBE = 20, the absorbed dose needed for an equivalent dose of 0.40 mSv would be 0.020 mGy, corresponding to a total absorbed energy of 2.4×10^{-5} J.

Radiation Hazards

Here are a few numbers for perspective. To convert from Sv to rem, simply multiply by 100. An ordinary chest x-ray exam delivers about 0.20–0.40 mSv to about 5 kg of tissue. Radiation exposure from cosmic rays and natural radioactivity in soil, building materials, and so on is of the order of 2–3 mSv per year at sea level and twice that at an elevation of 1500 m. A whole-body dose of up to about 0.20 Sv causes no immediately detectable effect. A short-term whole-body dose of 5 Sv or more usually causes death within a few days or weeks. A localised dose of 100 Sv causes complete destruction of the exposed tissues.



The long-term hazards of radiation exposure in causing various cancers and genetic defects have been widely publicised, and the question of whether there is any 'safe' level of radiation exposure has been hotly debated. Most regulations are based on a maximum *yearly* exposure, from all except natural resources, of 2 to 5 mSv. Workers with occupational exposure to radiation are permitted 50 mSv per year. Recent studies suggest that these limits are too high and that even extremely small exposures carry hazards, but it is very difficult to gather reliable statistics on the effects of low doses. It has become clear that any use of x-rays for medical diagnosis should be preceded by a very careful estimation of the relationship of risk to possible benefit.

Another sharply debated question is that of radiation hazards from nuclear power plants. The radiation level from these plants is *not* negligible. However, to make a meaningful evaluation of hazards, we must compare these levels with the alternatives, such as coal-powered plants. The health hazards of coal smoke are serious and well documented, and the natural radioactivity in the smoke from a coal-fired power plant is believed to be roughly 100 times as great as that from

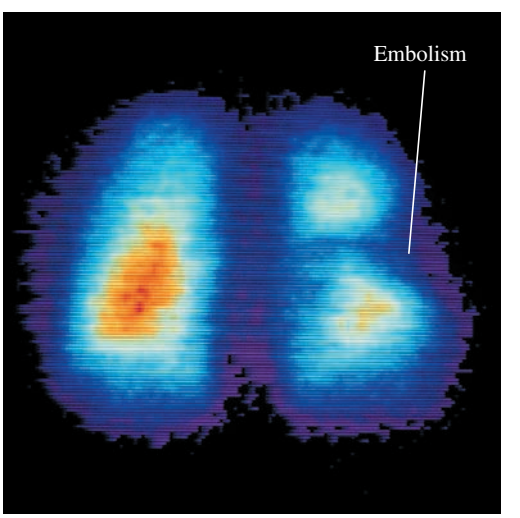
Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

a properly operating nuclear plant with equal capacity. But the comparison is not this simple; the possibility of a nuclear accident and the very serious problem of safe disposal of radioactive waste from nuclear plants must also be considered. It is clearly impossible to eliminate *all* hazards to health. Our goal should be to try to take a rational approach to the problem of *minimising* the hazard from all sources. Figure 43.10 shows one estimate of the various sources of radiation exposure for the U.S. population. Ionising radiation is a two-edged sword; it poses very serious health hazards, yet it also provides many benefits to humanity, including the diagnosis and treatments of disease and a wide variety of analytical techniques.

43.10 Contribution of various sources to the total average radiation exposure in the U.S. population, expressed as percentages of the total.

Beneficial Uses of Radiation

Radiation is widely used in medicine for intentional selective destruction of tissue such as tumours. The hazards are considerable, but if the disease would be fatal without treatment, any hazard may be preferable. Artificially produced isotopes are often used as radiation sources. Such isotopes have several advantages over naturally radioactive isotopes. They may have shorter half-lives and correspondingly greater activity. Isotopes can be chosen that emit the type and energy of radiation desired. Some artificial isotopes have been replaced by photon and electron beams from linear accelerators.



Nuclear medicine is an expanding field of application. Radioactive isotopes have virtually the same electron configurations and resulting chemical behaviour as stable isotopes of the same element. But the location and concentration of radioactive isotopes can easily be detected by measurements of the radiation they emit. A familiar example is the use of radioactive iodine for thyroid studies. Nearly all the iodine ingested is either eliminated or stored in the thyroid, and the body's chemical reactions do not discriminate between the unstable isotope ^{131}I and the stable isotope ^{127}I. A minute quantity of ^{131}I is fed or injected into the patient, and the speed with which it becomes concentrated in the thyroid provides a measure of thyroid function. The half-life is 8.02 days, so there are no long-lasting radiation hazards. By use of more sophisticated scanning detectors, one can also obtain a 'picture' of the thyroid, which shows enlargement and other abnormalities. This procedure, a type of *autoradiography*, is comparable to photographing the glowing filament of an incandescent light bulb by using the light emitted by the filament itself. If this process discovers cancerous thyroid nodules, they can be destroyed by much larger quantities of ^{131}I.

Another useful nuclide for nuclear medicine is technetium-99 (^{99}Tc), which is formed in an excited state by the β^- decay of molybdenum (^{99}Mo). The technetium then decays to its ground state by emitting a γ-ray photon with energy 143 keV. The half-life is 6.01 hours, unusually long for γ emission. (The ground state of ^{99}Tc is also unstable, with a half-life of 2.11×10^5 y; it decays by β^- emission to the stable ruthenium nuclide ^{99}Ru.) The chemistry of technetium is such that it can readily be attached to organic molecules that are taken up by various organs of the body. A small quantity of such technetium-bearing molecules is injected into a patient, and a scanning detector or *gamma camera* is used to produce an image, or *scintigram*, that reveals which parts of the body take up these γ-emitting molecules. This technique, in which ^{99}Tc acts as a radioactive *tracer*, plays an important role in locating cancers, embolisms and other pathologies (Fig. 43.11).

Tracer techniques have many other applications. Tritium (^3H), a radioactive hydrogen isotope, is used to tag molecules in complex organic reactions; radioactive tags on pesticide molecules, for example, can be used to trace their passage through food chains. In the world of machinery, radioactive iron can be used to study piston-ring wear. Laundry detergent manufacturers have even tested the effectiveness of their products using radioactive dirt.

Many direct effects of radiation are also useful, such as strengthening polymers by cross-linking, sterilising surgical tools, dispersing of unwanted static

43.11 This coloured scintigram shows where a chemical containing radioactive ^{99}Tc was taken up by a patient's lungs. The orange colour in the lung on the left indicates strong γ-ray emission by the ^{99}Tc, which shows that the chemical was able to pass into this lung through the bloodstream. The lung on the right shows weaker emission, indicating the presence of an embolism (a blood clot or other obstruction in an artery) that is restricting the flow of blood to this lung.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

electricity in the air and intentional ionisation of air in smoke detectors. Gamma rays are also being used to sterilise and preserve some food products.

Test Your Understanding of Section 43.5 Alpha particles have 20 times the relative biological effectiveness of 200 keV x-rays. Which would be better to use to radiate tissue deep inside the body? (i) a beam of alpha particles; (ii) a beam of 200-keV x-rays; (iii) both are equally effective.

43.6 Nuclear Reactions

In the preceding sections we studied the decay of unstable nuclei, especially spontaneous emission of an α or β particle, sometimes followed by γ emission. Nothing needs to be done to initiate this decay, and nothing can be done to control it. This section examines some *nuclear reactions*, rearrangements of nuclear components that result from a bombardment by a particle rather than a spontaneous natural process. Rutherford suggested in 1919 that a massive particle with sufficient kinetic energy might be able to penetrate a nucleus. The result would be either a new nucleus with greater atomic number and mass number or a decay of the original nucleus. Rutherford bombarded nitrogen $\left({}^{14}\mathrm{N}\right)$ with α particles and obtained an oxygen $\left({}^{17}\mathrm{O}\right)$ nucleus and a proton:

$$ {}^{4}_{2}\mathrm{He} + {}^{14}_{7}\mathrm{N} \rightarrow {}^{17}_{8}\mathrm{O} + {}^{1}_{1}\mathrm{H} \tag{43.22} $$

Rutherford used alpha particles from naturally radioactive sources. In Chapter 44 we'll describe some of the particle accelerators that are used nowadays to initiate nuclear reactions.

Nuclear reactions are subject to several *conservation laws*. The classical conservation principles for charge, momentum, angular momentum and energy (including rest energies) are obeyed in all nuclear reactions. An additional conservation law, not anticipated by classical physics, is conservation of the total number of nucleons. The numbers of protons and neutrons need not be conserved separately; we have seen that in β decay, neutrons and protons change into one another. We'll study the basis of the conservation of nucleon number in Chapter 44.

When two nuclei interact, charge conservation requires that the sum of the initial atomic numbers must equal the sum of the final atomic numbers. Because of conservation of nucleon number, the sum of the initial mass numbers must also equal the sum of the final mass numbers. In general, these are *not* elastic collisions and, correspondingly, the total initial mass does *not* equal the total final mass.

Reaction Energy

The difference between the masses before and after the reaction corresponds to the **reaction energy**, according to the mass-energy relationship $E = mc^2$. If initial particles A and B interact to produce final particles C and D, the reaction energy Q is defined as

$$ Q = \left(M_A + M_B - M_C - M_D\right)c^2 \qquad \text{(reaction energy)} \tag{43.23} $$

To balance the electrons, we use the neutral atomic masses in Eq. (43.23). That is, we use the mass of ${}^{1}_{1}\mathrm{H}$ for a proton, ${}^{2}_{1}\mathrm{H}$ for a deuteron, ${}^{4}_{2}\mathrm{He}$ for an α particle, and so on. When Q is positive, the total mass decreases and the total kinetic energy increases. Such a reaction is called an *exoergic reaction*. When Q is negative, the mass increases and the kinetic energy decreases, and the reaction is called an *endoergic reaction*. The terms *exothermal* and *endothermal*, borrowed from chemistry, are also used. In an endoergic reaction the reaction cannot occur at all unless the initial kinetic energy in the centre-of-mass reference frame is at

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

least as great as $|Q|$. That is, there is a **threshold energy**, the minimum kinetic energy to make an endoergic reaction go.

Example 43.11 Exoergic and endoergic reactions

(a) When lithium (^{7}Li) is bombarded by a proton, two alpha particles (^{4}He) are produced. Find the reaction energy. (b) Calculate the reaction energy for the nuclear reaction represented by Eq. (43.22).

SOLUTION

IDENTIFY: The reaction energy for any nuclear reaction is the total initial mass minus the total final mass, multiplied by c^2.

SET UP: In each case we determine the reaction energy using Eq. (43.23). The required masses are given in Table 43.2.

EXECUTE: (a) The reaction can be written

$$^1_1\text{H} + {}^7_3\text{Li} \rightarrow {}^4_2\text{He} + {}^4_2\text{He}$$

Here are the initial and final masses:

A:	$^1_1$H	1.007825 u	C:	$^4_2$He	4.002603 u
B:	$^7_3$Li	7.016004 u	D:	$^4_2$He	4.002603 u
		8.023829 u			8.005206 u

We see that

$$M_A + M_B - M_C - M_D = 0.018623 \text{ u}$$

Then Eq. (43.23) gives a reaction energy of

$$Q = (0.018623 \text{ u})(931.5 \text{ MeV/u}) = 17.35 \text{ MeV}$$

(b) The masses of the various particles are

A:	$^4_2$He	4.002603 u	C:	$^{17}_8$O	16.999132 u
B:	$^{14}_7$N	14.003074 u	D:	$^1_1$H	1.007825 u
		18.005677 u			18.006957 u

We see that the mass increases by 0.001280 u, and the corresponding reaction energy is

$$Q = (-0.001280 \text{ u})(931.5 \text{ MeV/u}) = -1.192 \text{ MeV}$$

EVALUATE: The reaction in (a) is *exoergic*: The final total kinetic energy of the two separating alpha particles is 17.35 MeV greater than the initial total kinetic energy of the proton and the lithium nucleus. By contrast, the reaction in (b) is *endoergic*: In the centre-of-mass system—that is, in a head-on collision with zero total momentum—the minimum total initial kinetic energy for this reaction to occur is 1.192 MeV.

Ordinarily, the endoergic reaction of part (b) of Example 43.11 would be produced by bombarding stationary ^{14}N nuclei with alpha particles from an accelerator. In this case an alpha's kinetic energy must be *greater than* 1.192 MeV. If all the alpha's kinetic energy went solely to increasing the rest energy, the final kinetic energy would be zero, and momentum would not be conserved. When a particle with mass m and kinetic energy K collides with a stationary particle with mass M, the total kinetic energy K_{cm} in the centre-of-mass coordinate system (the energy available to cause reactions) is

$$K_{\text{cm}} = \frac{M}{M + m}K \tag{43.24}$$

This expression assumes that the kinetic energies of the particles and nuclei are much less than their rest energies. We leave the derivation of Eq. (43.24) to you (see Problem 43.75). In the present example, $K_{\text{cm}} = (14.00/18.01)K$, so K must be at least $(18.01/14.00) \times (1.192 \text{ MeV}) = 1.533 \text{ MeV}$.

For a charged particle such as a proton or an α particle to penetrate the nucleus of another atom and cause a reaction, it must usually have enough initial kinetic energy to overcome the potential-energy barrier caused by the repulsive electrostatic forces. In the reaction of part (a) of Example 43.11, if we treat the proton and the ^{7}Li nucleus as spherically symmetric charges with radii given by Eq. (43.1), their centres will be 3.5×10^{-15} m apart when they touch. The repulsive potential energy of the proton (charge $+e$) and the ^{7}Li nucleus (charge $+3e$) at this separation r is

$$U = \frac{1}{4\pi\epsilon_0}\frac{(e)(3e)}{r} = (9.0 \times 10^9 \text{ N} \cdot \text{m}^2/\text{C}^2)\frac{(3)(1.6 \times 10^{-19} \text{ C})^2}{3.5 \times 10^{-15} \text{ m}}$$
$$= 2.0 \times 10^{-13} \text{ J} = 1.2 \text{ MeV}$$

Even though the reaction is exoergic, the proton must have a minimum kinetic energy of about 1.2 MeV for the reaction to occur, unless the proton *tunnels* through the barrier (see Section 40.3).

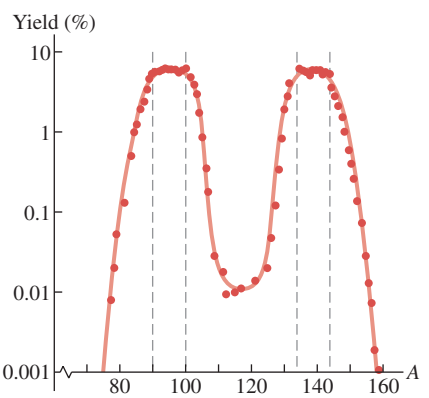
Neutron Absorption

Absorption of *neutrons* by nuclei forms an important class of nuclear reactions. Heavy nuclei bombarded by neutrons can undergo a series of neutron absorptions alternating with beta decays, in which the mass number A increases by as much as 25. Some of the *transuranic elements*, elements having Z larger than 92, are produced in this way. These elements have not been found in nature. Many transuranic elements, having Z possibly as high as 118, have been identified.

The analytical technique of *neutron activation analysis* uses similar reactions. When bombarded by neutrons, many stable nuclides absorb a neutron to become unstable and then undergo β^- decay. The energies of the β^- and associated γ emissions depend on the unstable nuclide and provide a means of identifying it and the original stable nuclide. Quantities of elements that are far too small for conventional chemical analysis can be detected in this way.

Test Your Understanding of Section 43.6 The reaction described in part (a) of Example 43.11 is exoergic. Can it happen naturally when a sample of solid lithium is placed in a flask of hydrogen gas?



43.7 Nuclear Fission

Nuclear fission is a decay process in which an unstable nucleus splits into two fragments of comparable mass. Fission was discovered in 1938 through the experiments of Otto Hahn and Fritz Strassman in Germany. Pursuing earlier work by Fermi, they bombarded uranium $(Z = 92)$ with neutrons. The resulting radiation did not coincide with that of any known radioactive nuclide. Urged on by their colleague Lise Meitner, they used meticulous chemical analysis to reach the astonishing but inescapable conclusion that they had found a radioactive isotope of barium $(Z = 56)$. Later, radioactive krypton $(Z = 36)$ was also found. Meitner and Otto Frisch correctly interpreted these results as showing that uranium nuclei were splitting into two massive fragments called *fission fragments*. Two or three free neutrons usually appear along with the fission fragments and, very occasionally, a light nuclide such as ^{3}H.

Both the common isotope (99.3%) ^{238}U and the uncommon isotope (0.7%) ^{235}U (as well as several other nuclides) can be easily split by neutron bombardment: ^{235}U by slow neutrons (kinetic energy less than 1 eV) but ^{238}U only by fast neutrons with a minimum of about 1 MeV of kinetic energy. Fission resulting from neutron absorption is called *induced fission*. Some nuclides can also undergo *spontaneous fission* without initial neutron absorption, but this is quite rare. When ^{235}U absorbs a neutron, the resulting nuclide ^{236}U* is in a highly excited state and splits into two fragments almost instantaneously. Strictly speaking, it is ^{236}U*, not ^{235}U, that undergoes fission, but it's usual to speak of the fission of ^{235}U.

Over 100 different nuclides, representing more than 20 different elements, have been found among the fission products. Figure 43.12 shows the distribution of mass numbers for fission fragments from the fission of ^{235}U. Most of the fragments have mass numbers from 90 to 100 and from 135 to 145; fission into two fragments with nearly equal mass is unlikely.

43.12 Mass distribution of fission fragments from the fission of ^{236}U* (an excited state of ^{236}U), which is produced when ^{235}U absorbs a neutron. The vertical scale is logarithmic.

Fission Reactions

You should check the following two typical fission reactions for conservation of nucleon number and charge:

$$^{235}_{92}\text{U} + {}^{1}_{0}\text{n} \rightarrow {}^{236}_{92}\text{U}^* \rightarrow {}^{144}_{56}\text{Ba} + {}^{89}_{36}\text{Kr} + 3{}^{1}_{0}\text{n}$$

$$^{235}_{92}\text{U} + {}^{1}_{0}\text{n} \rightarrow {}^{236}_{92}\text{U}^* \rightarrow {}^{140}_{54}\text{Xe} + {}^{94}_{38}\text{Sr} + 2{}^{1}_{0}\text{n}$$

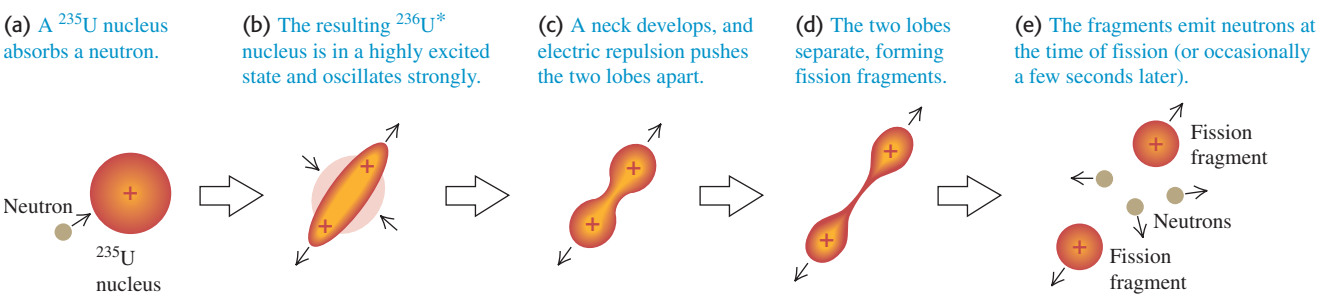
Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

The total kinetic energy of the fission fragments is enormous, about 200 MeV (compared to typical α and β energies of a few MeV). The reason for this is that nuclides at the high end of the mass spectrum (near $A = 240$) are less tightly bound than those nearer the middle ($A = 90$ to 145). Referring to Fig. 43.2, we see that the average binding energy per nucleon is about 7.6 MeV at $A = 240$ but about 8.5 MeV at $A = 120$. Therefore a rough estimate of the expected *increase* in binding energy during fission is about 8.5 MeV − 7.6 MeV = 0.9 MeV per nucleon, or a total of $(235)(0.9\ \text{MeV}) \approx 200\ \text{MeV}$.

CAUTION **Binding energy and rest energy** It may seem to be a violation of conservation of energy to have an increase in both the binding energy and the kinetic energy during a fission reaction. But relative to the total rest energy E_0 of the separated nucleons, the rest energy of the nucleus is E_0 *minus* E_B. Thus an *increase* in binding energy corresponds to a *decrease* in rest energy as rest energy is converted to the kinetic energy of the fission fragments.

Fission fragments always have too many neutrons to be stable. We noted in Section 43.3 that the neutron–proton ratio (N/Z) for stable nuclides is about 1 for light nuclides but almost 1.6 for the heaviest nuclides because of the increasing influence of the electrical repulsion of the protons. The N/Z value for stable nuclides is about 1.3 at $A = 100$ and 1.4 at $A = 150$. The fragments have about the same N/Z as ^{235}U, about 1.55. They usually respond to this surplus of neutrons by undergoing a series of β^- decays (each of which increases Z by 1 and decreases N by 1) until a stable value of N/Z is reached. A typical example is

$$^{140}_{54}\text{Xe} \xrightarrow{\beta^-} {}^{140}_{55}\text{Cs} \xrightarrow{\beta^-} {}^{140}_{56}\text{Ba} \xrightarrow{\beta^-} {}^{140}_{57}\text{La} \xrightarrow{\beta^-} {}^{140}_{58}\text{Ce}$$



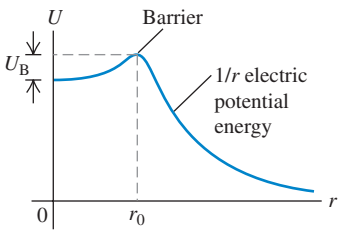
The nuclide ^{140}Ce is stable. This series of β^- decays produces, on average, about 15 MeV of additional kinetic energy. The neutron excess of fission fragments also explains why two or three free neutrons are released during the fission.

Fission appears to set an upper limit on the production of transuranic nuclei, mentioned in Section 43.6, that are relatively stable. There are theoretical reasons to expect that nuclei near $Z = 114$, $N = 184$ or 196, might be stable with respect to spontaneous fission. In the shell model (Section 43.2), these numbers correspond to filled shells and subshells in the nuclear energy-level structure. Such *superheavy nuclei* would still be unstable with respect to alpha emission, but they might live long enough to be identified. As of this writing, there is evidence that nuclei with $Z = 114$ have been produced in the laboratory.

Liquid-Drop Model

We can understand fission qualitatively on the basis of the liquid-drop model of the nucleus (Section 43.2). The process is shown in Fig. 46.13 in terms of an electrically charged liquid drop. These sketches shouldn't be taken too literally, but they may help to develop your intuition about fission. A ^{235}U nucleus absorbs a neutron (Fig. 43.13a), becoming a ^{236}U* nucleus with excess energy (Fig. 43.13b). This excess energy causes violent oscillations, during which a neck between two

43.13 A liquid–drop model of fission.



Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

lobes develops (Fig. 43.13c). The electrical repulsion of these two lobes stretches the neck farther (Fig. 43.13d), and finally two smaller fragments are formed (Fig. 43.13e) that move rapidly apart.

This qualitative picture has been developed into a more quantitative theory to explain why some nuclei undergo fission and others don't. Figure 43.14 shows a hypothetical potential-energy function for two possible fission fragments. If neutron absorption results in an excitation energy greater than the energy barrier height U_B, fission occurs immediately. Even when there isn't quite enough energy to surmount the barrier, fission can take place by quantum-mechanical *tunnelling*, discussed in Section 40.3. In principle, many stable heavy nuclei can fission by tunnelling. But the probability depends very critically on the height and width of the barrier. For most nuclei this process is so unlikely that it is never observed.

43.14 Hypothetical potential-energy function for two fission fragments in a fissionable nucleus. At distances r beyond the range of the nuclear force, the potential energy varies approximately as $1/r$. Fission occurs if there is an excitation energy greater than U_B or an appreciable probability for tunnelling through the potential-energy barrier.

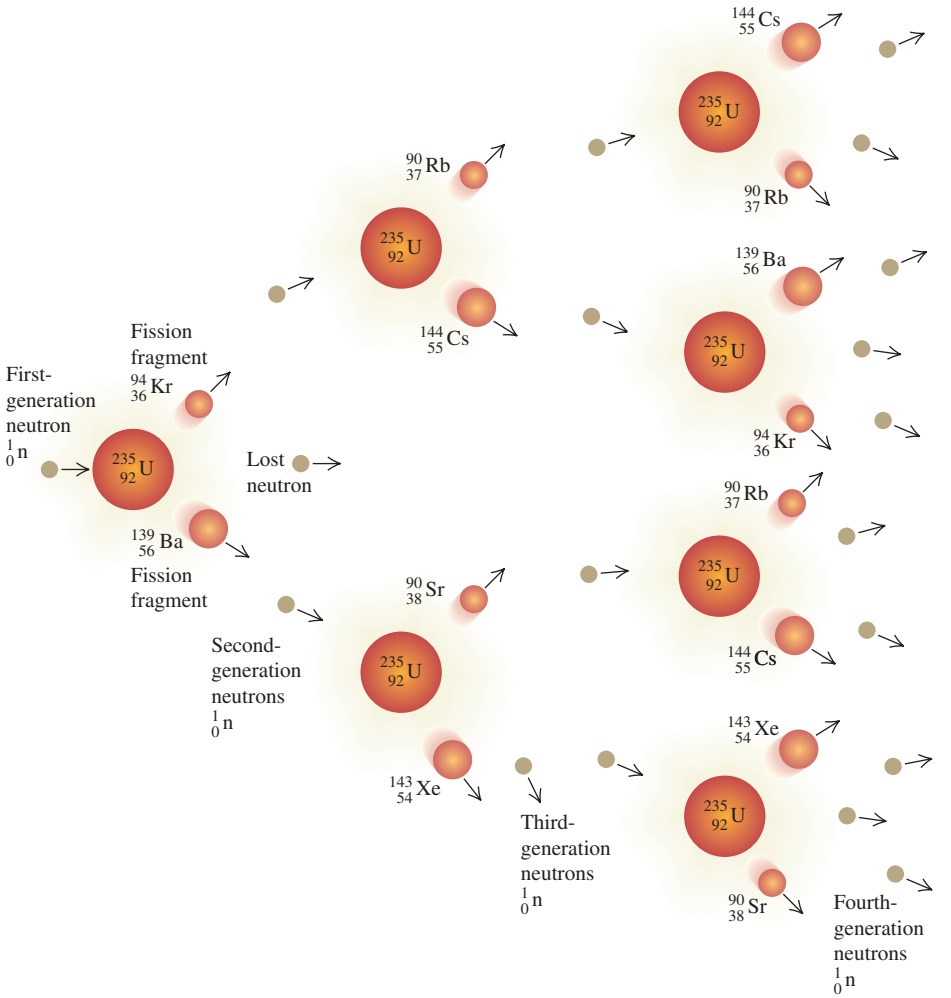
Chain Reactions

Fission of a uranium nucleus, triggered by neutron bombardment, releases other neutrons that can trigger more fissions, suggesting the possibility of a **chain reaction** (Fig. 43.15). The chain reaction may be made to proceed slowly and in a controlled manner in a nuclear reactor or explosively in a bomb. The energy release in a nuclear chain reaction is enormous, far greater than that in any chemical reaction. (In a sense, *fire* is a chemical chain reaction.) For example, when uranium is 'burned' to uranium dioxide in the chemical reaction

$$U + O_2 \rightarrow UO_2$$

the heat of combustion is about 4500 J/g. Expressed as energy per atom, this is about 11 eV per atom. By contrast, fission liberates about 200 MeV per atom, nearly 20 million times as much energy.

Nuclear Reactors



A *nuclear reactor* is a system in which a controlled nuclear chain reaction is used to liberate energy. In a nuclear power plant, this energy is used to generate steam, which operates a turbine and turns an electrical generator.

On average, each fission of a ^{235}U nucleus produces about 2.5 free neutrons, so 40% of the neutrons are needed to sustain a chain reaction. A ^{235}U nucleus is much more likely to absorb a low-energy neutron (less than 1 eV) than one of the higher-energy neutrons (1 MeV or so) that are liberated during fission. In a nuclear reactor the higher-energy neutrons are slowed down by collisions with nuclei in the surrounding material, called the *moderator*, so they are much more likely to cause further fissions. In nuclear power plants, the moderator is often water, occasionally graphite. The *rate* of the reaction is controlled by inserting or withdrawing *control rods* made of elements (such as boron or cadmium) whose nuclei *absorb* neutrons without undergoing any additional reaction. The isotope ^{238}U can also absorb neutrons, leading to $^{239}U^*$, but not with high enough probability for it to sustain a chain reaction by itself. Thus uranium that is used in reactors is often 'enriched' by increasing the proportion of ^{235}U above the natural value of 0.7%, typically to 3% or so, by isotope-separation processing.

The most familiar application of nuclear reactors is for the generation of electric power. As was noted above, the fission energy appears as kinetic energy of the fission fragments, and its immediate result is to increase the internal energy of the fuel elements and the surrounding moderator. This increase in internal energy is transferred as heat to generate steam to drive turbines, which spin the electrical generators. Figure 43.16 is a schematic diagram of a nuclear power plant. The energetic fission fragments heat the water surrounding the reactor core. The steam generator is a heat exchanger that takes heat from this highly radioactive water and generates nonradioactive steam to run the turbines.

43.15 Schematic diagram of a nuclear fission chain reaction.

A typical nuclear plant has an electric-generating capacity of 1000 MW (or 10^9 W). The turbines are heat engines and are subject to the efficiency limitations imposed by the second law of thermodynamics, discussed in Chapter 20. In modern nuclear plants the overall efficiency is about one-third, so 3000 MW of thermal power from the fission reaction is needed to generate 1000 MW of electrical power.

43.16 Schematic diagram of a nuclear power plant.

Australian Research

The Australian Nuclear Science and Technology Organisation's (ANSTO) OPAL reactor is Australia's only nuclear reactor which supplies isotopes for scientific research and medical and industrial applications.

Example 43.12 Uranium consumption in a nuclear reactor

What mass of ^{235}U has to undergo fission each day to provide 3000 MW of thermal power?

SOLUTION

IDENTIFY: The critical bit of information is that fission liberates about 200 MeV per atom.

SET UP: We use the energy released per atom along with the mass of the ^{235}U atom to determine the required amount of uranium.

EXECUTE: Each second, we need 3000 MJ or 3000×10^6 J. Each fission provides 200 MeV, which is

$$(200\ \text{MeV})(1.6 \times 10^{-13}\ \text{J/MeV}) = 3.2 \times 10^{-11}\ \text{J}$$

The number of fissions needed each second is

$$\frac{3000 \times 10^6\ \text{J}}{3.2 \times 10^{-11}\ \text{J}} = 9.4 \times 10^{19}$$

Each ^{235}U atom has a mass of $(235\ \text{u})(1.66 \times 10^{-27}\ \text{kg/u}) = 3.9 \times 10^{-25}$ kg, so the mass of ^{235}U needed each second is

$$(9.4 \times 10^{19})(3.9 \times 10^{-25}\ \text{kg}) = 3.7 \times 10^{-5}\ \text{kg} = 37\ \mu\text{g}$$

In one day (86,400 s), the total consumption of ^{235}U is

$$(3.7 \times 10^{-5}\ \text{kg/s})(86{,}400\ \text{s}) = 3.2\ \text{kg}$$

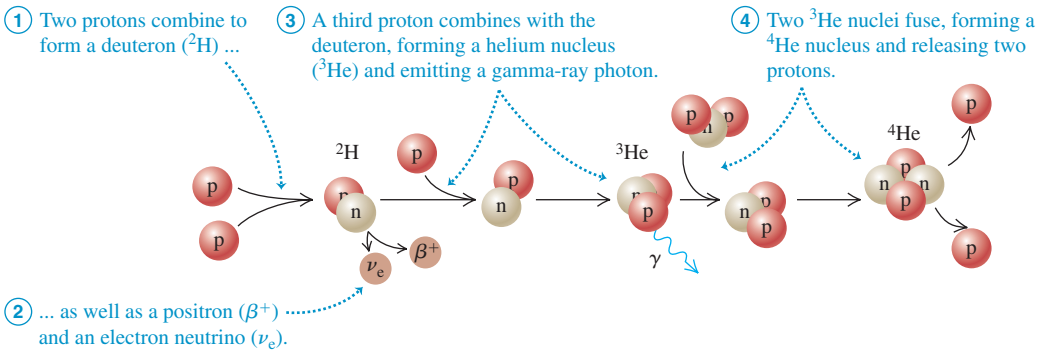
EVALUATE: For comparison, a 1000 MW coal-fired power plant burns about 10 million kg of coal per day!

Nuclear fission reactors have many other practical uses. Among these are the production of artificial radioactive isotopes for medical and other research, production of high-intensity neutron beams for research in nuclear structure, and production of fissionable nuclides such as ^{239}Pu from the common isotope ^{238}U. The last is the function of *breeder reactors*, which can produce more fuel than they use.

We mentioned above that about 15 MeV of the energy released after fission of a ^{235}U nucleus comes from the β^- decays of the fission fragments. This fact poses a serious problem with respect to control and safety of reactors. Even after the chain reaction has been completely stopped by insertion of control rods into the core, heat continues to be evolved by the β^- decays, which cannot be stopped. For a 3000 MW reactor this heat power is initially very large, about 200 MW. In the event of total loss of cooling water, this power is more than enough to cause a catastrophic meltdown of the reactor core and possible penetration of the containment vessel. The difficulty in achieving a 'cold shutdown' following an accident at the Three Mile Island nuclear power plant in Pennsylvania in March 1979 was a result of the continued evolution of heat due to β^- decays.

The catastrophe of 26 April 1986, at Chernobyl reactor No. 4 in Ukraine resulted from a combination of an inherently unstable design and several human errors committed during a test of the emergency core cooling system. Too many control rods were withdrawn to compensate for a decrease in power caused by a buildup of neutron absorbers such as ^{135}Xe. The power level rose from 1% of normal to 100 times normal in 4 seconds; a steam explosion ruptured pipes in the core cooling system and blew the heavy concrete cover off the reactor. The graphite moderator caught fire and burned for several days, and there was a meltdown of the core. The total activity of the radioactive material released into the atmosphere has been estimated as about 10^8 Ci.

Test Your Understanding of Section 43.7 The fission of ^{235}U can be triggered by the absorption of a slow neutron by a nucleus. Can a slow *proton* be used to trigger ^{235}U fission?



43.8 Nuclear Fusion

Activ Online Physics 19.3 Fusion

In a **nuclear fusion** reaction, two or more small light nuclei come together, or *fuse*, to form a larger nucleus. Fusion reactions release energy for the same reason as fission reactions: The binding energy per nucleon after the reaction is greater than before. Referring to Fig. 43.2, we see that the binding energy per

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

43.17 The proton-proton chain.

nucleon increases with A up to about $A = 60$, so fusion of nearly any two light nuclei to make a nucleus with A less than 60 is likely to be an exoergic reaction. In comparison to fission, we are moving towards the peak of this curve from the opposite side. Another way to express the energy relationships is that the total mass of the products is less than that of the initial particles.

Here are three examples of energy-liberating fusion reactions, written in terms of the neutral atoms:

$$
\begin{aligned}
{}^1_1\mathrm{H} + {}^1_1\mathrm{H} &\rightarrow {}^2_1\mathrm{H} + \beta^+ + \nu_e \\
{}^2_1\mathrm{H} + {}^1_1\mathrm{H} &\rightarrow {}^3_2\mathrm{He} + \gamma \\
{}^3_2\mathrm{He} + {}^3_2\mathrm{He} &\rightarrow {}^4_2\mathrm{He} + {}^1_1\mathrm{H} + {}^1_1\mathrm{H}
\end{aligned}
$$

In the first reaction, two protons combine to form a deuteron $({}^2\mathrm{H})$, with the emission of a positron (β^+) and an electron neutrino. In the second, a proton and a deuteron combine to form the nucleus of the light isotope of helium, ^{3}He, with the emission of a gamma ray. Now double the first two reactions to provide the two ^{3}He nuclei that fuse in the third reaction to form an alpha particle $({}^4\mathrm{He})$ and two protons. Together the reactions make up the process called the *proton-proton chain* (Fig. 43.17).

The net effect of the chain is the conversion of four protons into one α particle, two positrons, two electron neutrinos, and two γ's. We can calculate the energy release from this part of the process: The mass of an α particle plus two positrons is the mass of neutral ^{4}He, the neutrinos have zero (or negligible) mass, and the gammas have zero mass.

Mass of four protons	4.029106 u
Mass of ^{4}He	4.002603 u
Mass difference and energy release	0.026503 u and 24.69 MeV

The two positrons that are produced during the first step of the proton-proton chain collide with two electrons; mutual annihilation of the four particles takes place, and their rest energy is converted into $4(0.511\ \mathrm{MeV}) = 2.044\ \mathrm{MeV}$ of gamma radiation. Thus the total energy release is $(24.69 + 2.044)\ \mathrm{MeV} = 26.73\ \mathrm{MeV}$. The proton-proton chain takes place in the interior of the sun and other stars (Fig. 43.18). Each gram of the sun's mass contains about 4.5×10^{23} protons. If all of these protons were fused into helium, the energy released would be about 130 000 kWh. If the sun were to continue to radiate at its present rate, it would take about 75×10^9 years to exhaust its supply of protons. As we will see below, fusion reactions can occur only at extremely high temperatures; in the sun, these temperatures are found only deep within the interior. Hence the sun cannot fuse *all* of its protons, and can do so for a total of only about 10×10^9 years in total. The present age of the solar system (including the sun) is 4.6×10^9 years, so the sun is about halfway through its available store of protons.

43.18 The energy released as starlight comes from fusion reactions deep within a star's interior. When a star is first formed and for most of its life, it converts the hydrogen in its core into helium. As a star ages, the core temperature can become high enough for additional fusion reactions that convert helium into carbon, oxygen, and other elements.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

Example 43.13 A fusion reaction

Two deuterons fuse to form a *triton* (a nucleus of tritium, or ^{3}H) and a proton. How much energy is liberated?

SOLUTION

IDENTIFY: This is a nuclear reaction of the type discussed in Section 43.6.

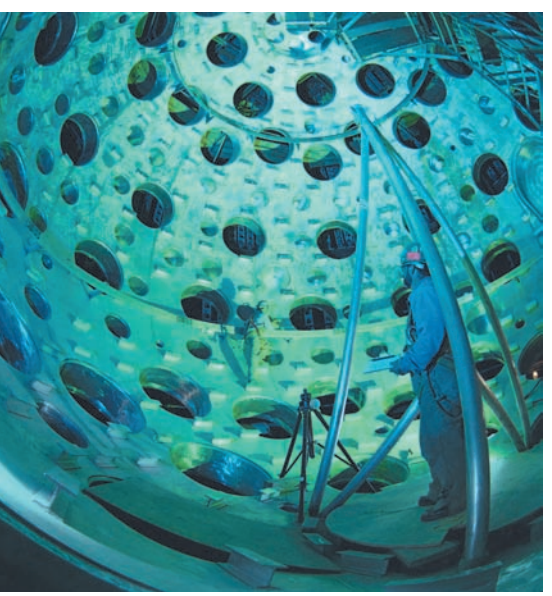
SET UP: We find the energy released using Eq. (43.23).

EXECUTE: Adding one electron to each particle makes each a neutral atom; we find their masses in Table 43.2. Substituting into Eq. (43.23), we find

$$\begin{aligned} Q &= [2(2.014102\ \text{u}) - 3.016049\ \text{u} - 1.007825\ \text{u}] \\ &\quad \times (931.5\ \text{MeV/u}) \\ &= 4.03\ \text{MeV} \end{aligned}$$

EVALUATE: Thus 4.03 MeV is released in the reaction; the triton and proton together have 4.03 MeV more kinetic energy than the two deuterons had together.

Achieving Fusion



For two nuclei to undergo fusion, they must come together to within the range of the nuclear force, typically of the order of 2×10^{-15} m. To do this, they must overcome the electrical repulsion of their positive charges. For two protons at this distance, the corresponding potential energy is about 1.2×10^{-13} J or 0.7 MeV; this represents the total initial *kinetic* energy that the fusion nuclei must have—for example, 0.6×10^{-13} J each in a head-on collision.

Atoms have this much energy only at extremely high temperatures. The discussion of Section 18.3 showed that the average translational kinetic energy of a gas molecule at temperature T is $\frac{3}{2}kT$, where k is Boltzmann's constant. The temperature at which this is equal to $E = 0.6 \times 10^{-13}$ J is determined by the relationship

$$E = \frac{3}{2}kT$$

$$T = \frac{2E}{3k} = \frac{2(0.6 \times 10^{-13}\ \text{J})}{3(1.38 \times 10^{-23}\ \text{J/K})} = 3 \times 10^9\ \text{K}$$

43.19 This target chamber at the National Ignition Facility in California has apertures for 192 powerful laser beams. When placed in operation in 2010, the lasers will deliver 5×10^{14} W of power for a few nanoseconds to a millimetre-sized pellet of deuterium and tritium at the centre of the chamber, thus triggering thermonuclear fusion.

Fusion reactions are possible at lower temperatures because the Maxwell-Boltzmann distribution function (see Section 18.5) gives a small fraction of protons with kinetic energies much higher than the average value. The proton-proton reaction occurs at 'only' 1.5×10^7 K at the centre of the sun, making it an extremely low-probability process; but that's why the sun is expected to last so long. At these temperatures the fusion reactions are called *thermonuclear* reactions.

Intensive efforts are under way to achieve controlled fusion reactions, which potentially represent an enormous new resource of energy (see Fig. 24.11). At the temperatures mentioned, light atoms are fully ionised, and the resulting state of matter is called a *plasma*. In one kind of experiment using *magnetic confinement*, a plasma is heated to extremely high temperature by an electrical discharge, while being contained by appropriately shaped magnetic fields. In another, using *inertial confinement*, pellets of the material to be fused are heated by a high-intensity laser beam (see Fig. 43.19). Some of the reactions being studied are

$$^2_1\text{H} + {}^2_1\text{H} \rightarrow {}^3_1\text{H} + {}^1_1\text{H} + 4.0\ \text{MeV} \qquad (1)$$

$$^3_1\text{H} + {}^2_1\text{H} \rightarrow {}^4_2\text{He} + {}^1_0\text{n} + 17.6\ \text{MeV} \qquad (2)$$

$$^2_1\text{H} + {}^2_1\text{H} \rightarrow {}^3_2\text{He} + {}^1_0\text{n} + 3.3\ \text{MeV} \qquad (3)$$

$$^3_2\text{He} + {}^2_1\text{H} \rightarrow {}^4_2\text{He} + {}^1_1\text{H} + 18.3\ \text{MeV} \qquad (4)$$

We considered reaction (1) in Example 43.13; two deuterons fuse to form a triton and a proton. In reaction (2) a triton combines with another deuteron to form an alpha particle and a neutron. The result of both of these reactions together is the

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

conversion of three deuterons into an alpha particle, a proton and a neutron, with the liberation of 21.6 MeV of energy. Reactions (3) and (4) together achieve the same conversion. In a plasma that contains deuterons, the two pairs of reactions occur with roughly equal probability. As yet, no one has succeeded in producing these reactions under controlled conditions in such a way as to yield a net surplus of usable energy.

Methods of achieving fusion that don't require high temperatures are also being studied; these are called *cold fusion*. One scheme that does work uses an unusual hydrogen molecule ion. The usual H_2^+ ion consists of two protons bound by one shared electron; the nuclear spacing is about 0.1 nm. If the protons are replaced by a deuteron $\left({}^2\text{H}\right)$ and a triton $\left({}^3\text{H}\right)$ and the electron by a *muon*, which is 208 times as massive as the electron, the spacing is made smaller by a factor of 208. The probability then becomes appreciable for the two nuclei to tunnel through the narrow repulsive potential-energy barrier and fuse in reaction (2) above. The prospect of making this process, called *muon-catalysed fusion*, into a practical energy source is still distant.

Test Your Understanding of Section 43.8 Are *all* fusion reactions exoergic?

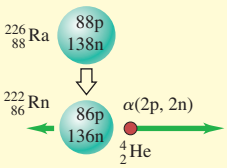
CHAPTER 43 SUMMARY

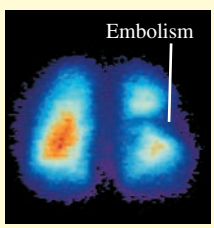
Nuclear properties: A nucleus is composed of A nucleons (Z protons and N neutrons). All nuclei have about the same density. The radius of a nucleus with mass number A is given approximately by Eq. (43.1). A single nuclear species of a given Z and N is called a nuclide. Isotopes are nuclides of the same element (same Z) that have different numbers of neutrons. Nuclear masses are measured in atomic mass units. Nucleons have angular momentum and a magnetic moment. (See Examples 43.1 and 43.2.)

$$R = R_0 A^{1/3} \qquad (R_0 = 1.2 \times 10^{-15}\ \text{m}) \tag{43.1}$$

Nuclear binding and structure: The mass of a nucleus is always less than the mass of the protons and neutrons within it. The mass difference multiplied by c^2 gives the binding energy E_B. The binding energy for a given nuclide is determined by the nuclear force, which is short range and favours pairs of particles, and by the electric repulsion between protons. A nucleus is unstable if A or Z is too large or if the ratio N/Z is wrong. Two widely used models of the nucleus are the liquid-drop model and the shell model; the latter is analogous to the central-field approximation for atomic structure. (See Examples 43.3 and 43.4.)

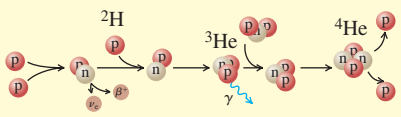


$$E_B = (ZM_H + Nm_n - {}^A_Z M)c^2 \tag{43.10}$$



Radioactive decay: Unstable nuclides usually emit an alpha particle (a $^4_2$He nucleus) or a beta particle (an electron) in the process of changing to another nuclide, sometimes followed by a gamma-ray photon. The rate of decay of an unstable nucleus is described by the decay constant λ, the half-life $T_{1/2}$, or the lifetime T_{mean}. If the number of nuclei at time $t = 0$ is N_0 and no more are produced, the number at time t is given by Eq. (43.17). (See Examples 43.5–43.9.)

$$N(t) = N_0 e^{-\lambda t} \tag{43.17}$$



$$T_{\text{mean}} = \frac{1}{\lambda} = \frac{T_{1/2}}{\ln 2} = \frac{T_{1/2}}{0.693} \tag{43.19}$$

Biological effects of radiation: The biological effect of any radiation depends on the product of the energy absorbed per unit mass and the relative biological effectiveness (RBE), which is different for different radiations. (See Example 43.10.)

Nuclear reactions: In a nuclear reaction, two nuclei or particles collide to produce two new nuclei or particles. Reactions can be exoergic or endoergic. Several conservation laws, including charge, energy, momentum, angular momentum and nucleon number, are obeyed. Energy is released by the fission of a heavy nucleus into two lighter, always unstable, nuclei. Energy is also released by the fusion of two light nuclei into a heavier nucleus. (See Examples 43.11–43.13.)

Answer to Chapter Opening Question ?

When an organism dies, it stops taking in carbon from atmospheric CO_2. Some of this carbon is radioactive ^{14}C, which decays with a half-life of 5730 years. By measuring the proportion of ^{14}C that remains in the specimen, scientists can determine how long ago the organism died. (See Section 43.4.)

Answers to Test Your Understanding Questions

43.1 Answers: (a) (iii), (b) (v) The radius R is proportional to the cube root of the mass number A, while the volume is proportional to R^3 and hence to $(A^{1/3})^3 = A$. Therefore, doubling the volume requires increasing the mass number by a factor of 2; doubling the radius implies increasing both the volume and the mass number by a factor of $2^3 = 8$.

43.2 Answer: (ii), (iii), (iv), (v), (i) You can find the answers by inspecting Fig. 43.2. The binding energy per nucleon is lowest for very light nuclei such as $^4_2$He, is greatest around $A = 60$, and then decreases with increasing A.

43.3 Answer (v) Two protons and two neutrons are lost in an α decay, so Z and N each decrease by 2. A β^+ decay changes a proton to a neutron, so Z decreases by 1 and N increases by 1. The net result is that Z decreases by 3 and N decreases by 1.

43.4 Answer: (iii) The activity $-dN(t)/dt$ of a sample is the product of the number of nuclei in the sample $N(t)$ and the decay constant $\lambda = (\ln 2)/T_{1/2}$. Hence $N(t) = (-dN(t)/dt)\,T_{1/2}/(\ln 2)$. Taking the ratio of this expression for ^{240}Pu to this same expression for ^{243}Am, the factors of $\ln 2$ cancel and we get

$$\frac{N_{\text{Pu}}}{N_{\text{Am}}} = \frac{(-dN_{\text{Pu}}/dt)\,T_{1/2\text{–Pu}}}{(-dN_{\text{Am}}/dt)\,T_{1/2\text{–Am}}} = \frac{(5.00\mu\text{Ci})\,(6560\text{ y})}{(4.45\mu\text{Ci})\,(7370\text{ y})} = 1.00$$

The two samples contain *equal* numbers of nuclei. The ^{243}Am sample has a longer half-life and hence a slower decay rate, so it has a lower activity than the ^{240}Pu sample.

43.5 Answer: (ii) We saw in Section 43.3 that alpha particles can travel only a very short distance before they are stopped. By contrast, x-ray photons are very penetrating, so they can easily pass into the body.

43.6 Answer: no The reaction $^1_1\text{H} + {}^7_3\text{Li} \rightarrow {}^4_2\text{He} + {}^4_2\text{He}$ is a *nuclear* reaction, which can take place only if a proton (a hydrogen nucleus) comes into contact with a lithium nucleus. If the hydrogen is in atomic form, the interaction between its electron cloud and the electron cloud of a lithium atom keeps the two nuclei from getting close to each other. Even if isolated protons are used, they must be fired at the lithium atoms with enough kinetic energy to overcome the electric repulsion between the protons and the lithium nuclei. The statement that the reaction is exoergic means that more energy is released by the reaction than had to be put in to make the reaction occur.

43.7 Answer: no Because the neutron has no electric charge, it experiences no electric repulsion from a ^{235}U nucleus. Hence a slow-moving neutron can approach and enter a ^{235}U nucleus, thereby providing the excitation needed to trigger fission. By contrast, a slow-moving *proton* (charge $+e$) feels a strong electric repulsion from a ^{235}U nucleus (charge $+92e$). It never gets close to the nucleus, so it cannot trigger fission.

43.8 Answer: no Fusion reactions between sufficiently light nuclei are exoergic because the binding energy per nucleon E_B/A increases. If the nuclei are too massive, however, E_B/A decreases and fusion is *endoergic* (i.e., it takes in energy rather than releasing it). As an example, imagine fusing together two nuclei of $A = 100$ to make a single nucleus with $A = 200$. From Fig. 43.2, E_B/A is more than 8.5 MeV for the $A = 100$ nuclei but is less than 8 MeV for the $A = 200$ nucleus. Such a fusion reaction is possible, but requires a substantial input of energy.

PROBLEMS

For instructor-assigned homework, go to **www.pearson.com.au/masteringphysics** MP

Exercises

Section 43.1 Properties of Nuclei

43.1. How many protons and how many neutrons are there in a nucleus of the most common isotope of (a) silicon, $^{28}_{14}$Si; (b) rubidium, $^{85}_{37}$Rb; (c) thallium, $^{205}_{81}$Tl?

43.2. Consider the three nuclei of Exercise 43.1. Estimate (a) the radius, (b) the surface area, and (c) the volume of each nucleus. Determine (d) the mass density (in kg/m^3) and (e) the nucleon density (in nucleons per cubic metre) for each nucleus. Assume that the mass of each nucleus is A atomic mass units.

43.3. Hydrogen atoms are placed in an external magnetic field. The protons can make transitions between states in which the nuclear spin component is parallel and antiparallel to the field by absorbing or emitting a photon. What magnetic-field magnitude is required for this transition to be induced by photons with frequency 22.7 MHz?

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

43.4. Neutrons are placed in a magnetic field with magnitude 2.30 T. (a) What is the energy difference between the states with the nuclear spin angular momentum components parallel and antiparallel to the field? Which state is lower in energy, the one with its spin component parallel to the field or the one with its spin component antiparallel to the field? How do your results compare with the energy states for a proton in the same field (see Example 43.2)? (b) The neutrons can make transitions from one of these states to the other by emitting or absorbing a photon with energy equal to the energy difference of the two states. Find the frequency and wavelength of such a photon.

43.5. Hydrogen atoms are placed in an external 1.65 T magnetic field. (a) The *protons* can make transitions between states where the nuclear spin component is parallel and antiparallel to the field by absorbing or emitting a photon. Which state has lower energy: the state with the nuclear spin component parallel or antiparallel to the field? What are the frequency and wavelength of the photon? In which region of the electromagnetic spectrum does it lie? (b) The *electrons* can make transitions between states where the electron spin component is parallel and antiparallel to the field by absorbing or emitting a photon. Which state has lower energy: the state with the electron spin component parallel or antiparallel to the field? What are the frequency and wavelength of the photon? In which region of the electromagnetic spectrum does it lie?

Section 43.2 Nuclear Binding and Nuclear Structure

43.6. The most common isotope of uranium, $^{238}_{92}$U, has atomic mass 238.050783 u. Calculate (a) the mass defect; (b) the binding energy (in MeV); (c) the binding energy per nucleon.

43.7. What is the maximum wavelength of a γ-ray that could break a deuteron into a proton and a neutron? (This process is called photodisintegration.)

43.8. Calculate (a) the total binding energy and (b) the binding energy per nucleon of ^{12}C (c) What percent of the rest mass of this nucleus is its total binding energy?

43.9. A photon with a wavelength of 3.50×10^{-13} m strikes a deuteron, splitting it into a proton and a neutron. (a) Calculate the kinetic energy released in this interaction. (b) Assuming the two particles share the energy equally, and taking their masses to be 1.00 u, calculate their speeds after the photodisintegration.

43.10. Calculate the mass defect, the binding energy (in MeV), and the binding energy per nucleon of (a) the nitrogen nucleus, $^{14}_{7}$N and (b) the helium nucleus, $^{4}_{2}$He. (c) How do the results of parts (a) and (b) compare?

43.11. The most common isotope of boron is $^{11}_{5}$B. (a) Determine the total binding energy of $^{11}_{5}$B from Table 43.2 in Section 43.1. (b) Calculate this binding energy from Eq. (43.11). (Why is the fifth term zero?) Compare to the result you obtained in part (a). What is the percent difference? Compare the accuracy of Eq. (43.11) for $^{11}_{5}$B to its accuracy for $^{62}_{28}$Ni (see Example 43.4).

43.12. The most common isotope of copper is $^{63}_{29}$Cu. The measured mass of the neutral atom is 62.929601 u. (a) From the measured mass, determine the mass defect, and use it to find the total binding energy and the binding energy per nucleon. (b) Calculate the binding energy from Eq. (43.11). (Why is the fifth term zero?) Compare to the result you obtained in part (a). What is the percent difference? What do you conclude about the accuracy of Eq. (43.11)?

Section 43.3 Nuclear Stability and Radioactivity

43.13. What nuclide is produced in the following radioactive decays? (a) α decay of $^{239}_{4}$Pu; (b) β^- decay of $^{24}_{11}$Na; (c) β^+ decay of $^{15}_{8}$O.

43.14. (a) Is the decay $n \rightarrow p + \beta^- + \bar{\nu}_e$ energetically possible? If not, explain why not. If so, calculate the total energy released. (b) Is the decay $p \rightarrow n + \beta^+ + \nu_e$ energetically possible? If not, explain why not. If so, calculate the total energy released.

43.15. The α decay of ^{238}U is accompanied by a γ ray of measured wavelength 0.0248 nm. This decay is due to a transition of the nucleus between two energy levels. What is the difference in energy (in MeV) between these two levels?

43.16. ^{238}U decays spontaneously by α emission to ^{234}Th. Calculate (a) the total energy released by this process and (b) the recoil velocity of the ^{234}Th nucleus. The atomic masses are 238.050788 u for ^{238}U and 234.043601 u for ^{234}Th.

43.17. The atomic mass of ^{14}C is 14.003242 u. Show that the β^- decay of ^{14}C is energetically possible, and calculate the energy released in the decay.

43.18. What particle (α particle, electron, or positron) is emitted in the following radioactive decays? (a) $^{27}_{14}\text{Si} \rightarrow {}^{27}_{13}\text{Al}$; (b) $^{238}_{92}\text{U} \rightarrow {}^{234}_{90}\text{Th}$; (c) $^{74}_{33}\text{As} \rightarrow {}^{74}_{34}\text{Se}$.

43.19. (a) Calculate the energy released by the electron-capture decay of $^{57}_{27}$Co (see Example 43.7). (b) A negligible amount of this energy goes to the resulting $^{57}_{26}$Fe atom as kinetic energy. About 90% of the time, the $^{57}_{26}$Fe nucleus emits two successive gamma-ray photons after the electron-capture process, of energies 0.122 MeV and 0.014 MeV, respectively, in decaying to its ground state. What is the energy of the neutrino emitted in this case?

Section 43.4 Activities and Half-Lives

43.20. The isotope ^{90}Sr undergoes β^- decay with a half-life of 28 years. (a) What nucleus is produced by this decay? (b) If a nuclear power plant is contaminated with ^{90}Sr, how long will it take for the radiation level to decrease to 1.0% of its initial value?

43.21. If a 6.13 g sample of an isotope having a mass number of 124 decays at a rate of 0.350 Ci, what is its half-life?

43.22. Radioactive isotopes used in cancer therapy have a 'shelf-life,' like pharmaceuticals used in chemotherapy. Just after it has been manufactured in a nuclear reactor, the activity of a sample of ^{60}Co is 5000 Ci. When its activity falls below 3500 Ci, it is considered too weak a source to use in treatment. You work in the radiology department of a large hospital. One of these ^{60}Co sources in your inventory was manufactured on 6 October 2007. It is now 6 April 2010. Is the source still usable? The half-life of ^{60}Co is 5.271 years.

43.23. A 12.0 g sample of carbon from living matter decays at the rate of 180.0 decays/min due to the radioactive ^{14}C in it. What will be the decay rate of this sample in (a) 1000 years and (b) 50 000 years?

43.24. Radioactive isotopes are often introduced into the body through the bloodstream. Their spread through the body can then be monitored by detecting the appearance of radiation in different organs. ^{131}I, a β^- emitter with a half-life of 8.0 d is one such tracer. Suppose a scientist introduces a sample with an activity of 375 Bq and watches it spread to the organs. (a) Assuming that the sample all went to the thyroid gland, what will be the decay rate in that gland 24 d (about $2\frac{1}{2}$ weeks) later? (b) If the decay rate in the thyroid 24 d later is actually measured to be 17.0 Bq, what percentage of the tracer went to that gland? (c) What isotope remains after the I-131 decays?

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

43.25. Tritium (^3H) undergoes β^- decay with a half-life of 12.3 years. It is also highly toxic to living things. (a) What nucleus is produced in the β^- decay of tritium? (b) Suppose some tritium gas is released into the atmosphere in a nuclear power plant accident. How long will it take for 90.0% of the tritium to become nonradioactive?

43.26. As a health physicist, you are being consulted about a spill in a radiochemistry lab. The isotope spilled was 500μCi of ^{131}Ba, which has a half-life of 12 days. (a) What mass of ^{131}Ba was spilled? (b) Your recommendation is to clear the lab until the radiation level has fallen 1.00μCi. How long will the lab have to be closed?

43.27. Measurements on a certain isotope tell you that the decay rate decreases from 8318 decays/min to 3091 decays/min in 4.00 days. What is the half-life of this isotope?

43.28. The isotope ^{226}Ra undergoes α decay with a half-life of 1620 years. What is the activity of 1.00 g of ^{226}Ra? Express your answer in Bq and in Ci.

43.29. The ratio of ^{14}C to ^{12}C in living matter is measured to be $^{14}\text{C}/^{12}\text{C} = 1.3 \times 10^{-12}$ at the present time. A 12.0 g sample of carbon produces 180 decays/min due to the small amount of ^{14}C in it. From this information, calculate the half-life of ^{14}C.

43.30. If you are of average mass, about 360 million nuclei in your body undergo radioactive decay each day. Express your activity in curies.

43.31. The radioactive nuclide ^{199}Pt has a half-life of 30.8 minutes. A sample is prepared that has an initial activity of 7.56×10^{11} Bq. (a) How many ^{199}Pt nuclei are initially present in the sample? (b) How many are present after 30.8 minutes? What is the activity at this time? (c) Repeat part (b) for a time 92.4 minutes after the sample is first prepared.

43.32. A sample from timbers at an archeological site containing 500 g of carbon provides 3070 decays/min. What is the age of the sample?

43.33. The unstable isotope ^{40}K is used for dating rock samples. Its half-life is 1.28×10^9 y. (a) How many decays occur per second in a sample containing 1.63×10^{-6} g of ^{40}K? (b) What is the activity of the sample in curies?

Section 43.5 Biological Effects of Radiation

43.34. A person exposed to fast neutrons receives a radiation dose of 200 rem on part of his hand, affecting 25 g of tissue. The RBE of these neutrons is 10. (a) How many rad did he receive? (b) How many joules of energy did this person receive? (c) Suppose the person received the same rad dosage, but from beta rays with a RBE of 1.0 instead of neutrons. How many rem would he have received?

43.35. A nuclear chemist receives an accidental radiation dose of 5.0 Gy from slow neutrons $(\text{RBE} = 4.0)$. What does she receive in rad, rem and J/kg?

43.36. It has become popular for some people to have yearly whole-body scans (CT scans, formerly called CAT scans) using x-rays, just to see if they detect anything suspicious. A number of medical people have recently questioned the advisability of such scans, due in part to the radiation they impart. Typically, one such scan gives a dose of 12 mSv, applied to the *whole body*. By contrast, a chest x-ray typically administers 0.20 mSv to only 5.0 kg of tissue. How many chest x-rays would deliver the same *total* amount of energy to the body of 75 kg person as one whole-body scan?

43.37. Food is often irradiated with either x-rays or electron beams to help prevent spoilage. A low dose of 5–75 kilorads (krad) helps to reduce and kill inactive parasites, a medium dose of 100–400 krad kills microorganisms and pathogens such as salmonella, and a high dose of 2300-5700 krad sterilises food so that it can be stored without refrigeration, (a) A dose of 175 krad kills spoilage microorganisms in fish. If x-rays are used, what would be the dose in Gy, Sv and rem, and how much energy would a 150 g portion of fish absorb? (See Table 43.3.) (b) Repeat part (a) if electrons of RBE 1.50 are used instead of x-rays.

43.38. In an industrial accident a 65 kg person receives a lethal whole-body equivalent dose of 5.4 Sv from x-rays. (a) What is the equivalent dose in rem? (b) What is the absorbed dose in rad? (c) What is the total energy absorbed by the person's body? How does this amount of energy compare to the amount of energy required to raise the temperature of 65 kg of water 0.010°C?

43.39. A 50 kg person accidentally ingests 0.35 Ci of tritium. (a) Assume that the tritium spreads uniformly throughout the body and that each decay leads on the average to the absorption of 5.0 keV of energy from the electrons emitted in the decay. The half-life of tritium is 12.3 y, and the RBE of the electrons is 1.0. Calculate the absorbed dose in rad and the equivalent dose in rem during one week. (b) The β^- decay of tritium releases more than 5.0 keV of energy. Why is the average energy absorbed less than the total energy released in the decay?

43.40. A person ingests an amount of a radioactive source with a very long lifetime and activity 0.72 μCi. The radioactive material lodges in the lungs, where all of the 4.0 MeV α particles emitted are absorbed within a 0.50 kg mass of tissue. Calculate the absorbed dose and the equivalent dose for one year.

Section 43.6 Nuclear Reactions, Section 43.7 Nuclear Fission and Section 43.8 Nuclear Fusion

43.41. Consider the nuclear reaction

$$^2_1\text{H} + {}^{14}_7\text{N} \rightarrow \text{X} + {}^{10}_5\text{B}$$

where X is a nuclide. (a) What are Z and A for the nuclide X? (b) Calculate the reaction energy Q (in MeV). (c) If the $^2_1$H nucleus is incident on a stationary $^{14}_7$N nucleus, what minimum kinetic energy must it have for the reaction to occur?

43.42. Calculate the energy released in the fusion reaction

$$^3_2\text{He} + {}^2_1\text{H} \rightarrow {}^4_2\text{He} + {}^1_1\text{H}$$

43.43. Consider the nuclear reaction

$$^2_1\text{H} + {}^9_4\text{Be} \rightarrow \text{X} + {}^4_2\text{He}$$

where X is a nuclide. (a) What are the values of Z and A for the nuclide X? (b) How much energy is liberated? (c) Estimate the threshold energy for this reaction.

43.44. A certain country uses 1.0×10^{19} J of electrical energy per year. If all this energy came from the fission of ^{235}U, which releases 200 MeV per fission event, (a) how many kilograms of ^{235}U would be used per year and (b) how many kilograms of uranium would have to be mined per year to provide that much ^{235}U? (Recall that only 0.70% of naturally occurring uranium is ^{235}U.)

43.45. At the beginning of Section 43.7 the equation of a fission process is given in which ^{235}U is struck by a neutron and undergoes fission to produce ^{144}Ba, ^{89}Kr, and three neutrons. The measured masses of these isotopes are 235.043930 u (^{235}U), 143.922953 u (^{144}Ba), 88.917630 u (^{89}Kr), and 1.0086649 u (neutron)

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

(a) Calculate the energy (in MeV) released by each fission reaction. (b) Calculate the energy released per gram of ^{235}U, in MeV/g.

43.46. Consider the nuclear reaction

$$^{28}_{14}\text{Si} + \gamma \rightarrow ^{24}_{12}\text{Mg} + \text{X}$$

where X is a nuclide. (a) What are Z and A for the nuclide X? (b) Ignoring the effects of recoil, what minimum energy must the photon have for this reaction to occur? The mass of a $^{28}_{14}$Si atom is 27.976927 u, and the mass of a $^{24}_{12}$Mg atom is 23.985042 u.

43.47. The second reaction in the proton–proton chain (see Fig. 43.17) produces a $^{3}_{2}$He nucleus. A $^{3}_{2}$He nucleus produced in this way can combine with a $^{4}_{2}$He nucleus:

$$^{3}_{2}\text{He} + ^{4}_{2}\text{He} \rightarrow ^{7}_{4}\text{Be} + \gamma$$

Calculate the energy liberated in this process. (This is shared between the energy of the photon and the recoil kinetic energy of the beryllium nucleus.) The mass of a $^{7}_{4}$Be atom is 7.016929 u.

43.48. Consider the nuclear reaction

$$^{4}_{2}\text{He} + ^{7}_{3}\text{Li} \rightarrow \text{X} + ^{1}_{0}\text{n}$$

where X is a nuclide. (a) What are Z and A for the nuclide X? (b) Is energy absorbed or liberated? How much?

Problems

43.49. Use conservation of mass-energy to show that the energy released in alpha decay is positive whenever the mass of the original neutral atom is greater than the sum of the masses of the final neutral atom and the neutral ^{4}He atom. (*Hint:* Let the parent nucleus have atomic number Z and nucleon number A. First write the reaction in terms of the nuclei and particles involved, and then add Z electron masses to both sides of the reaction and allot them as needed to arrive at neutral atoms.)

43.50. Use conservation of mass-energy to show that the energy released in β^- decay is positive whenever the neutral atomic mass of the original atom is greater than that of the final atom. (See the hint in Problem 43.49.)

43.51. Use conservation of mass-energy to show that the energy released in β^+ decay is positive whenever the neutral atomic mass of the original atom is at least two electron masses greater than that of the final atom. (See the hint in Problem 43.49.)

43.52. (a) When petrol is burned, it releases 1.3×10^8 J of energy for every 3.788 L. Given that the density of petrol is 737 kg/m^3, express the quantity of energy released in J/g of fuel. (b) During fission, when a neutron is absorbed by a ^{235}U nucleus, about 200 MeV of energy is released for each nucleus that undergoes fission. Express this quantity in J/g of fuel. (c) In the proton-proton chain that takes place in stars like our sun, the overall fusion reaction can be summarised as six protons fusing to form one ^{4}He nucleus with two leftover protons and the liberation of 26.7 MeV of energy. The fuel is the six protons. Express the energy produced here in units of J/g of fuel. Notice the huge difference between the two forms of nuclear energy, on the one hand, and the chemical energy from petrol, on the other (d) Our sun produces energy at a measured rate of 3.86×10^{26} W. If its mass of 1.99×10^{30} kg were all petrol, how long could it last before consuming all its fuel? (*Historical note*: Before the discovery of nuclear fusion and the vast amounts of energy it releases, scientists were confused. They knew that the earth was at least many millions of years old, but could not explain how the sun could survive that long if its energy came from chemical burning.)

43.53. The experimentally determined mass of the neutral ^{24}Na atom is 23.990963 u. Calculate the mass from the semiempirical mass formula, Eq. (43.12). What is the percent error of the result compared to the experimental value? What percent error is made if the E_B term is ignored entirely?

43.54. Thorium $^{230}_{90}$Th decays to radium $^{226}_{88}$Ra by α emission. The masses of the neutral atoms are 230.033127 u for $^{230}_{90}$Th and 226.025403 u for $^{226}_{88}$Ra. If the parent thorium nucleus is at rest, what is the kinetic energy of the emitted α particle? (Be sure to account for the recoil of the daughter nucleus.)

43.55. The atomic mass of $^{25}_{12}$Mg is 24.985837 u, and the atomic mass of $^{25}_{13}$Al is 24.990429 u. (a) Which of these nuclei will decay into the other? (b) What type of decay will occur? Explain how you determined this. (c) How much energy (in MeV) is released in the decay?

43.56. The polonium isotope $^{210}_{84}$Po has atomic mass 209.982857 u. Other atomic masses are $^{206}_{82}$Pb, 205.974449 u; $^{209}_{83}$Bi, 208.980383 u; $^{210}_{83}$Bi, 209.984105 u; $^{209}_{84}$Po, 208.982416 u; and $^{210}_{85}$At, 209.987131 u. (a) Show that the alpha decay of $^{210}_{84}$Po is energetically possible, and find the energy of the emitted α particle. (b) Is $^{210}_{84}$Po energetically stable with respect to emission of a proton? Why or why not? (c) Is $^{210}_{84}$Po energetically stable with respect to emission of a neutron? Why or why not? (d) Is $^{210}_{84}$Po energetically stable with respect to β^- decay? Why or why not? e) Is $^{210}_{84}$Po energetically stable with respect to β^+ decay? Why or why not?

43.57. The radiocarbon in our bodies is one of the naturally occurring sources of radiation. Let's see how large a dose we receive. ^{14}C decays via β^- emission, and 18% of our body's mass is carbon. (a) Write out the decay scheme of carbon-14 and show the end product. (A neutrino is also produced.) (b) Neglecting the effects of the neutrino, how much kinetic energy (in MeV) is released per decay? The atomic mass of C-14 is 14.003242 u. (See Table 43.2.) (c) How many grams of carbon are there in a 75 kg person? How many decays per second does this carbon produce? (d) Assuming that all the energy released in these decays is absorbed by the body, how many MeV/s and J/s does the C-14 release in this person's body? (e) Consult Table 43.3 and use the largest appropriate RBE for the particles involved. What radiation dose does the person give himself in a year, in Gy, rad, Sv and rem?

43.58. A neutral pion (π^0) has a mass of 264 times the electron mass and decays with a lifetime of 8.4×10^{-17} s to two photons. Such pions are used in the radiation treatment of some cancers. (a) Find the energy and wavelength of these photons. In which part of the electromagnetic spectrum do they lie? What is the RBE for these photons? (b) if you want to deliver a dose of 200 rem (which is typical) in a single treatment to 25 g of tumour tissue, how many π^0 mesons are needed?

43.59. Gold, $^{198}_{79}$Au, undergoes β^- decay to an excited state of $^{198}_{80}$Hg. If the excited state decays by emission of a γ photon with energy 0.412 MeV, what is the maximum kinetic energy of the electron emitted in the decay? This maximum occurs when the antineutrino has negligible energy. (The recoil energy of the $^{198}_{80}$Hg nucleus can be ignored. The masses of the neutral atoms in their ground states are 197.968225 u for $^{198}_{79}$Au and 197.966752 u for $^{198}_{80}$Hg.)

43.60. Calculate the mass defect for the β^+ decay of $^{11}_{6}$C. Is this decay energetically possible? Why or why not? The atomic mass of $^{11}_{6}$C is 11.011434 u.

43.61. Calculate the mass defect for the β^+ decay of $^{13}_{7}$N. Is this decay energetically possible? Why or why not? The atomic mass of $^{13}_{7}$N is 13.005739 u.

43.62. The results of activity measurements on a radioactive sample are given in the table. (a) Find the half-life. (b) How many radioactive nuclei were present in the sample at $t = 0$? (c) How many were present after 7.0 h?

Time (h)	Decays/s
0	20 000
0.5	14 800
1.0	11 000
1.5	8 130
2.0	6 020
2.5	4 460
3.0	3 300
4.0	1 810
5.0	1 000
6.0	550
7.0	300

43.63. If $A(t)$ is the activity of a sample at some time t and A_0 is the activity at $t = 0$, show that $A(t) = A_0 e^{-\lambda t}$.

43.64. Show that Eq. (43.17) may be written as $N(t) = N_0(\frac{1}{2})^n$, where $n = t/T_{1/2}$ is the number of half-lives that have elapsed since $t = 0$. (This expression is valid even if n is not a whole number.)

43.65. In 1952 spectral lines of the element technetium-99 (^{99}Tc) were discovered in a red giant star. Red giants are very old stars, often around 10 billion years old, and near the end of their lives. Technetium has *no* stable isotopes, and the half-life of ^{99}Tc is 200 000 years. (a) For how many half-lives has the ^{99}Tc been in the red-giant star if its age is 10 billion years? (b) What fraction of the original ^{99}Tc would be left at the end of that time? This discovery was extremely important because it provided convincing evidence for the theory (now essentially known to be true) that most of the atoms heavier than hydrogen and helium were made inside of stars by thermonuclear fusion and other nuclear processes. If the ^{99}Tc had been part of the star since it was born, the amount remaining after 10 billion years would have been so minute that it would not have been detectable. This knowledge is what led the late astronomer Carl Sagan to proclaim that 'we are stardust.'

43.66. Some radioisotopes such as samarium (^{149}Sm) and gadolinium (^{152}Gd) have half-lives that are much longer than the age of the universe, so we can't measure their half-lives by watching their decay rate decrease. Luckily, there is another way of calculating the half-life, using Eq. (43.16). Suppose a 12.0 g sample of ^{149}Sm is observed to decay at a rate of 2.65 Bq. Calculate the half-life of the sample in years. (*Hint:* How many nuclei are there in the 12.0-g sample?)

43.67. Measurements indicate that 27.83% of all rubidium atoms currently on the earth are the radioactive ^{87}Rb isotope. The rest are the stable ^{85}Rb isotope. The half-life of ^{87}Rb is 4.75×10^{10}y. Assuming that no rubidium atoms have been formed since, what percentage of rubidium atoms were ^{87}Rb when our solar system was formed 4.6×10^9y ago?

43.68. A 70.0 kg person experiences a whole-body exposure to α radiation with energy 4.77 MeV. A total of 6.25×10^{12} α particles are absorbed. (a) What is the absorbed dose in rad? (b) What is the equivalent dose in rem? (c) If the source is 0.0320 g of ^{226}Ra (half-life 1600 y) somewhere in the body, what is the activity of this source? (d) If all the alpha particles produced are absorbed, what time is required for this dose to be delivered?

43.69. A ^{60}Co source with activity 2.6×10^{-4}Ci is embedded in a tumour that has mass 0.500 kg. The source emits γ photons with average energy 1.25 MeV. Half the photons are absorbed in the tumour, and half escape. (a) What energy is delivered to the tumour per second? (b) What absorbed dose (in rad) is delivered per second? (c) What equivalent dose (in rem) is delivered per second if the RBE for these γ-rays is 0.70? (d) What exposure time is required for an equivalent dose of 200 rem?

43.70. The nucleus $^{15}_{8}$O has a half-life of 122.2 s; $^{19}_{8}$O has a half-life of 26.9 s. If at some time a sample contains equal amounts of $^{15}_{8}$O and $^{19}_{8}$O, what is the ratio of $^{15}_{8}$O to $^{19}_{8}$O (a) after 4.0 minutes and (b) after 15.0 minutes?

43.71. A bone fragment found in a cave believed to have been inhabited by early humans contains 0.21 times as much ^{14}C as an equal amount of carbon in the atmosphere when the organism containing the bone died. (See Example 43.9 in Section 43.4.) Find the approximate age of the fragment.

43.72. Nuclear weapons tests in the 1950s and 1960s released significant amounts of radioactive tritium ($^{3}_{1}$H, half-life 12.3 years) into the atmosphere. The tritium atoms were quickly bound into water molecules and rained out of the air, most of them ending up in the ocean. For any of this tritium-tagged water that sinks below the surface, the amount of time during which it has been isolated from the surface can be calculated by measuring the ratio of the decay product, $^{3}_{2}$He, to the remaining tritium in the water. For example, if the ratio of $^{3}_{1}$He to $^{3}_{1}$H in a sample of water is 1:1, the water has been below the surface for one half-life, or approximately 12 years. This method has provided oceanographers with a convenient way to trace the movements of subsurface currents in parts of the ocean. Suppose that in a particular sample of water, the ratio of $^{3}_{2}$He to $^{3}_{1}$H is 4.3 to 1.0. How many years ago did this water sink below the surface?

43.73. Consider the fusion reaction

$$^{2}_{1}\mathrm{H} + {}^{2}_{1}\mathrm{H} \rightarrow {}^{3}_{2}\mathrm{He} + {}^{1}_{0}\mathrm{n}$$

(a) Estimate the barrier energy by calculating the repulsive electrostatic potential energy of the two $^{2}_{1}$H nuclei when they touch. (b) Compute the energy liberated in this reaction in MeV and in joules. (c) Compute the energy liberated *per mole* of deuterium, remembering that the gas is diatomic, and compare with the heat of combustion of hydrogen, about 2.9×10^5J/mol.

43.74. In the 1986 disaster at the Chernobyl reactor in the Soviet Union (now Ukraine), about $\frac{1}{8}$ of the ^{137}Cs present in the reactor was released. The isotope ^{137}Cs has a half-life for β decay of 30.07 y and decays with the emission of a total of 1.17 MeV of energy per decay. Of this, 0.51 MeV goes to the emitted electron and the remaining 0.66 MeV to a γ ray. The radioactive ^{137}Cs is absorbed by plants, which are eaten by livestock and humans. How many ^{137}Cs atoms would need to be present in each kilogram of body tissue if an equivalent dose for one week is 3.5 Sv? Assume that all of the energy from the decay is deposited in that 1.0 kg of tissue and that the RBE of the electrons is 1.5.

43.75. (a) Prove that when a particle with mass m and kinetic energy K collides with a stationary particle with mass M, the total kinetic energy K_{cm} in the centre-of-mass coordinate system (the energy available to cause reactions) is

$$K_{\mathrm{cm}} = \frac{M}{M+m}K$$

Assume that the kinetic energies of the particles and nuclei are much lower than their rest energies. (b) If K_{th} is the minimum, or threshold, kinetic energy to cause an endoergic reaction to occur in the situation of part (a), show that

$$K_{\mathrm{th}} = -\frac{M+m}{M}Q$$

43.76. A $^{186}_{76}$Os nucleus at rest decays by the emission of a 2.76 MeV α particle. Calculate the atomic mass of the daughter nuclide produced by this decay, assuming that it is produced in its ground state. The atomic mass of $^{186}_{76}$Os is 185.953838 u.

43.77. Calculate the energy released in the fission reaction

$$^{235}_{92}\text{U} + ^{1}_{0}\text{n} \rightarrow ^{140}_{54}\text{Xe} + ^{94}_{38}\text{Sr} + 2^{1}_{0}\text{n}$$

You can ignore the initial kinetic energy of the absorbed neutron. The atomic masses are $^{235}_{92}$U, 235.043923 u; $^{140}_{54}$Xe, 139.921636 u; and $^{94}_{38}$Sr, 93.915360 u.

Challenge Problems

43.78. The results of activity measurements on a mixed sample of radioactive elements are given in the table. (a) How many different nuclides are present in the mixture? (b) What are their half-lives? (c) How many nuclei of each type are initially present in the sample? (d) How many of each type are present at $t = 5.0$ h?

Time (h)	Decays/s
0	7500
0.5	4120
1.0	2570
1.5	1790
2.0	1350
2.5	1070
3.0	872
4.0	596
5.0	414
6.0	288
7.0	201
8.0	140
9.0	98
10.0	68
12.0	33

43.79. In an experiment, the isotope ^{128}I is created by the irradiation of ^{127}I with a beam of neutrons that creates 1.5×10^{6} ^{128}I nuclei per second. Initially no ^{128}I nuclei are present. The half-life of ^{128}I is 25 minutes. (a) Graph the number of ^{128}I nuclei present as a function of time. (b) What is the activity of the sample 1, 10, 25, 50, 75 and 180 minutes after irradiation begins? (c) What is the maximum number of ^{128}I atoms that can be created in the sample after it is irradiated for a long time? (This steady-state situation is called *saturation*.) (d) What is the maximum activity that can be produced?

43.80. Engineering. Radioisotopes are used in a variety of manufacturing and testing techniques. Wear measurements can be made using the following method. An automobile engine is produced using piston rings with a total mass of 100 g, which includes 9.4 μCi of ^{59}Fe whose half-life is 45 days. The engine is test-run for 1000 hours, after which the oil is drained and its activity is measured. If the activity of the engine oil is 84 decays/s, how much mass was worn from the piston rings per hour of operation?

PARTICLE PHYSICS AND COSMOLOGY

44

?This image from the Hubble Space Telescope shows galaxies—immense groupings of stars, gas and dust—strewn across the cosmos like grains of sand. Approximately what fraction of all the mass and energy in the universe is in the form of such 'normal' matter?

LEARNING GOALS

By studying this chapter, you will be able to explain:

- The key varieties of fundamental subatomic particles and how they were discovered.
- How physicists use accelerators and detectors to probe the properties of subatomic particles.
- The four ways in which subatomic particles interact with each other.
- How the structure of protons, neutrons and other particles can be explained in terms of quarks.
- How physicists probe the limits of the standard model of particles and interactions.
- The evidence that the universe is expanding and that the expansion is speeding up.
- The history of the first 380 000 years after the Big Bang.

What is the world made of? What are the most fundamental constituents of matter? Philosophers and scientists have been asking these questions for at least 2500 years. We still don't have anything that could be called a final answer, but we've come a long way. This final chapter is a progress report on where we are now and where we hope to go.

The chapter title, 'Particle Physics and Cosmology', may seem strange. Fundamental particles are the *smallest* things in the universe, and cosmology deals with the *biggest* thing there is—the universe itself. Nonetheless, we'll see in this chapter that physics on the most microscopic scale plays an essential role in determining the nature of the universe on the largest scale.

Fundamental particles, we'll find, are not permanent entities; they can be created and destroyed. The development of high-energy particle accelerators and associated detectors has been crucial in our emerging understanding of particles. We can classify particles and their interactions in several ways in terms of conservation laws and symmetries, some of which are absolute and others of which are obeyed only in certain kinds of interactions. We'll try in this final chapter to convey some idea of the remaining frontiers in this vital and exciting area of fundamental research. We'll conclude by discussing our present understanding of the nature and evolution of the universe as a whole.

44.1 Fundamental Particles—A History

The idea that the world is made of *fundamental particles* has a long history. In about 400 B.C. the Greek philosophers Democritus and Leucippus suggested that matter is made of indivisible particles that they called *atoms*, a word derived from *a-* (not) and *tomos* (cut or divided). This idea lay dormant until about 1804, when the English scientist John Dalton (1766–1844), often called the father of modern chemistry, discovered that many chemical phenomena could be explained if atoms of each element are the basic, indivisible building blocks of matter.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

The Electron and the Proton

Towards the end of the 19th century it became clear that atoms are *not* indivisible. The existence of characteristic atomic spectra of elements suggested that atoms have internal structure, and J. J. Thomson's discovery of the *electron* in 1897 showed that atoms could be taken apart into charged particles. The hydrogen nucleus was identified as a *proton*, and in 1911 the sizes of nuclei were measured by Rutherford's experiments. Quantum mechanics, including the Schrödinger equation, blossomed during the next 15 years. Scientists were on their way to understanding the principles that underlie atomic structure, although many details remained to be worked out.

The Photon

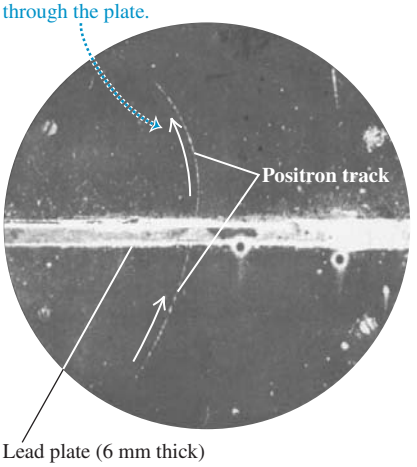
Einstein explained the photoelectric effect in 1905 by assuming that the energy of electromagnetic waves is quantised; that is, it comes in little bundles called *photons* with energy $E = hf$. Atoms and nuclei can emit (create) and absorb (destroy) photons. Considered as particles, photons have zero charge and zero rest mass. (Note that any discussions of a particle's mass in this chapter will refer to its rest mass.) In particle physics, a photon is denoted by the symbol γ (the Greek letter gamma).

The Neutron

The discovery of the neutron was an important milestone. In 1930 the German physicists Walther Bothe and Herbert Becker observed that when beryllium, boron or lithium was bombarded by α particles from radioactive polonium, the target material emitted a radiation that had much greater penetrating power than the original α particles. Experiments by the English physicist James Chadwick in 1932 showed that the emitted particles were electrically neutral, with mass approximately equal to that of the proton. Chadwick christened these particles *neutrons*. A typical reaction of the type studied by Bothe and Becker, using a beryllium target, is

$$^4_2\text{He} + {}^9_4\text{Be} \rightarrow {}^{12}_6\text{C} + {}^1_0\text{n} \qquad (44.1)$$

It was difficult to detect neutrons directly because they have no charge. Hence they produce little ionisation when they pass through matter and they are not deflected by electric or magnetic fields. Neutrons almost always interact only with nuclei; they can be slowed down during scattering, and they can penetrate the nucleus. Slow neutrons can be detected by means of a nuclear reaction in which a neutron is absorbed and an α particle is emitted. An example is



$$^1_0\text{n} + {}^{10}_5\text{B} \rightarrow {}^7_3\text{Li} + {}^4_2\text{He} \qquad (44.2)$$

The ejected α particle is easy to detect because it is charged. Later experiments showed that neutrons, like protons and electrons, are spin-$\frac{1}{2}$ particles (see Section 43.1).

The neutron was a welcome discovery because it cleared up a mystery about the composition of the nucleus. Before 1930 the mass of a nucleus was thought to be due only to protons, but no one understood why the charge-to-mass ratio was not the same for all nuclides. It soon became clear that all nuclides (except ^1_1H) contain both protons and neutrons. In fact, the proton, the neutron and the electron are the building blocks of atoms. One might think that would be the end of the story. On the contrary, it is barely the beginning. These are not the only particles, and they can do more than build atoms.

The Positron

The positive electron, or *positron*, was discovered by the American physicist Carl D. Anderson in 1932, during an investigation of particles bombarding the earth from space. Figure 44.1 shows a historic photograph made with a *cloud*

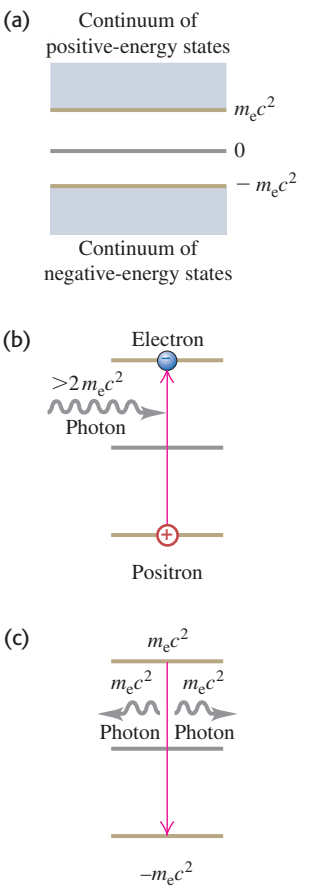
44.1 Photograph of the cloud-chamber track made by the first positron ever identified. The photograph was made by Carl D. Anderson in 1932.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

chamber, an instrument that is used to visualise the tracks of charged particles. The chamber contained a supercooled vapour; ions created by the passage of charged particles through the vapour served as nucleation centres, and liquid droplets formed around them, making a visible track.

The cloud chamber in Fig. 44.1 is in a magnetic field directed into the plane of the photograph. The particle has passed through a thin lead plate (which extends from left to right in the figure) that lies within the chamber. The track is more tightly curved above the plate than below it, showing that the speed was less above the plate than below it. Therefore the particle had to be moving upward; it could not have gained energy passing through the lead. The thickness and curvature of the track suggested that its mass and the magnitude of its charge equalled those of the electron. But the directions of the magnetic field and the velocity in the magnetic force equation $\vec{F} = q\vec{v} \times \vec{B}$ showed that the particle had *positive* charge. Anderson christened this particle the *positron*.

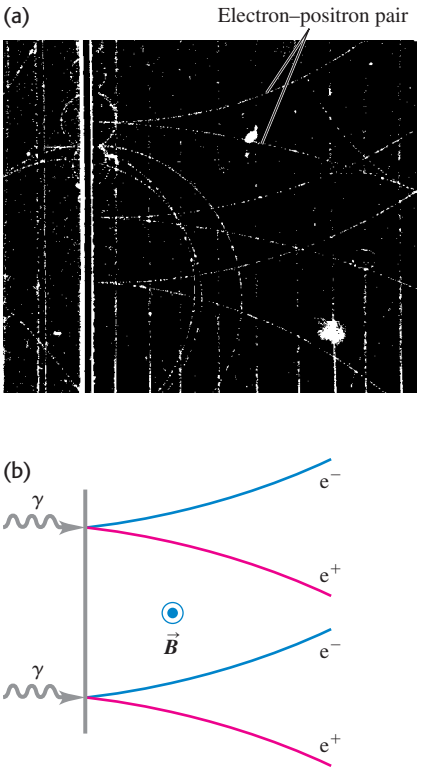
To theorists, the appearance of the positron was a welcome development. In 1928 the English physicist Paul Dirac had developed a relativistic generalisation of the Schrödinger equation for the electron. In Section 41.3 we discussed how Dirac's generalisation helped to explain the spin magnetic moment of the electron.



One of the puzzling features of the Dirac equation was that for a *free* electron it predicted not only a continuum of energy states greater than its rest energy $m_e c^2$, as should be expected, but also a continuum of *negative* energy states *less than* $-m_e c^2$ (Fig. 44.2a). That posed a problem. What was to prevent an electron from emitting a photon with energy $2m_e c^2$ or greater and hopping from a positive state to a negative state? It wasn't clear what these negative-energy states meant, and there was no obvious way to get rid of them. Dirac's ingenious interpretation was that all the negative-energy states were filled with electrons, and that these electrons were for some reason unobservable. The exclusion principle would then forbid a transition to a state that was already occupied.

A vacancy in a negative-energy state would act like a positive charge, just as a hole in the valence band of a semiconductor (see Section 42.6) acts like a positive charge. Initially, Dirac tried to argue that such vacancies were protons. But after Anderson's discovery it became clear that the vacancies were observed physically as *positrons*. Furthermore, the Dirac energy-state picture provides a mechanism for the *creation* of positrons. When an electron in a negative-energy state absorbs a photon with energy greater than $2m_e c^2$, it goes to a positive state (Fig. 44.2b), in which it becomes observable. The vacancy that it leaves behind is observed as a positron; the result is the creation of an electron–positron pair. Similarly, when an electron in a positive-energy state falls into a vacancy, both the electron and the vacancy (that is, the positron) disappear, and photons are emitted (Fig. 44.2c). Thus the Dirac theory leads naturally to the conclusion that, like photons, *electrons can be created and destroyed*. While photons can be created and destroyed singly, electrons can be produced or destroyed only in electron–positron pairs or in association with other particles. We'll see why later.

In 1949 the American physicist Richard Feynman showed that a positron could be described mathematically as an electron travelling backwards in time. His reformulation of the Dirac theory eliminated difficult calculations involving the infinite sea of negative-energy states and put electrons and positrons on the same footing. But the creation and destruction of electron–positron pairs remain. The Dirac theory is inherently a *many-particle* theory, and it provides the beginning of a theoretical framework for creation and destruction of all fundamental particles.



Experiment and theory tell us that the masses of the positron and electron are identical, and that their charges are equal in magnitude but opposite in sign. The

44.2 (a) Energy states for a free electron predicted by the Dirac equation. (b) Raising an electron from an $E < 0$ state to an $E > 0$ state corresponds to electron– positron pair production. (c) An electron dropping from an $E > 0$ state to a vacant $E < 0$ state corresponds to electron– positron pair annihilation.

44.3 (a) Photograph of bubble-chamber tracks of electron–positron pairs that are produced when 300 MeV photons strike a lead sheet. A magnetic field directed out of the photograph made the electrons and positrons curve in opposite directions. (b) Diagram showing the pair-production process for two of the photons.

positron's spin angular momentum $\vec{S}$ and magnetic moment $\vec{\mu}$ are parallel; they are opposite for the electron. However, $\vec{S}$ and $\vec{\mu}$ have the same magnitude for both particles because they have the same spin. We use the term **antiparticle** for a particle that is related to another particle as the positron is to the electron. Each kind of particle has a corresponding antiparticle. For a few kinds of particles (necessarily all neutral) the particle and antiparticle are identical, and we can say that they are their own antiparticles. The photon is an example; there is no way to distinguish a photon from an antiphoton. We'll use the standard symbols e^- for the electron and e^+ for the positron, and the generic term 'electron' will often include both electrons and positrons. Other antiparticles are often denoted by a bar over the particle's symbol; for example, an antiproton is $\bar{p}$. We'll see several other examples of antiparticles later.

Positrons do not occur in ordinary matter. Electron–positron pairs are produced during high-energy collisions of charged particles or γ rays with matter, an example of the process called e^+e^- *pair production* (Fig. 44.3). Electric charge is conserved, and enough energy E must be available to account for the rest energy $2m_ec^2$ of the two particles. The minimum energy for electron–positron pair production is

$$E_{\text{min}} = 2m_ec^2 = 2(9.109 \times 10^{-31}\,\text{kg})(2.998 \times 10^8\,\text{m/s})^2$$
$$= 1.637 \times 10^{-13}\,\text{J} = 1.022\,\text{MeV}$$

The inverse process, e^+e^- *pair annihilation*, occurs when a positron and an electron collide. Both particles disappear, and two (or occasionally three) photons can appear, with total energy of at least $2m_ec^2 = 1.022$ MeV. Decay into a *single* photon is impossible because such a process could not conserve both energy and momentum. It's easiest to analyse e^+e^- annihilation processes in the frame of reference called the *centre-of-momentum system*, in which the total momentum is zero. It is the relativistic generalisation of the centre-of-mass system that we discussed in Section 8.5.

Example 44.1 Pair annihilation

An electron and a positron are very far apart and moving towards each other with the same speed. They collide head-on, annihilating each other and producing two photons. Find the energies, wavelengths and frequencies of the two photons if the initial kinetic energies of the e^- and e^+ are (a) both negligibly small and (b) both 5.000 MeV. The rest energy of an electron is 0.511 MeV.

SOLUTION

IDENTIFY: As in the ordinary collisions we studied in Chapter 8, in this process both momentum and energy are conserved.

SET UP: Because the electron and positron are initially very far apart, the initial electric potential energy is zero and the initial energy is all kinetic. The final energy is the sum of the energies of the two photons. Before the collision the momenta of the electron and positron have the same magnitude and opposite directions, so the total momentum is zero and we are in the centre-of-momentum system; the total momentum of the two photons after the collision must likewise be zero. We solve for the energy E of each photon using conservation of energy, conservation of momentum, and the relationship $E = pc$ for each photon (see Section 38.2). We then calculate the wavelengths and frequencies using the relationships $E = hc/\lambda = hf$.

EXECUTE: For momentum to be conserved, the two photons must have momenta of equal magnitude p and opposite directions. Since $E = pc = hc/\lambda = hf$, the two photons must also have the same energy E, wavelength λ, and frequency f.

Before the collision the energy of each electron is $K + mc^2$, where K is its kinetic energy and $mc^2 = 0.511$ MeV. The equation for conservation of energy is therefore

$$(K + mc^2) + (K + mc^2) = E + E$$

Hence the energy of each photon is $E = K + mc^2$.

(a) If the electron kinetic energy K is negligible compared to its rest energy mc^2, then each photon has energy $E = mc^2 = 0.511$ MeV. The wavelength and frequency of each photon are

$$\lambda = \frac{hc}{E} = \frac{(4.136 \times 10^{-15}\,\text{eV}\cdot\text{s})(3.00 \times 10^8\,\text{m/s})}{0.511 \times 10^6\,\text{eV}}$$
$$= 2.43 \times 10^{-12}\,\text{m} = 2.43\,\text{pm}$$

$$f = \frac{E}{h} = \frac{0.511 \times 10^6\,\text{eV}}{4.136 \times 10^{-15}\,\text{eV}\cdot\text{s}} = 1.24 \times 10^{20}\,\text{Hz}$$

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

(b) Now $K = 5.000$ MeV for each electron, so each photon has energy $E = 5.000\ \text{MeV} + 0.511\ \text{MeV} = 5.511\ \text{MeV}$. The wavelength and frequency of each photon are 0.2250 pm and 1.333×10^{21} Hz, respectively.

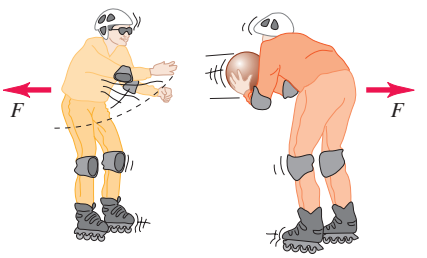
EVALUATE: As a check on our results, recall from Section 38.2 that a visible-light photon with an energy of 2 eV has wavelength 600 nm and frequency 5×10^{14} Hz. Each photon in part (a) has an energy that is about 2.5×10^5 times greater; as expected, the photon's wavelength is smaller and its frequency larger than those for a visible-light photon by the same factor. You can check the results for part (b) in the same way.

Positrons also occur in the decay of some unstable nuclei, in which they are called beta-plus particles (β^+). We discussed β^+ decay in Section 43.3.

It's often convenient to represent particle masses in terms of the equivalent rest energy using $m = E/c^2$. Then typical mass units are MeV/c^2; for example, $m = 0.511\ \text{MeV}/c^2$ for an electron or positron. We'll use these units frequently in the following discussions.

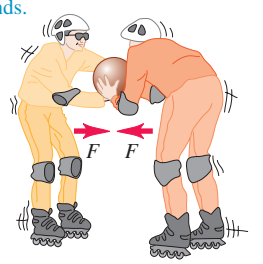
Particles As Force Mediators

In classical physics we describe the interaction of charged particles in terms of Coulomb's-law forces. In quantum mechanics we can describe this interaction in terms of emission and absorption of photons. Two electrons repeal each other as one emits a photon and the other absorbs it, just as two skaters can push each other apart by tossing a heavy ball back and forth between them (Fig. 44.4a). For an electron and a proton, in which the charges are opposite and the force is attractive, we imagine the skaters trying to grab the ball away from each other (Fig. 44.4b). The electromagnetic interaction between two charged particles is *mediated* or transmitted by photons.



If charged-particle interactions are mediated by photons, where does the energy to create the photons come from? Recall from our discussion of the uncertainty principle (see Section 39.3) that a state that exists for a short time Δt has an uncertainty ΔE in its energy such that

$$\Delta E\, \Delta t \geq \hbar \tag{44.3}$$



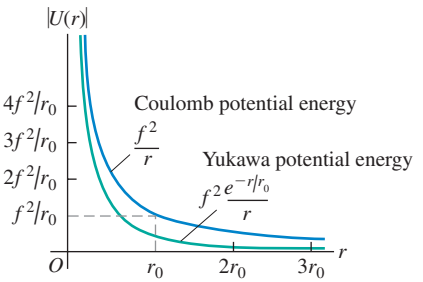
This uncertainty permits the creation of a photon with energy ΔE, provided that it lives no longer than the time Δt given by Eq. (44.3). A photon that can exist for a short time because of this energy uncertainty is called a *virtual photon*. It's as though there were an energy bank; you can borrow energy, provided that you pay it back within the time limit. According to Eq. (44.3), the more you borrow, the sooner you have to pay it back. Later we'll discuss other virtual particles that live for a short time on 'borrowed' energy.

44.4 An analogy for how particles act as force mediators.

(a) Two skaters exert repulsive forces on each other by tossing a ball back and forth.

(b) Two skaters exert attractive forces on each other when one tries to grab the ball out of the other's hands.

Mesons



Is there a particle that mediates the *nuclear* force? By the mid-1930s the nuclear force between two nucleons (neutrons or protons) appeared to be described by a potential energy $U(r)$ with the general form

$$U(r) = -f^2 \frac{e^{-r/r_0}}{r} \qquad \text{(nuclear potential energy)} \tag{44.4}$$

The constant f characterises the strength of the interaction, and r_0 describes its range. Figure 44.5 shows a graph of the absolute value of this function and compares it with the function f^2/r, which would be analogous to the *electric* interaction of two protons:

$$U(r) = \frac{1}{4\pi\epsilon_0}\frac{e^2}{r} \qquad \text{(electric potential energy)} \tag{44.5}$$

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

44.5 Graph of the magnitude of the Yukawa potential-energy function for nuclear forces, $|U(r)| = f^2 e^{-r/r_0}/r$. The function $U(r) = f^2/r$, proportional to the potential energy for Coulomb's law, is also shown. The two functions are similar at small r, but the Yukawa potential energy drops off much more quickly at large r.

In 1935 the Japanese physicist Hideki Yukawa suggested that a hypothetical particle that he called a **meson** might act as a mediator of the nuclear force. He showed that the range of the force was related to the mass of the particle. His argument went like this: The particle must live for a time Δt long enough to travel a distance comparable to the range of the nuclear force. This range was known from the sizes of nuclei and other information to be of the order of $r_0 = 1.5 \times 10^{-15}\ \text{m} = 1.5\ \text{fm}$. If we assume that the particle's speed is comparable to c, its lifetime Δt must be of the order of

$$\Delta t = \frac{r_0}{c} = \frac{1.5 \times 10^{-15}\ \text{m}}{3.0 \times 10^8\ \text{m/s}} = 5.0 \times 10^{-24}\ \text{s}$$

From Eq. (44.3), the minimum necessary uncertainty ΔE in energy is

$$\Delta E = \frac{\hbar}{\Delta t} = \frac{1.05 \times 10^{-34}\ \text{J} \cdot \text{s}}{5.0 \times 10^{-24}\ \text{s}} = 2.1 \times 10^{-11}\ \text{J} = 130\ \text{MeV}$$

The mass equivalent Δm of this energy is

$$\Delta m = \frac{\Delta E}{c^2} = \frac{2.1 \times 10^{-11}\ \text{J}}{(3.00 \times 10^8\ \text{m/s})^2} = 2.3 \times 10^{-28}\ \text{kg} = 130\ \text{MeV}/c^2$$

This is about 250 times the electron mass, and Yukawa postulated that a particle with this mass serves as the messenger for the nuclear force. This was a courageous act; at the time, there was not a shred of experimental evidence that such a particle existed.

A year later, Carl Anderson and his colleague Seth Neddermeyer discovered in cosmic radiation two new particles, now called **muons**. The μ^- has charge equal to that of the electron, and its antiparticle the μ^+ has a positive charge with equal magnitude. The two particles have equal mass, about 207 times the electron mass. But it soon became clear that muons were *not* Yukawa's particles because they interacted with nuclei only very weakly.

In 1947 a family of three particles, called π *mesons* or **pions**, were discovered. Their charges are $+e$, $-e$, and zero, and their masses are about 270 times the electron mass. The pions interact strongly with nuclei, and they *are* the particles predicted by Yukawa. Other, heavier mesons, the ω and ρ, evidently also act as shorter-range messengers of the nuclear force. The complexity of this explanation suggests that it has simpler underpinnings; these involve the quarks and gluons that we'll discuss in Section 44.4. Before discussing mesons further, we'll describe some particle accelerators and detectors to see how mesons and other particles are created in a controlled fashion and observed.

Test Your Understanding of Section 44.1 Each of the following particles can be exchanged between two protons, two neutrons, or a neutron and a proton as part of the nuclear force. Rank the particles in order of the range of the interaction that they mediate, from largest to smallest range. (i) the π^+ (pi-plus) meson of mass 140 MeV/c^2; (ii) the ρ^+ (rho-plus) meson of mass 776 MeV/c^2; (iii) the η^0 (eta-zero) meson of mass 548 MeV/c^2; (iv) the ω^0 (omega-zero) meson of mass 783 MeV/c^2.

44.2 Particle Accelerators and Detectors

Early nuclear physicists used alpha and beta particles from naturally occurring radioactive elements for their experiments, but they were restricted in energy to the few MeV that are available in such random decays. Present-day particle accelerators can produce precisely controlled beams of particles, from electrons and positrons up to heavy ions, with a wide range of energies. These beams have

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

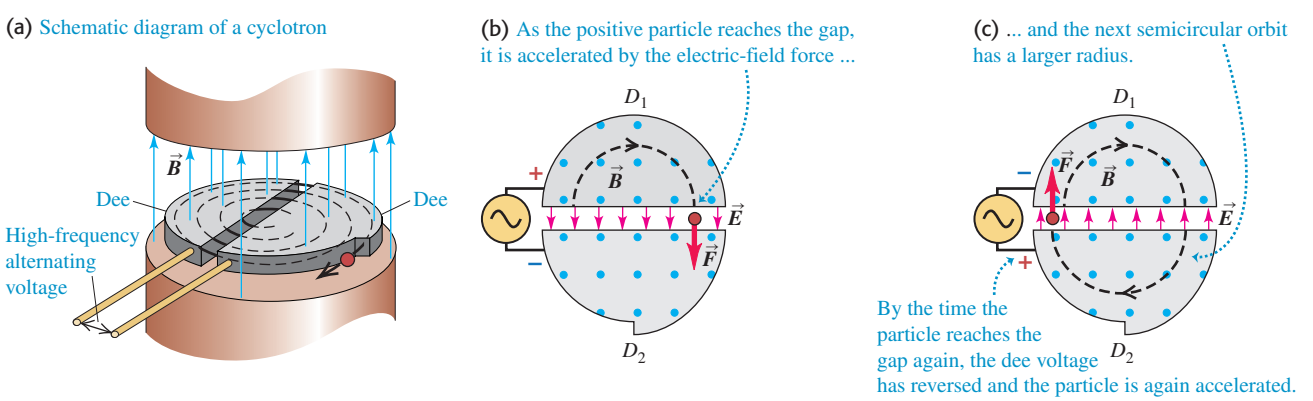
three main uses. First, high-energy particles can collide to produce new particles, just as a collision of an electron and a positron can produce photons. Second, a high-energy particle has a short de Broglie wavelength and so can probe the small-scale interior structure of other particles, just as electron microscopes (see Section 39.4) can give better resolution than optical microscopes. Third, they can be used to produce nuclear reactions of scientific or medical use.

Linear Accelerators

Particle accelerators use electric and magnetic fields to accelerate and guide beams of charged particles. A *linear accelerator* (linac) accelerates particles in a straight line. The earliest examples were J. J. Thomson's cathode-ray tubes and William Coolidge's x-ray tubes. More sophisticated linacs use a series of electrodes with gaps to give the beam of particles a series of boosts. Most present-day high-energy linear accelerators use a travelling electromagnetic wave; the charged particles 'ride' the wave in more or less the way that a surfer rides an incoming ocean wave. In the highest-energy linac in the world today, at the Stanford Linear Accelerator Center (SLAC), electrons and positrons can be accelerated to 50 GeV in a tube 3 km long. At this energy their de Broglie wavelengths are 0.025 fm, much smaller than the size of a proton or a neutron.

The Cyclotron

Many accelerators use magnets to deflect the charged particles into circular paths. The first of these was the *cyclotron*, invented in 1931 by E. O. Lawrence and M. Stanley Livingston at the University of California. In the cyclotron, shown schematically in Fig. 44.6a, particles with mass m and charge q move inside a vacuum chamber in a uniform magnetic field $\vec{B}$ that is perpendicular to the plane of their paths. In Section 27.4 we showed that in such a field, a particle with speed v moves in a circular path with radius r given by



$$r = \frac{mv}{|q|B} \tag{44.6}$$

and with angular speed (angular frequency) ω given by

$$\omega = \frac{v}{r} = \frac{|q|B}{m} \tag{44.7}$$

An alternating potential difference is applied between the two hollow electrodes D_1 and D_2 (called *dees*), creating an electric field in the gap between them. The polarity of the potential difference and electric field is changed precisely twice each revolution (Figs. 44.6b and 44.6c), so that the particles get a push each time they cross the gap. The pushes increase their speed and kinetic energy,

44.6 Layout and operation of a cyclotron.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

boosting them into paths of larger radius. The maximum speed v_{max} and kinetic energy K_{max} are determined by the radius R of the largest possible path. Solving Eq. (44.6) for v, we find $v = |q|BR/m$ and $v_{max} = |q|BR/m$. Assuming nonrelativistic speeds, we have

$$K_{max} = \frac{1}{2}mv_{max}^2 = \frac{q^2B^2R^2}{2m} \tag{44.8}$$

Example 44.2 A proton cyclotron

One cyclotron built during the 1930s has a path of maximum radius 0.500 m and a magnetic field of magnitude 1.50 T. If it is used to accelerate protons, (a) calculate the frequency of the alternating voltage applied to the dees, and (b) find the maximum particle energy.

SOLUTION

IDENTIFY: The frequency of the cyclotron voltage must equal the frequency of the proton orbital motion. The particle reaches its maximum energy when the radius of its orbit equals the radius of the dees.

SET UP: Equation (44.7) gives the angular frequency of the proton orbital motion. The target variable in part (a) is the ordinary frequency $f = \omega/2\pi$. The maximum kinetic energy of the protons is given by Eq. (44.8).

EXECUTE: (a) For protons, $q = 1.60 \times 10^{-19}\,\text{C}$ and $m = 1.67 \times 10^{-27}\,\text{kg}$. Using Eq. (44.7), we have

$$f = \frac{\omega}{2\pi} = \frac{|q|B}{2\pi m} = \frac{(1.60 \times 10^{-19}\,\text{C})(1.50\,\text{T})}{2\pi(1.67 \times 10^{-27}\,\text{kg})}$$
$$= 2.3 \times 10^7\,\text{Hz} = 23\,\text{MHz}$$

(b) From Eq. (44.8) the maximum kinetic energy is

$$K_{max} = \frac{(1.60 \times 10^{-19}\,\text{C})^2(1.50\,\text{T})^2(0.50\,\text{m})^2}{2(1.67 \times 10^{-27}\,\text{kg})}$$
$$= 4.3 \times 10^{-12}\,\text{J} = 2.7 \times 10^7\,\text{eV} = 27\,\text{MeV}$$

This energy, which is much larger than energies that are available from natural radioactivity, can cause a variety of interesting nuclear reactions.

EVALUATE: From Eq. (44.6) or Eq. (44.7), the proton speed is $v = 7.2 \times 10^7\,\text{m/s}$, which is about 25% of the speed of light. At such speeds, relativistic effects are beginning to become important. Since we ignored these effects in our calculation, the above results for f and K_{max} are in error by a few percent; this is why we kept only two significant figures.

The maximum energy that can be attained with a cyclotron is limited by relativistic effects. The relativistic version of Eq. (44.7) is

$$\omega = \frac{|q|B}{m}\sqrt{1 - v^2/c^2}$$

As the particles speed up, their angular frequency ω *decreases*, and their motion gets out of phase with the alternating dee voltage. In the *synchrocyclotron* the particles are accelerated in bursts. For each burst, the frequency of the alternating voltage is decreased as the particles speed up, maintaining the correct phase relationship with the particles' motion.

Another limitation of the cyclotron is the difficulty of building very large electromagnets. The largest synchrocyclotron ever built has a vacuum chamber that is about 8 m in diameter and accelerates protons to energies of about 600 MeV.

The Synchrotron

To attain higher energies, another type of machine, called the *synchrotron*, is more practical. Particles move in a vacuum chamber in the form of a thin doughnut, called the *accelerating ring*. The particle beam is bent to follow the ring by a series of electromagnets placed around the ring. As the particles speed up, the magnetic field is increased so that the particles retrace the same trajectory over and over. The Tevatron at the Fermi National Accelerator Laboratory (Fermilab) in Batavia, Illinois, is currently the highest-energy accelerator in the world; it can accelerate protons to a maximum energy of nearly 1 TeV $(10^{12}\,\text{eV})$. The accelerating ring is 2 km in diameter and uses superconducting electromagnets

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

(Fig. 44.7). In each machine cycle, a few seconds long, the Tevatron accelerates approximately 10^{13} protons.

As we pointed out in Section 38.5, accelerated charges radiate electromagnetic energy. Examples include the transmissions from radio and TV antennas. In an accelerator in which the particles move in curved paths, this radiation is often called *synchrotron radiation*. High-energy accelerators are typically constructed underground to provide protection from this radiation. From the accelerator standpoint, synchrotron radiation is undesirable, since the energy given to an accelerated particle is radiated right back out. It can be minimised by making the accelerator radius r large so that the centripetal acceleration v^2/r is small. On the positive side, synchrotron radiation is used as a source of well-controlled high-frequency electromagnetic waves.

44.7 An aerial view of the main accelerator ring of the Tevatron, the 1 TeV (1000 GeV) accelerator at the Fermi National Accelerator Laboratory in Illinois.

Available Energy

When a beam of high-energy particles collides with a stationary target, not all the kinetic energy of the incident particles is *available* to form new particle states. Because momentum must be conserved, the particles emerging from the collision must have some net motion and thus some kinetic energy. The discussion following Example 43.11 (Section 43.6) presented a nonrelativistic example of this principle. The maximum available energy is the kinetic energy in the frame of reference in which the total momentum is zero. We called this the *centre-of-momentum system* in Section 44.1. In this system the total kinetic energy after the collision can be zero, so that the maximum amount of the initial kinetic energy becomes available to cause the reaction being studied.

Consider the *laboratory system*, in which a target particle with mass M is initially at rest and is bombarded by a particle with mass m and total energy (including rest energy) E_m. The total available energy E_a in the centre-of-momentum system (including rest energies of all the particles) can be shown to be given by

$$E_a^2 = 2Mc^2E_m + (Mc^2)^2 + (mc^2)^2 \qquad \text{(available energy)} \qquad (44.9)$$

When the masses of the target and projectile particles are equal, this can be simplified to

$$E_a^2 = 2mc^2(E_m + mc^2) \qquad \text{(available energy, equal masses)} \qquad (44.10)$$

In the *extreme-relativistic range*, in which the kinetic energy of the bombarding particle is much larger than its rest energy, available energy is very severely limited. If the beam and target particles have equal masses and E_m is much greater than mc^2, we can neglect the second term in the parentheses in Eq (44.10). Then E_a is

$$E_a = \sqrt{2mc^2E_m} \qquad \text{(available energy, equal masses, } E_m \gg mc^2\text{)} \qquad (44.11)$$

Example 44.3 Threshold energy for pion production

A proton (rest energy 938 MeV) with kinetic energy K collides with another proton at rest. Both protons survive the collision, but in addition a neutral pion (π^0, rest energy 135 MeV) is produced. What is the threshold energy (minimum value of K) needed for this process?

SOLUTION

IDENTIFY: The final state includes the two original protons (mass m) and the pion (mass m_π). The threshold energy corresponds to the minimum-energy case in which all three particles are at rest in the centre-of-momentum system.

SET UP: The total available energy in the centre-of-momentum system must be at least their total rest energy, $2mc^2 + m_\pi c^2$. We use this in Eq. (44.10) and solve for the total energy E_m of the bombarding proton; the kinetic energy K (our target variable) is the total energy minus the proton rest energy mc^2.

EXECUTE: We substitute $E_a = 2mc^2 + m_\pi c^2$ into Eq. (44.10), simplify, and solve for E_m:

$$4m^2c^4 + 4mm_\pi c^4 + m_\pi^2c^4 = 2mc^2E_m + 2(mc^2)^2$$

$$E_m = mc^2 + m_\pi c^2\left(2 + \frac{m_\pi}{2m}\right)$$

Continued

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

The first term in the expression for E_m is the rest energy of the bombarding proton, and the remaining terms give its kinetic energy. We see that the kinetic energy must be somewhat greater than twice the rest energy of the pion we want to create. Using $mc^2 = 938$ MeV and $m_\pi c^2 = 135$ MeV in this expression, we find $m_\pi/2m = 0.072$ and

$$E_m = mc^2 + (135\text{ MeV})(2 + 0.072) = mc^2 + 280\text{ MeV}$$

To create a pion with rest energy 135 MeV, a bombarding proton needs a kinetic energy of at least 280 MeV.

EVALUATE: You should compare this result with the result of Example 37.12 (Section 37.8), which required only 67.5 MeV of kinetic energy for each proton in a head-on collision. We discuss the energy advantage of such collisions in the next subsection.

Example 44.4 Increasing the available energy

(a) The Fermilab accelerator was originally designed for a proton beam energy of 800 GeV $(800 \times 10^9\text{ eV})$ on a stationary target. Find the available energy in a proton–proton collision. (b) If the proton beam energy is increased to 980 GeV, what is the available energy?

SOLUTION

IDENTIFY: The example concerns the available energy in a stationary-target collision experiment.

SET UP: Our target variable is the available energy E_a. In both parts (a) and (b) the two particles are identical and the beam energy E_m is much larger than the proton rest energy $mc^2 = 938\text{ MeV} = 0.938\text{ GeV}$, so we can safely use Eq. (44.11).

EXECUTE: (a) When $E_m = 800$ GeV,

$$E_a = \sqrt{2(0.938\text{ GeV})(800\text{ GeV})} = 38.7\text{ GeV}$$

(b) When $E_m = 980$ GeV,

$$E_a = \sqrt{2(0.938\text{ GeV})(980\text{ GeV})} = 42.9\text{ GeV}$$

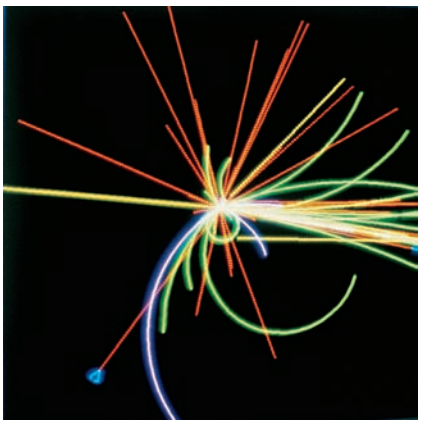
EVALUATE: With a stationary proton target, increasing the proton beam energy by 200 GeV increases the available energy by only 4.2 GeV! This shows a major limitation of experiments in which one of the colliding particles is initially at rest. Below we describe how physicists can overcome these limitations.

Colliding Beams

The limitation illustrated by Example 44.4 is circumvented in *colliding-beam* experiments. In these experiments there is no stationary target; instead, beams of particles moving in opposite directions are tightly focused onto one another so that head-on collisions can occur. Usually the two colliding particles have momenta of equal magnitude and opposite direction, so the total momentum is zero. Hence the laboratory system is also the centre-of-momentum system, and the available energy is maximised. If one beam contains particles and the other beam contains antiparticles (for instance, electrons and positrons or protons and antiprotons), the available energy E_a is the *total* energy of the two colliding particles.

The highest-energy colliding beams currently available are those at the Tevatron at Fermilab (Fig. 44.7). A beam of 980 GeV (0.980 TeV) protons circulates around a ring in the opposite direction from a beam of 0.980 TeV antiprotons. Magnets are used to steer the beams into each other at various points around the ring. The available energy in the resulting head-on collisions is $2(0.980\text{ TeV}) = 1.96$ TeV. These colliding beams were used in the discovery of the top quark, to be discussed in Section 44.4.

Other laboratories use colliding beams of electrons and positrons. A common design uses *storage rings*, in which bunches of electrons and positrons are kept circulating in opposite directions around a circular tunnel, giving them many opportunities to interact. At present the largest e^+e^- storage ring is the Large Electron-Positron Collider (LEP), situated in an underground tunnel 27 km in circumference at the European Laboratory for Particle Physics (CERN) in Geneva, Switzerland. The total available energy E_a is 180 GeV. Experiments using a lower-energy e^+e^- storage ring at the Stanford Linear Accelerator Center (SLAC) revealed the properties of the charm quark and were used to discover the tau lepton, a particle that is closely related to the electron and the muon. (In Section 44.4 we will see how physicists systematise their knowledge of these and many other particles.)



Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

When it begins operating, even higher-energy colliding beams will be available with the Large Hadron Collider (LHC) at CERN, which will use the same tunnel as the LEP but will accelerate colliding beams of protons to 7 TeV each, giving an available energy of 14 TeV. It will also be possible to collide electrons from the LEP with protons from the LHC, giving an available energy of 1.5 TeV. See <www.physicsworld.com> for the latest developments.

Detectors

Ordinarily, we can't see or feel individual subatomic particles or photons. How, then, do we measure their properties? A wide variety of devices have been designed. Many detectors use the ionisation caused by charged particles as they move through a gas, liquid, or solid. The ions along the particle's path act as nucleation centres for droplets of liquid in the supersaturated vapour of a cloud chamber (Fig. 44.1) or cause small volumes of vapour in the superheated liquid of a bubble chamber (Fig. 44.3a). In a semiconducting solid the ionisation can take the form of electron–hole pairs. We discussed their detection in Section 42.7. *Wire chambers* contain arrays of closely spaced wires that detect the ions. The charge collected and time information from each wire are processed using computers to reconstruct the particle trajectories (Fig. 44.8). The photograph that opens Chapter 28 shows a detector array for the LHC under construction. The completed array includes a variety of different detectors for measuring the properties of particles of different types.

44.8 This computer-generated image shows a typical result of a proton–antiproton collision in the Tevatron recorded by the Collider Detector. Particles produced in the collision include pions, kaons, muons and others, each indicated by a different colour.

Cosmic-Ray Experiments

Large numbers of particles called *cosmic rays* continually bombard the earth from sources both within and beyond our galaxy. These particles consist mostly of neutrinos, protons and heavier nuclei, with energies ranging from less than 1 MeV to more than 10^{20} eV. The earth's atmosphere and magnetic field protect us from much of this radiation. This means that cosmic-ray experimentation often must be carried out above all or most of the atmosphere by means of rockets or high-altitude balloons.

In contrast, neutrino detectors are buried below the earth's surface in tunnels or mines or submerged deep in the ocean. This is done to screen out all other types of particles so that only neutrinos, which interact only very weakly with matter, reach the detector. It would take a light-year's thickness of lead to absorb a sizable fraction of a beam of neutrinos. Thus neutrino detectors consist of huge amounts of matter: The Super-Kamiokande detector looks for flashes of light produced when a neutrino interacts in a tank containing 5×10^7 kg of water (see Section 44.5).

Cosmic rays were important in early particle physics, and their study currently brings us important information about the rest of the universe. Although cosmic rays provide a source of high-energy particles that does not depend on expensive accelerators, most particle physicists use accelerators because the high-energy cosmic-ray particles they want are too few and too random.

Test Your Understanding of Section 44.2 In a colliding-beam experiment, a 90 GeV electron collides head-on with a 90 GeV positron. The electron and the positron annihilate each other, forming a single virtual photon that then transforms into other particles. Does the virtual photon obey the same relationship $E = pc$ as real photons do?

44.3 Particles and Interactions

We have mentioned the array of subatomic particles that were known as of 1947: photons, electrons, positrons, protons, neutrons, muons and pions. Since then, literally hundreds of additional particles have been discovered in accelerator

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

experiments. The vast majority of known particles are *unstable* and decay spontaneously into other particles. Particles of all kinds, whether stable or unstable, can be created or destroyed in interactions between particles. Each such interaction involves the exchange of virtual particles, which exist on borrowed energy allowed by the uncertainty principle.

Although the world of subatomic particles and their interactions is complex, some key results bring order and simplicity to the seeming chaos. One key simplification is that there are only four fundamental types of interactions, each mediated or transmitted by the exchange of certain characteristic virtual particles. Furthermore, not all particles respond to all four kinds of interaction. In this section we will examine the fundamental interactions more closely and see how physicists classify particles in terms of the ways in which they interact.

Four Forces and Their Mediating Particles

44.9 The ties that bind us together originate in the fundamental interactions of nature. The nuclei within our bodies are held together by the strong interaction. The electromagnetic interaction binds nuclei and electrons together to form atoms, binds atoms together to form molecules, and binds molecules together to form us.

In Section 5.5 we first described the four fundamental types of forces or interactions (Fig. 44.9). They are, in order of decreasing strength:

1. The strong interaction
2. The electromagnetic interaction
3. The weak interaction
4. The gravitational interaction

The *electromagnetic* and *gravitational* interactions are familiar from classical physics. Both are characterised by a $1/r^2$ dependence on distance. In this scheme, the mediating particles for both interactions have mass zero and are stable as ordinary particles. The mediating particle for the electromagnetic interaction is the familiar photon, which has spin 1. (That means its spin quantum number is $s = 1$, so the magnitude of its spin angular momentum is $S = \sqrt{s(s+1)}\hbar = \sqrt{2}\hbar$.) That particle for the gravitational force is the spin-2 *graviton* ($s = 2$, $S = \sqrt{s(s+1)}\hbar = \sqrt{6}\hbar$). The graviton has not yet been observed experimentally because the gravitational force is very much weaker than the electromagnetic force. For example, the gravitational attraction of two protons is smaller than their electrical repulsion by a factor of about 10^{36}. The gravitational force is of primary importance in the structure of stars and the large-scale behaviour of the universe, but it is not believed to play a significant role in particle interactions at the energies that are currently attainable.

The other two forces are less familiar. One, usually called the *strong interaction*, is responsible for the nuclear force and also for the production of pions and several other particles in high-energy collisions. At the most fundamental level, the mediating particle for the strong interaction is called a *gluon*. However, the force between nucleons is more easily described in terms of mesons as the mediating particles. We'll discuss the spin-1, massless gluon in Section 44.4.

Equation (44.4) is a possible potential-energy function for the nuclear force. The strength of the interaction is described by the constant f^2, which has units of energy times distance. A better basis for comparison with other forces is the dimensionless ratio $f^2/\hbar c$, called the *coupling constant* for the interaction. (We invite you to verify that this ratio is a pure number and so must have the same value in all systems of units.) The observed behaviour of nuclear forces suggests that $f^2/\hbar c \approx 1$. The dimensionless coupling constant for *electromagnetic* interactions is

$$\frac{1}{4\pi\epsilon_0}\frac{e^2}{\hbar c} = 7.297 \times 10^{-3} = \frac{1}{137.0} \tag{44.12}$$

Thus the strong interaction is roughly 100 times as strong as the electromagnetic interaction; however, it drops off with distance more quickly than $1/r^2$.

The fourth interaction is called the *weak* interaction. It is responsible for beta decay, such as the conversion of a neutron into a proton, an electron and an antineutrino. It is also responsible for the decay of many unstable particles (pions

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

into muons, muons into electrons, and so on). Its mediating particles are the short-lived particles W^+, W^- and Z^0. The existence of these particles was confirmed in 1983 in experiments at CERN, for which Carlo Rubbia and Simon van der Meer were awarded the Nobel Prize in 1984. The $W^\pm$ and Z^0 have spin 1 like the photon and the gluon, but they are *not* massless. In fact, they have enormous masses, 80.4 GeV/c^2 for the W's and 91.2 GeV/c^2 for the Z^0. With such massive mediating particles the weak interaction has a much shorter range than the strong interaction. It also lives up to its name by being weaker than the strong interaction by a factor of about 10^9.

Table 44.1 compares the main features of these four fundamental interactions.

More Particles

In Section 44.1 we mentioned the discoveries of muons in 1937 and of pions in 1947. The electric charges of the muons and the charged pions have the same magnitude e as the electron charge. The positive muon μ^+ is the antiparticle of the negative muon μ^-. Each has spin $\frac{1}{2}$, like the electron, and a mass of about $207m_e = 106\ \text{MeV}/c^2$. Muons are unstable; each decays with a lifetime of 2.2×10^{-6} s into an electron of the same sign, a neutrino and an antineutrino.

There are three kinds of pions, all with spin 0; they have *no* spin angular momentum. The π^+ and π^- have masses of $273m_e = 140\ \text{MeV}/c^2$. They are unstable; each $\pi^\pm$ decays with a lifetime of 2.6×10^{-8} s into a muon of the same sign along with a neutrino for the π^+ and an antineutrino for the π^-. The π^0 is somewhat less massive, $264m_e = 135\ \text{MeV}/c^2$, and it decays with a lifetime of 8.4×10^{-17} s into two photons. The π^+ and π^- are antiparticles of one another, while the π^0 is its own antiparticle. (That is, there is no distinction between particle and antiparticle for the π^0.)

The existence of the *antiproton* $\bar{p}$ had been suspected ever since the discovery of the positron. The $\bar{p}$ was found in 1955, when proton–antiproton $(p\bar{p})$ pairs were created by use of a beam of 6-GeV protons from the Bevatron at the University of California, Berkeley. The *antineutron* $\bar{n}$ was found soon afterward. After 1960, as higher-energy accelerators and more sophisticated detectors were developed, a veritable blizzard of new unstable particles were identified. To describe and classify them, we need a small blizzard of new terms.

Initially, particles were classified by mass into three categories: (1) leptons ('light ones' such as electrons); (2) mesons ('intermediate ones' such as pions); and (3) baryons ('heavy ones' such as nucleons and more massive particles). But this scheme has been superseded by a more useful one in which particles are classified in terms of their *interactions*. For instance, *hadrons* (which include mesons and baryons) have strong interactions, and *leptons* do not.

In the following discussion we will also distinguish between **fermions**, which have half-integer spins, and **bosons**, which have zero or integer spins. Fermions obey the exclusion principle, on which the Fermi-Dirac distribution function (see Section 42.5) is based. Bosons do not obey the exclusion principle and have a different distribution function, the Bose-Einstein distribution.

Table 44.1 Four Fundamental Interactions

Interaction	Relative Strength	Range	Mediating Particle			
			Name	Mass	Charge	Spin
Strong	1	Short (~1 fm)	Gluon	0	0	1
Electromagnetic	$\frac{1}{137}$	Long ($1/r^2$)	Photon	0	0	1
Weak	10^{-9}	Short (~0.001 fm)	$W^\pm$, Z^0	80.4, 91.2 GeV/c^2	$\pm e$, 0	1
Gravitational	10^{-38}	Long ($1/r^2$)	Graviton	0	0	2

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

Leptons

The **leptons**, which do not have strong interactions, include six particles; the electron (e^-) and its neutrino (ν_e), the muon (μ^-) and its neutrino (ν_μ), and the tau particle (τ^-) and its neutrino (ν_τ). Each of the six particles has a distinct antiparticle. All leptons have spin $1/2$ and thus are fermions. The family of leptons is shown in Table 44.2. The taus have mass $3478m_e = 1777\ \text{MeV}/c^2$. Taus and muons are unstable; a τ^- decays into a μ^- plus a tau neutrino and a muon antineutrino, or an electron plus a tau neutrino and an electron antineutrino. A μ^- decays into a electron plus a muon neutrino and an electron antineutrino. They have relatively long lifetimes because their decays are mediated by the weak interaction. Despite their zero charge, a neutrino is distinct from an antineutrino; the spin angular momentum of a neutrino has a component that is opposite its linear momentum, while for an antineutrino that component is parallel to its linear momentum. Because neutrinos are so elusive, physicists have only been able to place upper limits on the rest masses of the ν_e, the ν_μ, and the ν_τ. Until recently, it was thought that the rest masses of the neutrinos were zero; compelling evidence now indicates that they have small but nonzero masses. We'll return to this point and its implications later.

Leptons obey a *conservation principle*. Corresponding to the three pairs of leptons are three lepton numbers L_e, L_μ, and L_τ. The electron e^- and the electron neutrino ν_e are assigned $L_e = 1$, and their antiparticles e^+ and $\bar{\nu}_e$ are given $L_e = -1$. Corresponding assignments of L_μ and L_τ are made for the μ and τ particles and their neutrinos. **In all interactions, each lepton number is separately conserved.** For example, in the decay of the μ^-, the lepton numbers are

$$\begin{array}{ccccccc} \mu^- & \rightarrow & e^- & + & \bar{\nu}_e & + & \nu_\mu \\ L_\mu = 1 & & L_e = 1 & & L_e = -1 & & L_\mu = 1 \end{array}$$

These conservation principles have no counterpart in classical physics.

Table 44.2 The Six Leptons

Particle Name	Symbol	Anti-particle	Mass (MeV/c^2)	L_e	L_μ	L_τ	Lifetime (s)	Principal Decay Modes
Electron	e^-	e^+	0.511	+1	0	0	Stable	
Electron neutrino	ν_e	$\bar{\nu}_e$	$<3 \times 10^{-6}$	+1	0	0	Stable	
Muon	μ^-	μ^+	105.7	0	+1	0	2.20×10^{-6}	$e^-\bar{\nu}_e\nu_\mu$
Muon neutrino	ν_μ	$\bar{\nu}_\mu$	<0.19	0	+1	0	Stable	
Tau	τ^-	τ^+	1777	0	0	+1	2.9×10^{-13}	$\mu^-\bar{\nu}_\mu\nu_\tau$ or $e^-\bar{\nu}_e\nu_\tau$
Tau neutrino	ν_τ	$\bar{\nu}_\tau$	<18.2	0	0	+1	Stable	

Example 44.5 Lepton number conservation

Check conservation of lepton numbers for the following decay schemes:

(a) $\mu^+ \rightarrow e^+ + \nu_e + \bar{\nu}_\mu$

(b) $\pi^- \rightarrow \mu^- + \bar{\nu}_\mu$

(c) $\pi^0 \rightarrow \mu^- + e^+ + \nu_e$

SOLUTION

IDENTIFY: In order for lepton number to be conserved, each of the quantities L_e, L_μ, and L_τ must have the same value before the decay as after the decay.

SET UP: We use Table 44.2 to find the lepton numbers L_e, L_μ, and L_τ for each particle, and then compare the total value of each lepton number before the process and after the process.

EXECUTE: In each of the three decays, there are no τ particles or any τ neutrinos, so $L_\tau = 0$ both before and after each decay; L_τ is therefore conserved.

(a) The initial lepton numbers are $L_e = 0$ and $L_\mu = -1$. The final values are $L_e = -1 + 1 + 0 = 0$ and $L_\mu = 0 + 0 + (-1) = -1$. All lepton numbers are conserved.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

(b) All lepton numbers are initially zero (the π^- is *not* a lepton). The final values are $L_\mu = 1 + (-1) = 0$ and $L_e = 0$. Again, all lepton numbers are conserved.

(c) The initial L's are again all zero; in the final state, $L_e = 0 + (-1) + 1 = 0$ and $L_\mu = 1 + 0 + 0 = 1$. Thus L_μ is *not* conserved.

EVALUATE: Decays (a) and (b), which are consistent with the conservation of lepton number, are observed in nature. Decay (c), which violates the conservation of L_μ, has *never* been observed. Physicists used these and many other experimental results to deduce the principle that all three lepton numbers must be conserved.

Hadrons

Hadrons, the strongly interacting particles, are a more complex family than leptons. Each hadron has an antiparticle, often denoted with an overbar, as with the antiproton $\bar{p}$. There are two subclasses of hadrons: *mesons* and *baryons*. Table 44.3 shows some of the many hadrons that are currently known. (We'll discuss what is meant by *strangeness* and *quark content* later in this section and in the next one.)

Mesons include the pions that have already been mentioned, K mesons or *kaons*, η mesons and others that we will discuss later. Mesons have spin 0 or 1 and therefore are all bosons. There are no stable mesons; all can and do decay to less massive particles, obeying all the conservation laws for such decays.

Baryons include the nucleons and several particles called *hyperons*, including the Λ, Σ, Ξ and Ω. These resemble the nucleons but are more massive. Baryons have half-integer spin, and therefore all are fermions. The only stable baryon is the proton; a free neutron decays to a proton, and the hyperons decay to other hyperons or to nucleons by various processes. Baryons obey the principle of *conservation of baryon number*, analogous to conservation of lepton numbers, again with no counterpart in classical physics. We assign a baryon number $B = 1$ to each baryon (p, n, Λ, Σ and so on) and $B = -1$ to each antibaryon ($\bar{p}$, $\bar{n}$, $\bar{\Lambda}$, $\bar{\Sigma}$, and so on).

In all interactions, the total baryon number is conserved.

This principle is the reason the mass number A was conserved in all the nuclear reactions that we studied in Chapter 43.

Table 44.3 Some Hadrons and Their Properties

Particle	Mass (MeV/c^2)	Charge Ratio, Q/e	Spin	Baryon Number, B	Strangeness, S	Mean Lifetime (s)	Typical Decay Modes	Quark Content

Example 44.6 Baryon number conservation

Which of the following reactions obey the principle of conservation of baryons?

(a) $n + p \rightarrow n + p + p + \bar{p}$

(b) $n + p \rightarrow n + p + \bar{p}$

SOLUTION

IDENTIFY: This example is similar to Example 44.5: We need only compare the total baryon number before the process to the total baryon number after the process.

SET UP: Table 44.3 lists all of the needed baryon numbers.

EXECUTE: In both reactions the initial baryon number is $1 + 1 = 2$.

(a) The final baryon number is $1 + 1 + 1 + (-1) = 2$. Baryon number is conserved.

(b) The final baryon number for this reaction is $1 + 1 + (-1) = 1$. Baryon number is *not* conserved.

EVALUATE: Reaction (a) can and does occur, provided that enough energy is available in the n + p collision. Reaction (b), which violates the principle of conservation, has never been observed. Can you show that this reaction also violates the law of conservation of electric charge?

Example 44.7 Antiproton creation

Antiprotons can be produced by bombarding a stationary proton target (liquid hydrogen) with a beam of protons. Find the minimum beam energy that is needed for this reaction to occur.

SOLUTION

IDENTIFY: The reaction must satisfy the conservation of baryon number, of charge, and of energy.

SET UP: Since the target and bombarding protons are of equal mass and the target is at rest, we determine the minimum energy E_m of the bombarding proton using Eq. (44.10)

EXECUTE: Conservation of charge and conservation of baryon number forbid the creation of an antiproton by itself; it must be created as part of a proton—antiproton pair. The appropriate reaction is

$$p + p \rightarrow p + p + p + \bar{p}$$

For this reaction to occur, the minimum available energy E_a in Eq. (44.10) is the final rest energy $4mc^2$. With that substitution, Eq. (44.10) gives

$$(4mc^2)^2 = 2mc^2(E_m + mc^2)$$
$$E_m = 7mc^2$$

EVALUATE: The energy E_m of the bombarding particle includes its rest energy mc^2, so its minimum *kinetic* energy must be $6mc^2 = 6(938\ \text{MeV}) = 5.63\ \text{GeV}$.

The search for the antiproton was one of the principal reasons for the construction of the Bevatron at the University of California, Berkeley, with beam energy of 6 GeV. The search was successful; in 1959, Emilio Segrè and Owen Chamberlain were awarded the Nobel Prize for its discovery.

Strangeness

The K mesons and the Λ and Σ hyperons were discovered during the late 1950s. Because of their unusual behaviour they were called *strange particles*. They were produced in high-energy collisions such as $\pi^- + p$, and a K meson and a hyperon were always produced *together*. The relatively high rate of production of these particles suggested that it was a *strong*-interaction process, but their relatively long lifetimes suggested that their decay was a *weak*-interaction process. The K^0 appeared to have *two* lifetimes, one about 9×10^{-11} s and another nearly 600 times longer. Were the K mesons strongly interacting hadrons or not?

The search for the answer to this question led physicists to introduce a new quantity called **strangeness**. The hyperons Λ^0 and $\Sigma^{\pm,0}$ were assigned a strangeness quantum number $S = -1$, and the associated K^0 and K^+ mesons were assigned $S = +1$. The corresponding antiparticles had opposite strangeness, $S = +1$ for $\bar{\Lambda}^0$ and $\bar{\Sigma}^{\pm,0}$ and $S = -1$ for $\bar{K}^0$ and K^-. Then strangeness was *conserved* in production processes such as

$$p + \pi^- \rightarrow \Sigma^- + K^+$$
$$p + \pi^- \rightarrow \Lambda^0 + K^0$$

The process

$$p + \pi^- \rightarrow p + K^-$$

does not conserve strangeness and it does not occur.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

When strange particles decay individually, strangeness is usually *not* conserved. Typical processes include

$$\Sigma^+ \to \mathrm{n} + \pi^+$$
$$\Lambda^0 \to \mathrm{p} + \pi^-$$
$$\mathrm{K}^- \to \pi^+ + \pi^- + \pi^-$$

In each of these decays, the initial strangeness is 1 or -1, and the final value is zero. All observations of these particles are consistent with the conclusion that *strangeness is conserved in strong interactions but it can change by zero or one unit in weak interactions*. There is no counterpart to the strangeness quantum number in classical physics.

CAUTION **Strangeness vs. spin** Take care not to confuse the symbol S for strangeness with the identical symbol for the magnitude of the spin angular momentum.

Conservation Laws

The decay of strange particles provides our first example of a conditional conservation law, one that is obeyed in some interactions and not in others. Let's review *all* the conservation laws we know about and see what conclusions we can draw from them.

Several conservation laws are obeyed in *all* interactions. These include the familiar conservation laws; energy, momentum, angular momentum and electric charge. These are called *absolute conservation laws*. Baryon number and the three lepton numbers are also conserved in all interactions. Strangeness is conserved in strong and electromagnetic interactions but *not* in all weak interactions.

Two other quantities, which are conserved in some but not all interactions, are useful in classifying particles and their interactions. One is *isospin*, a quantity that is used to describe the charge independence of the strong interactions. The other is *parity*, which describes the comparative behaviour of two systems that are mirror images of each other. Isospin is conserved in strong interactions, which are charge independent, but not in electromagnetic or weak interactions. (The electromagnetic interaction is certainly *not* charge independent.) Parity is conserved in strong and electromagnetic interactions but not in weak ones. The Chinese-American physicists T. D. Lee and C. N. Yang received the Nobel Prize in 1957 for laying the theoretical foundations for nonconservation of parity in weak interactions.

This discussion shows that conservation laws provide another basis for classifying particles and their interactions. Each conservation law is also associated with a *symmetry* property of the system. A familiar example is angular momentum. If a system is in an environment that has spherical symmetry, there can be no torque acting on it because the direction of the torque would violate the symmetry. In such a system, total angular momentum is *conserved*. When a conservation law is violated, the interaction is often described as a *symmetry-breaking interaction*.

Test Your Understanding of Section 44.3 From conservation of energy, a particle of mass m and rest energy mc^2 can decay only if the decay products have a total mass less than m. (The remaining energy goes into the kinetic energy of the decay products.) Can a proton decay into less massive mesons?

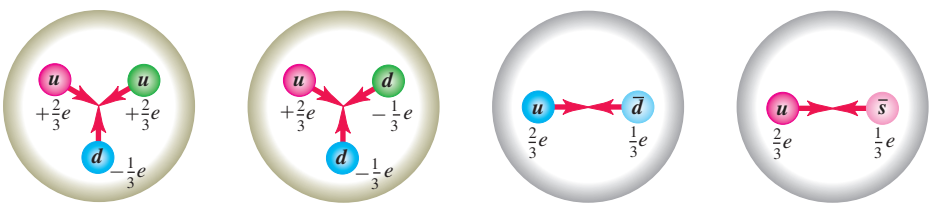
44.4 Quarks and the Eightfold Way

The leptons form a fairly neat package: three particles and three neutrinos, each with its antiparticle, and a conservation law relating their numbers. Physicists believe that leptons are genuinely fundamental particles. The hadron family, by

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

comparison, is a mess. Table 44.3 contains only a sample of well over 100 hadrons that have been discovered since 1960, and it has become clear that these particles *do not* represent the most fundamental level of the structure of matter.

Our present understanding of the structure of hadrons is based on a proposal made initially in 1964 by the American physicist Murray Gell-Mann and his collaborators. In this proposal, hadrons are not fundamental particles but are composite structures whose constituents are spin-$\frac{1}{2}$ fermions called **quarks**. (The name is found in the line 'Three quarks for Muster Mark!' from *Finnegans Wake* by James Joyce.) Each baryon is composed of three quarks $(\boldsymbol{qqq})$, each antibaryon of three antiquarks $(\boldsymbol{\overline{qqq}})$, and each meson of a quark–antiquark pair $(\boldsymbol{q\bar{q}})$. Table 44.3 of the preceding section gives the quark content of many hadrons. No other compositions seem to be necessary. This scheme requires that quarks have electric charges with magnitudes $\frac{1}{3}$ and $\frac{2}{3}$ of the electron charge e, which had previously been thought to be the smallest unit of charge. Each quark also has a fractional value $\frac{1}{3}$ for its baryon number B, and each antiquark has a baryon-number value $-\frac{1}{3}$. In a meson, a quark and antiquark combine with net baryon number 0 and can have their spin angular momentum components parallel to form a spin-1 meson or antiparallel to form a spin-0 meson. Similarly, the three quarks in a baryon combine with net baryon number 1 and can form a spin-$\frac{1}{2}$ baryon or a spin-$\frac{3}{2}$ baryon.



The Three Original Quarks

The first (1964) quark theory included three types (called *flavors*) of quarks, labelled $\boldsymbol{u}$ (up), $\boldsymbol{d}$ (down), and $\boldsymbol{s}$ (strange). Their principal properties are listed in Table 44.4. The corresponding antiquarks $\boldsymbol{\bar{u}}$, $\boldsymbol{\bar{d}}$, and $\boldsymbol{\bar{s}}$ have opposite values of charge Q, B, and S. Protons, neutrons, π and K mesons, and several hyperons can be constructed from these three quarks. For example, the proton quark content is $\boldsymbol{uud}$. Checking Table 44.4, we see that the values of Q/e add to 1 and that the values of the baryon number B also add to 1, as we should expect. The neutron is $\boldsymbol{udd}$, with total $Q = 0$ and $B = 1$. The π^+ meson is $\boldsymbol{u\bar{d}}$, with $Q/e = 1$ and $B = 0$, and the K^+ meson is $\boldsymbol{u\bar{s}}$. Checking the values of S for the quark content, we see that the proton, neutron, and π^+ have strangeness 0 and that the K^+ has strangeness 1, in agreement with Table 44.3. The antiproton is $\boldsymbol{\bar{p} = \bar{u}\bar{u}\bar{d}}$, the negative pion is $\boldsymbol{\pi^- = \bar{u}d}$, and so on. The quark content can also be used to explain dynamic properties of hadrons such as their excited states and magnetic moments. Figure 44.10 shows the quark content of two baryons and two mesons.

Table 44.4 Properties of the Three Original Quarks

Symbol	Q/e	Spin	Baryon Number, B	Strangeness, S	Charm, C	Bottomness, B'	Topness, T
$\boldsymbol{u}$	$\frac{2}{3}$	$\frac{1}{2}$	$\frac{1}{3}$	0	0	0	0
$\boldsymbol{d}$	$-\frac{1}{3}$	$\frac{1}{2}$	$\frac{1}{3}$	0	0	0	0
$\boldsymbol{s}$	$-\frac{1}{3}$	$\frac{1}{2}$	$\frac{1}{3}$	-1	0	0	0

44.10 Quark content of four different hadrons. The various colour combinations that are needed for colour neutrality are not shown.

Example 44.8 Determining the quark content of baryons

Given that they contain only $\boldsymbol{u}$, $\boldsymbol{d}$, $\boldsymbol{s}$, $\overline{\boldsymbol{u}}$, $\overline{\boldsymbol{d}}$ and/or $\overline{\boldsymbol{s}}$, find the quark content of (a) Σ^+ and (b) $\overline{\Lambda}^0$. The Σ^+ and Λ^0 particles are both baryons with strangeness $S = -1$.

SOLUTION

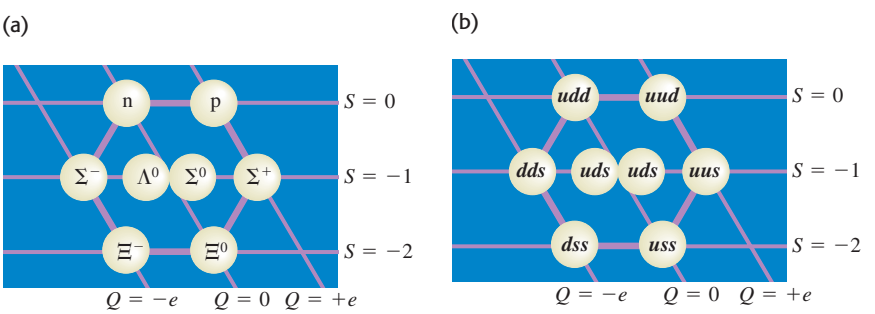
IDENTIFY: We use the idea that the total charge of each baryon is the sum of the individual quark charges, and similarly for the baryon number and strangeness.

SET UP: We use the quark properties given in Table 44.4

EXECUTE: Baryons contain three quarks; if $S = -1$, one and only one of the three must be an $\boldsymbol{s}$ quark.

(a) The Σ^+ has $Q/e = +1$, so the other two quarks must both be **u.** Hence the quark content of Σ^+ is $\boldsymbol{uus}$.

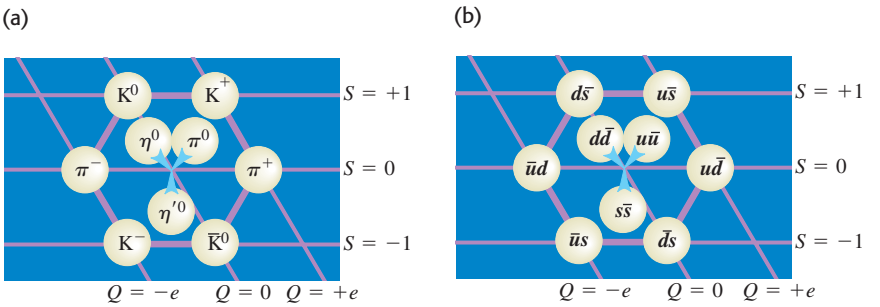
(b) First we find the quark content of the Λ^0. For zero total charge, the other two quarks must be $\boldsymbol{u}$ and $\boldsymbol{d}$, so the quark content of the Λ^0 is $\boldsymbol{uds}$. The $\overline{\Lambda}^0$ is the antiparticle of the Λ^0, so its quark content is $\overline{\boldsymbol{u}}\overline{\boldsymbol{d}}\overline{\boldsymbol{s}}$.



EVALUATE: Note that while the Λ^0 and $\overline{\Lambda}^0$ are both electrically neutral, and both have the same mass, they are different particles: Λ^0 has $B = 1$ and $S = -1$, while $\overline{\Lambda}^0$ has $B = -1$ and $S = 1$.

Motivating the Quark Model

What caused physicists to suspect that hadrons were made up of something smaller? The magnetic moment of the neutron (see Section 43.1) was one of the first reasons. In Section 27.7 we learned that a magnetic moment results from a circulating current (a motion of electric charge). But the neutron has *no* charge, or, to be more accurate, no *total* charge. It could be made up of smaller particles whose charges add to zero. The quantum motion of these particles within the neutron would then give its surprising nonzero magnetic moment. To verify this hypothesis by 'seeing' inside a neutron, we need a probe with a wavelength that is much less than the neutron's size of about a femtometer. This probe should not be affected by the strong interaction, so that it won't interact with the neutron as a whole but will penetrate into it and interact electromagnetically with these supposed smaller charged particles. A probe with these properties is an electron with energy above 10 GeV. In experiments carried out at SLAC, such electrons were scattered from neutrons and protons to help show that nucleons are indeed made up of fractionally charged, spin-$\frac{1}{2}$ pointlike particles.



The Eightfold Way

Symmetry considerations play a very prominent role in particle theory. Here are two examples. Consider the eight spin-$\frac{1}{2}$ baryons we've mentioned: the familiar p and n, the strange Λ^0, Σ^+, Σ^0, and Σ^-; and the doubly strange Ξ^0 and Ξ^-. For each we plot the value of strangeness S versus the value of charge Q in Fig. 44.11. The result is a hexagonal pattern. A similar plot for the nine spin-0 mesons (six shown in Table 44.3 plus three others not included in that table) is shown in Fig. 44.12 (next page); the particles fall in exactly the same hexagonal pattern! In each plot, all the particles have masses that are within about $\pm 200\ \text{MeV}/c^2$ of the median mass value of that plot, with variations due to differences in quark masses and internal potential energies.

44.11 (a) Plot of S and Q values for spin-$\frac{1}{2}$ baryons, showing the symmetry pattern of the eightfold way. (b) Quark content of each spin-$\frac{1}{2}$ baryon. The quark contents of the Σ^0 and Λ^0 are the same; the Σ^0 is an excited state of the Λ^0 and can decay into it by photon emission.

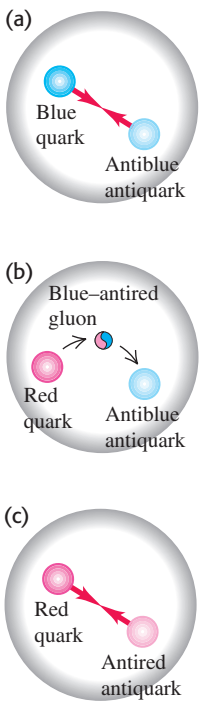
44.12 (a) Plot of S and Q values for nine spin-0 mesons, showing the symmetry pattern of the eightfold way. Each particle is on the opposite side of the hexagon from its antiparticle; each of the three particles in the centre is its own antiparticle. (b) Quark content of each spin-0 meson. The particles in the centre are different mixtures of the three quark–antiquark pairs shown.

The symmetries that lead to these and similar patterns are collectively called the **eightfold way**. They were discovered in 1961 by Murray Gell-Mann and independently by Yu'val Ne'eman. (The name is a slightly irreverent reference to the Noble Eightfold Path, a set of principles for right living in Buddhism.) A similar pattern for the spin-$\frac{3}{2}$ baryons contains *ten* particles, arranged in a triangular pattern like pins in a bowling alley. When this pattern was first discovered, one of the particles was missing. But Gell-Mann gave it a name anyway (Ω^-), predicted the properties it should have, and told experimenters what they should look for. Three years later, the particle was found during an experiment at Brookhaven National Laboratory, a spectacular success for Gell-Mann's theory. The whole series of events is reminiscent of the way in which Mendeleev used gaps in the periodic table of the elements to predict properties of undiscovered elements and to guide chemists in their search for these elements.



What binds quarks to one another? The attractive interactions among quarks are mediated by massless spin-1 bosons called **gluons** in much the same way that photons mediate the electromagnetic interaction or that pions mediated the nucleon–nucleon force in the old Yukawa theory.

Colour

Quarks, having spin $\frac{1}{2}$, are fermions and so are subject to the exclusion principle. This would seem to forbid a baryon having two or three quarks with the same flavor and same spin component. To avoid this difficulty, it is assumed that each quark comes in three varieties, which are whimsically called *colours*. Red, green and blue are the usual choices. The exclusion principle applies separately to each colour. A baryon always contains one red, one green and one blue quark, so the baryon itself has no net colour. Each gluon has a colour–anticolour combination (for example, blue–antired) that allows it to transmit colour when exchanged, and colour is conserved during emission and absorption of a gluon by a quark. The gluon-exchange process changes the colours of the quarks in such a way that there is always one quark of each colour in every baryon. The colour of an individual quark changes continually as gluons are exchanged.

Similar processes occur in mesons such as pions. The quark–antiquark pairs of mesons have canceling colour and anticolour (for example, blue and antiblue), so mesons also have no net colour. Suppose a pion initially consists of a blue quark and an antiblue antiquark. The blue quark can become a red quark by emitting a blue–antired virtual gluon. The gluon is then absorbed by the antiblue antiquark, converting it to an antired antiquark (Fig. 44.13). Colour is conserved in each emission and absorption, but a blue–antiblue pair has become a red–antired pair. Such changes occur continually, so we have to think of a pion as a superposition of three quantum states, blue–antiblue, green–antigreen and red–antired. On a larger scale, the strong interaction between nucleons was described in Section 44.3 as due to the exchange of virtual mesons. In terms of quarks and gluons, these mediating virtual mesons are quark–antiquark systems bound together by the exchange of gluons.

44.13 (a) A pion containing a blue quark and an antiblue antiquark. (b) The blue quark emits a blue–antired gluon, changing to a red quark. (c) The gluon is absorbed by the antiblue antiquark, which becomes an antired antiquark. The pion now consists of a red–antired quark–antiquark pair. The actual quantum state of the pion is an equal superposition of red–antired, green–antigreen and blue–antiblue pairs.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

The theory of strong interactions is known as *quantum chromodynamics* (QCD). No one has yet been able to isolate an individual quark for study. Most QCD theories contain phenomena associated with the binding of quarks that make it impossible to obtain a free quark. An impressive body of experimental evidence supports the correctness of the quark structure of hadrons and the belief that quantum chromodynamics is the key to understanding the strong interactions.

Three More Quarks

Before the tau particles were discovered, there were four known leptons. This fact, together with some puzzling decay rates, led to the speculation that there might be a fourth quark flavor. This quark is labelled $\boldsymbol{c}$ (the *charmed* quark); it has $Q/e = \frac{2}{3}$, $B = \frac{1}{3}$, $S = 0$, and a new quantum number **charm** $C = +1$. This was confirmed in 1974 by the observation at both SLAC and the Brookhaven National Laboratory of a meson, now named ψ, with mass 3097 MeV/c^2. This meson was found to have several decay modes, decaying into e^+e^-, $\mu^+\mu^-$, or hadrons. The mean lifetime was found to be about 10^{-20} s. These results are consistent with ψ being a spin-1 $\boldsymbol{c\bar{c}}$ system. Almost immediately after this, similar mesons of greater mass were observed and identified as excited states of the $\boldsymbol{c\bar{c}}$ system. A few years later, individual mesons with a nonzero net charm quantum number were also observed. These mesons, D^0 $(\boldsymbol{c\bar{u}})$ and D^+ $(\boldsymbol{c\bar{d}})$, and their excited states are now firmly established. A charmed baryon, Λ_c^+ $(\boldsymbol{udc})$, has also been observed.

In 1977 a meson with mass 9460 MeV/c^2, called upsilon (Υ), was discovered at Brookhaven. Because it had properties similar to ψ, it was conjectured that the meson was really the bound system of a new quark, $\boldsymbol{b}$ (the *bottom* quark), and its antiquark, $\boldsymbol{\bar{b}}$. The bottom quark has the value 1 of a new quantum number B' (not to be confused with baryon number B) called *bottomness*. Excited states of the Υ were soon observed, and the B^+ $(\boldsymbol{\bar{b}u})$ and B^0 $(\boldsymbol{\bar{b}d})$ mesons are now well established.

With five flavors of quarks ($\boldsymbol{u}$, $\boldsymbol{d}$, $\boldsymbol{s}$, $\boldsymbol{c}$ and $\boldsymbol{b}$) and the six flavors of leptons (e, μ, τ, ν_e, ν_μ and ν_τ) it was an appealing conjecture that nature is symmetrical in its building blocks and that therefore there should be a *sixth* quark. This quark, labelled $\boldsymbol{t}$ (top), would have $Q/e = \frac{2}{3}$, $B = \frac{1}{3}$, and a new quantum number, $T = 1$. In 1995, groups using two different detectors at Fermilab's Tevatron announced the discovery of the top quark. The groups collided 0.9 TeV protons with 0.9 TeV antiprotons, but even with 1.8 TeV of available energy, a top–antitop $(\boldsymbol{t\bar{t}})$ pair was detected in fewer than two of every 10^{11} collisions! Table 44.5 lists some properties of the six quarks. Each has a corresponding antiquark with opposite values of Q, B, S, C, B', and T.

Table 44.5 Properties of the Six Quarks

Symbol	Q/e	Spin	Baryon Number, B	Strangeness, S	Charm, C	Bottomness, B'	Topness, T
$\boldsymbol{u}$	$\frac{2}{3}$	$\frac{1}{2}$	$\frac{1}{3}$	0	0	0	0
$\boldsymbol{d}$	$-\frac{1}{3}$	$\frac{1}{2}$	$\frac{1}{3}$	0	0	0	0
$\boldsymbol{s}$	$-\frac{1}{3}$	$\frac{1}{2}$	$\frac{1}{3}$	-1	0	0	0
$\boldsymbol{c}$	$\frac{2}{3}$	$\frac{1}{2}$	$\frac{1}{3}$	0	$+1$	0	0
$\boldsymbol{b}$	$-\frac{1}{3}$	$\frac{1}{2}$	$\frac{1}{3}$	0	0	$+1$	0
$\boldsymbol{t}$	$\frac{2}{3}$	$\frac{1}{2}$	$\frac{1}{3}$	0	0	0	$+1$

Test Your Understanding of Section 44.4 Is it possible to have a baryon with charge $Q = +e$ and strangeness $S = -2$?

44.5 The Standard Model and Beyond

The particles and interactions that we've discussed in this chapter provide a reasonably comprehensive picture of the fundamental building blocks of nature. There is enough confidence in the basic correctness of this picture that it is called the **standard model**.

The standard model includes three families of particles: (1) the six leptons, which have no strong interactions; (2) the six quarks, from which all hadrons are made; and (3) the particles that mediate the various interactions. These mediators are gluons for the strong interaction among quarks, photons for the electromagnetic interaction, the $W^{\pm}$ and Z^0 particles for the weak interaction and the graviton for the gravitational interaction.

Electroweak Unification

Theoretical physicists have long dreamed of combining all the interactions of nature into a single unified theory. As a first step, Einstein spent much of his later life trying to develop a field theory that would unify gravitation and electromagnetism. He was only partly successful.

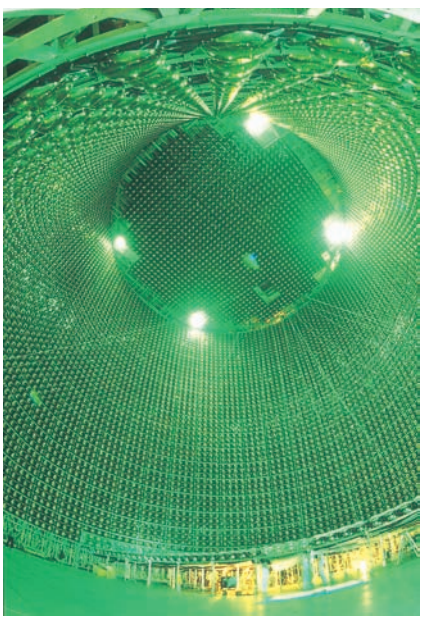
Between 1961 and 1967, Sheldon Glashow, Abdus Salam and Steven Weinberg developed a theory that unifies the weak and electromagnetic forces. One outcome of their **electroweak theory** is a prediction of the weak-force mediator particles, the Z^0 and $W^{\pm}$ bosons, including their masses. The basic idea is that the mass difference between photons (zero mass) and the weak bosons $(\approx 100\ \text{GeV}/c^2)$ makes the electromagnetic and weak interactions behave quite differently at low energies. At sufficiently high energies (well above 100 GeV), however, the distinction disappears, and the two merge into a single interaction. This prediction was verified experimentally in 1983 by two experimental groups working at the $p\bar{p}$ collider at CERN, as was mentioned in Section 44.3. The weak bosons were found, again with the help provided by the theoretical description, and their observed masses agreed with the predictions of the electroweak theory, a wonderful convergence of theory and experiment. The electroweak theory and quantum chromodynamics form the backbone of the standard model. Glashow, Salam and Weinberg received the Nobel Prize in 1979.

A remaining difficulty in the electroweak theory is that photons are massless but the weak bosons are very massive. To account for the broken symmetry among these interaction mediators, a particle called the Higgs boson has been proposed. Its mass is expected to be less than $1\ \text{TeV}/c^2$, but to produce it in the laboratory may require a much greater available energy. The search for the Higgs particle (or particles) will be part of the mission of the Large Hadron Collider at CERN.

Grand Unified Theories

Perhaps at sufficiently high energies the strong interaction and the electroweak interaction have a convergence similar to that between the electromagnetic and weak interactions. If so, they can be unified to give a comprehensive theory of strong, weak and electromagnetic interactions. Such schemes, called **grand unified theories** (GUTs), lean heavily on symmetry considerations, and they are still speculative.

One interesting feature of some grand unified theories is that they predict the decay of the proton (in violation of conservation of baryon number), with an estimated lifetime of more than 10^{28} years. (For comparison the age of the universe is estimated to be of the order of 10^{10} years.) With a lifetime of 10^{28} years, six metric tons of protons would be expected to have only one decay per day, so huge



Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

amounts of material must be examined. Some of the neutrino detectors that we mentioned in Section 44.2 originally looked for, and failed to find, evidence of proton decay. Nevertheless, experimental work continues, with current estimates setting the proton lifetime well over 10^{30} years. Some GUTs also predict the existence of magnetic monopoles, which we mentioned in Chapter 27. At present there is no confirmed experimental evidence that magnetic monopoles exist, but the search goes on.

In the standard model, the neutrinos have zero mass. Nonzero values are controversial because experiments to determine neutrino masses are difficult both to perform and to analyse. In most GUTs the neutrinos *must* have nonzero masses. If neutrinos do have mass, transitions called *neutrino oscillations* can occur, in which one type of neutrino (ν_e, ν_μ or ν_τ) changes into another type. In 1998, scientists using the Super-Kamiokande neutrino detector in Japan (Fig. 44.14) reported the discovery of oscillations between muon neutrinos and tau neutrinos. Subsequent measurements at the Sudbury Neutrino Observatory in Canada have confirmed the existence of neutrino oscillations. This discovery is the first evidence for exciting new physics beyond that predicted by the standard model.

The discovery of neutrino oscillations has cleared up a long-standing mystery about the sun. Since the 1960s, physicists have been using sensitive detectors to look for electron neutrinos produced by nuclear fusion reactions in the sun's core (see Section 43.8). However, the observed flux of solar electron neutrinos is only one-third of the predicted value. The resolution of this mystery was provided in 2002 by physicists using the Sudbury Neutrino Observatory, which can detect neutrinos of all three flavors. The results showed that the combined flux of solar neutrinos of *all* flavors is equal to the theoretical prediction for the flux of *electron* neutrinos. The explanation is that the sun is indeed producing electron neutrinos at the rate predicted by theory, but that two-thirds of these electron neutrinos are transformed into muon or tau neutrinos during their flight from the sun's core to a detector on earth.

44.14 This photo shows the interior of the Super-Kamiokande neutrino detector in Japan. When in operation, the detector is filled with 5×10^7 kg of water. A neutrino passing through the detector can produce a faint flash of light, which is detected by the 13 000 photomultiplier tubes lining the detector walls. Data from this detector were the first to indicate that neutrinos have mass.

Supersymmetric Theories and TOEs

The ultimate dream of theorists is to unify all four fundamental interactions, adding gravitation to the strong and electroweak interactions that are included in GUTs. Such a unified theory is whimsically called a Theory of Everything (TOE). It turns out that an essential ingredient of such theories is a space-time continuum with more than four dimensions. The additional dimensions are 'rolled up' into extremely tiny structures that we ordinarily do not notice. Depending on the scale of these structures, it may be possible for the next generation of particle accelerators to reveal the presence of extra dimensions.

Another ingredient of many theories is *supersymmetry*, which gives every boson and fermion a 'superpartner' of the other spin type. For example, the proposed supersymmetric partner of the spin-$\frac{1}{2}$ electron is a spin-0 particle called the *selectron*, and that of the spin-1 photon is a spin-$\frac{1}{2}$ *photino*. As yet, no superpartner particles have been discovered, perhaps because they are too massive to be produced by the present generation of accelerators. Within a few years, new data from the Large Hadron Collider and other proposed accelerators will help us decide whether these intriguing theories have merit or whether nature is even more exotic than we imagine.

Test Your Understanding of Section 44.5 One aspect of the standard model is that a ***d*** quark can transform into a ***u*** quark, an electron, and an antineutrino by means of the weak interaction. If this happens to a ***d*** quark inside a neutron, what kind of particle remains afterward in addition to the electron and antineutrino? (i) a proton; (ii) a Σ^-; (iii) a Σ^+; (iv) a Λ^0 or a Σ^0; (v) any of these.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

44.6 The Expanding Universe

In the last two sections of this chapter we'll explore briefly the connections between the early history of the universe and the interactions of fundamental particles. It is remarkable that there are such close ties between physics on the smallest scale that we've explored experimentally (the range of the weak interaction, of the order of 10^{-18} m) and physics on the largest scale (the universe itself, of the order of at least 10^{26} m).

Gravitational interactions play an essential role in the large-scale behaviour of the universe. One of the great achievements of Newtonian mechanics, including the law of gravitation, was the understanding it brought to the motion of planets in the solar system. Astronomical evidence, such as observations of the motions of binary stars around their common centre of mass, shows that gravitational interactions also operate in larger astronomical systems, including stars, galaxies and nebulae.

Until early in the 20th century it was usually assumed that the universe was *static*; stars might move relative to each other, but there was not thought to be any overall expansion or contraction. But stars have gravitational attractions. If everything is initially sitting still in the universe, why doesn't gravity just pull it all together into one big clump? Newton himself recognised the seriousness of this troubling question.

Measurements that were begun in 1912 by Vesto Slipher at Lowell Observatory in Arizona, and continued in the 1920s by Edwin Hubble with the help of Milton Humason at Mount Wilson in California, indicated that the universe is *not* static. The motions of galaxies relative to the earth can be measured by observing the shifts in the wavelengths of their spectra. For distant galaxies these shifts are always towards longer wavelength, so they appear to be receding from us and from each other. Astronomers first assumed that these were Doppler shifts and used a relationship between the wavelength λ_0 of light measured now from a source receding at speed v and the wavelength λ_S measured in the rest frame of the source when it was emitted. We can derive this relationship by inverting Eq. (37.25) for the Doppler effect, making subscript changes and using $\lambda = c/f$; the result is

$$\lambda_0 = \lambda_S \sqrt{\frac{c+v}{c-v}} \tag{44.13}$$

Wavelengths from receding sources are always shifted towards longer wavelengths; this increase in λ is called the **redshift**. We can solve Eq. (44.13) for v; the result is

$$v = \frac{(\lambda_0/\lambda_S)^2 - 1}{(\lambda_0/\lambda_S)^2 + 1} c \tag{44.14}$$

CAUTION **Redshift, not Doppler shift** Equations (44.13) and (44.14) are from the *special* theory of relativity and refer to the Doppler effect. As we'll see, the redshift from *distant* galaxies is caused by an effect that is explained by the *general* theory of relativity and is *not* a Doppler shift. However, as the ratio v/c and the fractional wavelength change $(\lambda_0 - \lambda_S)/\lambda_S$ become small, the general theory's equations approach Eqs. (44.13) and (44.14), and those equations may be used.

Example 44.9 Recession speed of a galaxy

The spectral lines of various elements are detected in light from a galaxy in the constellation Ursa Major. An ultraviolet line from singly ionised calcium ($\lambda_S = 393$ nm) is observed with a wavelength $\lambda_0 = 414$ nm, redshifted into the visible portion of the spectrum. At what speed is this galaxy receding from the earth?

SOLUTION

IDENTIFY: This example uses the relationship between redshift and speed of recession for a distant galaxy.

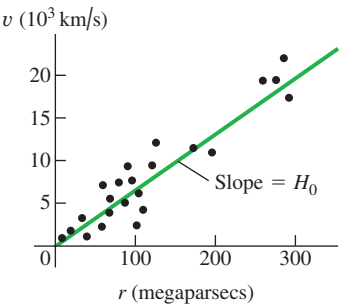
Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

SET UP: We are given the wavelength at which the light is emitted and the wavelength that we detect on earth. We use these in Eq. (44.14) to determine the recession speed v of the galaxy, provided the fractional wavelength shift is not too great.

EXECUTE: First we calculate $\lambda_0/\lambda_S = (414\text{ nm})/(393\text{ nm}) = 1.053$. This is only a 5.3% increase, so we can use Eq. (44.14) with reasonable accuracy:

$$v = \frac{(1.053)^2 - 1}{(1.053)^2 + 1}c = 0.0516c = 1.55 \times 10^7\text{ m/s}$$

EVALUATE: The galaxy is receding from the earth at 5.16% of the speed of light. Note that rather than doing this calculation, astronomers often simply state the recession speed in terms of the *redshift*, defined as $z = (\lambda_0 - \lambda_S)/\lambda_S = (\lambda_0/\lambda_S) - 1$. Thus this galaxy has redshift $z = 0.053$.



The Hubble Law

Analysis of redshifts from many distant galaxies led Edwin Hubble to a remarkable conclusion: The speed of recession v of a galaxy is proportional to its distance r from us (Fig. 44.15). This relationship is now called the **Hubble law**; its symbolic statement is

$$v = H_0 r \tag{44.15}$$

where H_0 is an experimental quantity commonly called the *Hubble constant*, since at any given time it is constant over space. Determining H_0 has been a key goal of the Hubble Space Telescope, which can measure distances to galaxies with unprecedented accuracy. The current best value is $2.3 \times 10^{-18}\text{ s}^{-1}$, with an uncertainty of 5%.

44.15 Graph of recession speed versus distance for several galaxies. The best-fit straight line illustrates Hubble's law. The slope of the line is the Hubble constant, H_0.

Astronomical distances are often measured in *parsecs* (pc); one parsec is the distance at which there is a one-arcsecond $(1/3600°)$ angular separation between two objects 1.50×10^{11} m apart (the average distance from the earth to the sun). A distance of 1 pc is equal to 3.26 *light-years* (ly), where 1 ly $= 9.46 \times 10^{15}$ m is the distance that light travels in one year. The Hubble constant is then commonly expressed in the mixed units (km/s)/Mpc (kilometres per second per megaparsec), where 1 Mpc $= 10^6$ pc:

$$H_0 = (2.3 \times 10^{-18}\text{ s}^{-1})\left(\frac{9.46 \times 10^{15}\text{ km}}{1\text{ ly}}\right)\left(\frac{3.26\text{ ly}}{1\text{ pc}}\right)\left(\frac{10^6\text{ pc}}{1\text{ Mpc}}\right) = 71\frac{\text{km/s}}{\text{Mpc}}$$

Example 44.10 Determining distance with the Hubble law

Find the distance from earth to the galaxy in Example 44.9, according to the Hubble law.

SOLUTION

IDENTIFY: The Hubble law relates the redshift of a distant galaxy to its distance from earth.

SET UP: We solve Eq. (44.15) for the distance r and then substitute the value of the recession speed v from Example 44.9.

EXECUTE: Using $H_0 = 71\text{ (km/s)/Mpc} = 7.1 \times 10^4\text{ (m/s)/Mpc}$,

$$r = \frac{v}{H_0} = \frac{1.55 \times 10^7\text{ m/s}}{7.1 \times 10^4\text{ (m/s)/Mpc}}$$
$$= 220\text{ Mpc} = 2.2 \times 10^8\text{ pc} = 7.1 \times 10^8\text{ ly} = 6.7 \times 10^{24}\text{ m}$$

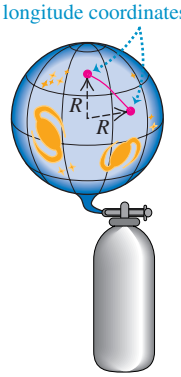
EVALUATE: A distance of 220 million parsecs (710 million light-years) is truly stupendous, but many galaxies lie much farther away. In contrast, the closest known galaxy to ours is the Sagittarius Dwarf, only 80 000 light-years from us—so close that it is held in gravitational orbit around our galaxy. To appreciate the immensity of even this relatively small distance, consider that our farthest-ranging unmanned spacecraft have travelled only about 0.001 ly from our planet.

Another aspect of Hubble's observations was that, *in all directions*, distant galaxies appeared to be receding from us. There is no particular reason to think that our galaxy is at the very centre of the universe; if we lived in some other galaxy, every distant galaxy would still seem to be moving away. That is, at any

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

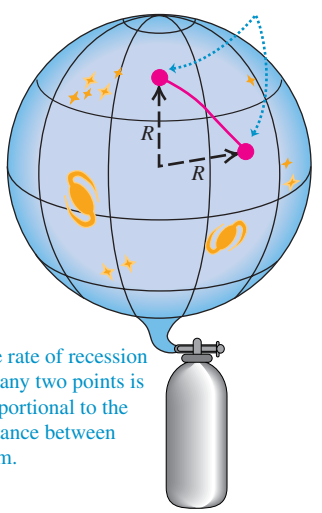
given time, *the universe looks more or less the same, no matter where in the universe we are*. This important idea is called the **cosmological principle**. There are local fluctuations in density, but on average, the universe looks the same from all locations. Thus the Hubble constant is constant in space although not necessarily constant in time, and the laws of physics are the same everywhere.

The Big Bang



The Hubble law suggests that at some time in the past, all the matter in the universe was far more concentrated than it is today. It was then blown apart in an immense explosion called the **Big Bang**, giving all observable matter more or less the velocities that we observe today. When did this happen? According to the Hubble law, matter at a distance r away from us is travelling with speed $v = H_0 r$. The time t needed to travel a distance r is

$$t = \frac{r}{v} = \frac{r}{H_0 r} = \frac{1}{H_0} = 4.3 \times 10^{17}\ \text{s} = 1.4 \times 10^{10}\ \text{y}$$



By this hypothesis the Big Bang occurred about 14 billion years ago. It assumes that all speeds are *constant* after the Big Bang; that is, it neglects any change in the expansion rate due to gravitational attraction or other effects. We'll return to this point later. For now, however, notice that the age of the earth determined from radioactive dating (see Section 43.4) is 4.6 billion (4.6×10^9) years. It's encouraging that our simple hypothesis tells us that the universe is older than the earth!

44.16 An inflating balloon as an analogy for an expanding universe.

(a) Points (representing galaxies) on the surface of a balloon are described by their latitude and longitude coordinates.

(b) The radius R of the balloon has increased. The coordinates of the points are the same, but the distance between them has increased.

The rate of recession for any two points is proportional to the distance between them.

Expanding Space

The general theory of relativity takes a radically different view of the expansion just described. According to this theory, the increased wavelength is *not* caused by a Doppler shift as the universe expands into a previously empty void. Rather, the increase comes from *the expansion of space itself* and everything in intergalactic space, including the wavelengths of light travelling to us from distant sources. This is not an easy concept to grasp, and if you haven't encountered it before, it may sound like doubletalk.

Here's an analogy that may help to develop some intuition on this point. Imagine we are all bugs crawling around on a horizontal surface. We can't leave the surface, and we can see in any direction along the surface, but not up or down. We are then living in a two-dimensional world; some writers have called such a world *flatland*. If the surface is a plane, we can locate our position with two Cartesian coordinates (x, y). If the plane extends indefinitely in both the x- and y-directions, we described our space as having *infinite* extent, or as being *unbounded*. No matter how far we go, we never reach an edge or a boundary.

An alternative habitat for us bugs would be the surface of a sphere with radius R. The space would still seem infinite in the sense that we could crawl forever and never reach an edge or a boundary. Yet in this case the space is *finite* or *bounded*. To describe the location of a point in this space, we could still use two coordinates: latitude and longitude, or the spherical coordinates θ and ϕ shown in Fig. 40.23.

Now suppose the spherical surface is that of a balloon (Fig. 44.16). As we inflate the balloon more and more, increasing the radius R, the coordinates of a point don't change, yet the distance between any two points gets larger and larger. Furthermore, as R increases, the *rate of change* of distance between two points (their recession speed) is proportional to their distance apart. *The recession speed is proportional to the distance*, just as with the Hubble law.

We see that although the quantity R isn't one of the two coordinates giving the position of a point on the balloon's surface, it nevertheless plays an essential role

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

in any discussion of distance. It is the radius of curvature of our two-dimensional space, and it is also a varying *scale factor* that changes as this two-dimensional universe expands.

Generalising this picture to three dimensions isn't so easy. We have to think of our three-dimensional space as being embedded in a space with four or more dimensions, just as we visualised the two-dimensional spherical flatland as being embedded in a three-dimensional Cartesian space. Our real three-space is *not Cartesian*; to describe its characteristics in any small region requires at least one additional parameter, the curvature of space, which is analogous to the radius of the sphere. In a sense, this scale factor, which we'll continue to call R, describes the *size* of the universe, just as the radius of the sphere described the size of our two-dimensional spherical universe. We'll return later to the question of whether the universe is bounded or unbounded.

Any length that is measured in intergalactic space is proportional to R, so the wavelength of light travelling to us from a distant galaxy increases along with every other dimension as the universe expands. That is,

$$\frac{\lambda_0}{\lambda} = \frac{R_0}{R} \tag{44.16}$$

The zero subscripts refer to the values of the wavelength and scale factor *now*, just as H_0 is the current value of the Hubble constant. The quantities λ and R without subscripts are the values at *any* time, past, present, or future. In the situation described in Example 44.9, we have $\lambda_0 = 414$ nm and $\lambda = \lambda_S = 393$ nm, so Eq. (44.16) gives $R_0/R = 1.053$. That is, the scale factor *now* (R_0) is 5.3% larger than it was 710 million years ago when the light was emitted from that galaxy in Ursa Major. This increase of wavelength with time as the scale factor increases in our expanding universe is called the *cosmological redshift*. The farther away an object is, the longer its light takes to get to us and the greater the change in R and λ. The current largest measured wavelength ratio for galaxies is about 7, meaning that the volume of space itself is about $7^3 \approx 340$ times larger than it was when the light was emitted. Do *not* attempt to substitute $\lambda_0/\lambda_S = 7$ into Eq. (44.14) to find the recession speed; that equation is accurate only for small cosmological redshifts and $v \ll c$. The actual value of v depends on the density of the universe, the value of H_0, and the expansion history of the universe.

Here's a surprise for you: If the distance from us in the Hubble law is large enough, then the speed of recession will be greater than the speed of light! This does *not* violate the special theory of relativity because the recession speed is *not* caused by the motion of the astronomical object relative to some coordinates in its region of space. Rather, we can have $v > c$ when two sets of coordinates move apart fast enough as space itself expands. In other words, there are objects whose coordinates have been moving away from our coordinates so fast that light from them hasn't had enough time in the entire history of the universe to reach us. What we see is just the *observable* universe; we have no direct evidence about what lies beyond its horizon.

CAUTION **The universe isn't expanding into emptiness** The balloon shown in Fig. 44.16 is expanding into the empty space around it. It's a common misconception to picture the universe in the same way as a large but finite collection of galaxies that's expanding into unoccupied space. The reality is quite different! All the accumulated evidence shows that our universe is *infinite*: It has no edges, so there is nothing 'outside' it and it isn't 'expanding into' anything. The expansion of the universe simply means that the scale factor of the universe is increasing. A good two-dimensional analogy is to think of the universe as a flat, infinitely large rubber sheet that's stretching and expanding much like the surface of the balloon in Fig. 44.16. In a sense, the infinite universe is simply becoming more infinite!

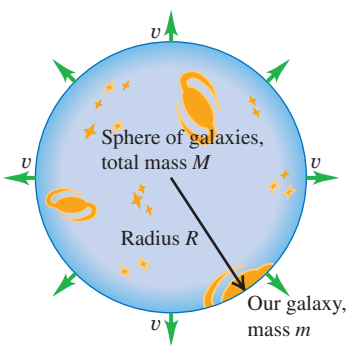
Critical Density

We've mentioned that the law of gravitation isn't consistent with a static universe. We need to look at the role of gravity in an *expanding* universe. Gravitational attractions should slow the initial expansion, but by how much? If these attractions are strong enough, the universe should expand more and more slowly, eventually stop, and then begin to contract, perhaps all the way down to what's been called a *Big Crunch*. On the other hand, if gravitational forces are much weaker, they slow the expansion only a little, and the universe should continue to expand forever.

The situation is analogous to the problem of escape speed of a projectile launched from the earth. We studied this problem in Example 12.5 (Section 12.3); now would be an excellent time to review that discussion. The total energy $E = K + U$ when a projectile of mass m and speed v is at a distance r from the centre of the earth (mass m_E) is



$$E = \frac{1}{2}mv^2 - \frac{Gmm_E}{r}$$

If E is positive, the projectile has enough kinetic energy to move infinitely far from the earth $(r \to \infty)$ and have some kinetic energy left over. If E is negative, the kinetic energy $K = \frac{1}{2}mv^2$ becomes zero and the projectile stops when $r = -Gmm_E/E$. In that case, no greater value of r is possible, and the projectile can't escape the earth's gravity.

We can carry out a similar analysis for the universe. Whether the universe continues to expand indefinitely should depend on the average *density* of matter. If matter is relatively dense, there is a lot of gravitational attraction to slow and eventually stop the expansion and make the universe contract again. If not, the expansion should continue indefinitely. We can derive an expression for the *critical density* ρ_c needed to just barely stop the expansion.

Here's a calculation based on Newtonian mechanics; it isn't relativistically correct, but it illustrates the idea. Consider a large sphere with radius R, containing many galaxies (Fig. 44.17), with total mass M. Suppose our own galaxy has mass m and is located at the surface of this sphere. According to the cosmological principle, the average distribution of matter within the sphere is uniform. The total gravitational force on our galaxy is just the force due to the mass M inside the sphere. The force on our galaxy and potential energy U due to this spherically symmetric distribution are the same as though m and M were both points, so $U = -GmM/R$, just as in Section 12.3. The net force from all the uniform distribution of mass *outside* the sphere is zero, so we'll ignore it.

44.17 An imaginary sphere of galaxies. The net gravitational force exerted on our galaxy (at the surface of the sphere) by the other galaxies is the same as if all of their mass were concentrated at the centre of the sphere. (Since the universe is infinite, there's also an infinity of galaxies outside this sphere.)

The total energy E (kinetic plus potential) for our galaxy is

$$E = \frac{1}{2}mv^2 - \frac{GmM}{R} \qquad (44.17)$$

If E is *positive*, our galaxy has enough energy to escape from the gravitational attraction of the mass M inside the sphere; in this case the universe should keep expanding forever. If E is negative, our galaxy cannot escape and the universe should eventually pull back together. The crossover between these two cases occurs when $E = 0$, so that

$$\frac{1}{2}mv^2 = \frac{GmM}{R} \qquad (44.18)$$

The total mass M inside the sphere is the volume $4\pi R^3/3$ times the density ρ_c:

$$M = \frac{4}{3}\pi R^3 \rho_c$$

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

We'll assume that the speed v of our galaxy relative to the centre of the sphere is given by the Hubble law: $v = H_0R$. Substituting these expressions for M and v into Eq. (44.18), we get

$$\frac{1}{2}m(H_0R)^2 = \frac{Gm}{R}\left(\frac{4}{3}\pi R^3\rho_c\right) \qquad \text{or}$$

$$\rho_c = \frac{3H_0^2}{8\pi G} \qquad \text{(critical density of the universe)} \tag{44.19}$$

This is the *critical density*. If the average density is less than ρ_c, the universe should continue to expand indefinitely; if it is greater, the universe should eventually stop expanding and begin to contract.

Putting numbers into Eq. (44.19), we find

$$\rho_c = \frac{3(2.3 \times 10^{-18}\ \text{s}^{-1})^2}{8\pi(6.67 \times 10^{-11}\ \text{kg} \cdot \text{m}^2/\text{s}^2)} = 6.3 \times 10^{-27}\ \text{kg/m}^3$$

The mass of a hydrogen atom is 1.67×10^{-27} kg, so this density is equivalent to about four hydrogen atoms per cubic metre.

Dark Matter, Dark Energy and the Accelerating Universe

Astronomers have made extensive studies of the average density of matter in the universe. One way to do so is to count the number of galaxies in a patch of sky. Based on the mass of an average star and the number of stars in an average galaxy, this effort gives an estimate of the average density of *luminous* matter in the universe—that is, matter that emits electromagnetic radiation. (You are made of luminous matter because you emit infrared radiation as a consequence of your temperature; see Sections 17.7 and 38.8.) It's also necessary to take into account other luminous matter within a galaxy, including the tenuous gas and dust between the stars.

Another technique is to study the motions of galaxies within clusters of galaxies (Fig. 44.18). The motions are so slow that we can't actually see galaxies changing positions within a cluster. However, observations show that different galaxies within a cluster have somewhat different redshifts, which indicates that the galaxies are moving relative to the centre of mass of the cluster. The speeds of these motions are related to the gravitational force exerted on each galaxy by the other members of the cluster, which in turn depends on the total mass of the cluster. By measuring these speeds, astronomers can determine the average density of *all* kinds of matter within the cluster, whether or not the matter emits electromagnetic radiation.

Observations using these and other techniques show that the average density of *all* matter in the universe is 26% of the critical density, but the average density of *luminous* matter is only 4% of the critical density. In other words, most of the matter in the universe is not luminous: it does not emit electromagnetic radiation of *any* kind. At present, the nature of this **dark matter** remains an outstanding mystery. Some proposed candidates for dark matter are WIMPs (weakly interacting massive particles, which are hypothetical subatomic particles far more massive than those produced in accelerator experiments) and MACHOs (massive compact halo objects, which include objects such as black holes that might form 'halos' around galaxies). Whatever the true nature of dark matter, it is by far the dominant form of matter in the universe. For every kilogram of the ordinary matter that has been our subject for most of this book—including electrons, protons, atoms, molecules, blocks on inclined planes, planets and stars—there are *five and a half* kilograms of dark matter.

Since the average density of matter in the universe is less than the critical density, it might seem fair to conclude that the universe will continue to expand indefinitely, and that gravitational attraction between matter in different parts of

44.18 The bright spots in this image are not stars, but entire galaxies. They are part of a cluster of galaxies about 1000 Mpc (330 Mly) away. When the galaxies emitted the light used to make this image, the scale factor of the universe was about 25% smaller than it is now. Dr Brian Schmidt from the Australian National University was the leader of the team that discovered that the universe is accelerating.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

the universe should slow the expansion down (albeit not enough to stop it). One way to test this prediction is to examine the redshifts of extremely distant objects. When astronomers look at a galaxy 10^9 light-years away, the light they receive has been in transit for 10^9 years, so they are seeing 10^9 years into the past. If the expansion of the universe has been slowing down, the expansion must have been more rapid in the distant past. Thus we would expect very distant galaxies to have *greater* redshifts than predicted by the Hubble law, Eq. (44.15).

Only since the 1990s has it become possible to accurately measure both the distances and the redshifts of extremely distant galaxies. The results have been totally surprising: Very distant galaxies actually have *smaller* redshifts than predicted by the Hubble law! The implication is that the expansion of the universe was slower in the past than it is now, so the expansion has been *speeding up* rather than slowing down.

If gravitational attraction should make the expansion slow down, why is it speeding up instead? The explanation generally accepted by astronomers and physicists is that space is suffused with a kind of energy that has no gravitational effect and emits no electromagnetic radiation, but rather acts as a kind of 'antigravity' that produces a universal *repulsion*. This invisible, immaterial energy is called **dark energy**. As the name suggests, the nature of dark energy is poorly understood but is the subject of very active research.

Observations show that the *energy* density of dark energy (measured in, say, joules per cubic metre) is 74% of the critical density times c^2; that is, it is equal to $0.74\rho_c c^2$. As described above, the average density of matter of all kinds is 26% of the critical density. From the Einstein relationship $E = mc^2$, the average *energy* density of matter in the universe is therefore $0.26\rho_c c^2$. Because the energy density of dark energy is nearly three times greater than that of matter, the expansion of the universe will continue to accelerate. This expansion will never stop, and the universe will never contract.

If we account for energy of *all* kinds, the average energy density of the universe is equal to $0.74\rho_c c^2 + 0.26\rho_c c^2 = 1.00\rho_c c^2$. Of this, 74% is the mysterious dark energy, 22% is the no less mysterious dark matter, and a mere 4% is the well-understood ordinary matter. How little we know about the contents of our universe!

What is the significance of the result that within observational error, the average energy density of the universe is equal to $\rho_c c^2$? It tells us that the universe is infinite and unbounded, but just barely so. If the average energy density were even slightly larger than $\rho_c c^2$, the universe would be finite like the surface of the balloon depicted in Fig. 44.16. As of this writing, the observational error in the average energy density is still large enough that we can't be totally sure that the universe *is* unbounded. Improving these measurements will be an important task for physicists and astronomers in the years ahead.

Test Your Understanding of Section 44.6 Is it accurate to say that your body is made of 'ordinary' matter?

FRONTIERS OF RESEARCH

BRIAN SCHMIDT
Australian National University

A Fellow of the Australian Academy of Science and the United States National Academy of Science, Dr Brian Schmidt was the leader of the famous High-Z SN search that discovered that the universe was accelerating. The discovery was named *Science* magazine's Breakthrough of the Year for 1998. Dr Schmidt is continuing his research into exploding stars and is the leader of the team that built the Skymapper telescope at the Australian National University's Siding Spring Observatories. The telescope is among the first of a new breed of surveying telescopes and it will provide a deep digital map of the southern sky. This will allow astronomers to make a detailed study of nearby objects, such as asteroids in our solar system, to the most distant objects in the universe, called quasars. The data from the telescope will be shared with astronomers world wide through the Virtual Observatory initiative.

44.7 The Beginning of Time

What an odd title for the very last section of a book! We will describe in general terms some of the current theories about the very early history of the universe and their relationship to fundamental particle interactions. We'll find that an

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

astonishing amount happened in the very first second. A lot of loose ends will be left untied, and many questions will be left unanswered. This is, after all, one of the frontiers of theoretical physics and continually brings new theories, new discoveries and new questions.

Temperatures

The early universe was extremely dense and extremely hot, and the average particle energies were extremely large, all many orders of magnitude beyond anything that exists in the present universe. We can compare particle energy E and absolute temperature T using the equipartition principle (see Section 18.4):

$$E = \frac{3}{2}kT \tag{44.20}$$

In this equation k is Boltzmann's constant, which we'll often express in eV/K:

$$k = 8.617 \times 10^{-5}\,\text{eV}/\text{K}$$

Thus we can replace Eq. (44.20) by $E \approx (10^{-4}\,\text{eV}/\text{K})T = (10^{-13}\,\text{GeV}/\text{K})T$ when we're discussing orders of magnitude.

Example 44.11 Temperature and energy

(a) What is the average kinetic energy in electron volts of particles at room temperature $(T = 290\,\text{K})$ and at the surface of the sun $(T = 5800\,\text{K})$? (b) What approximate temperature corresponds to the ionisation energy of the hydrogen atom, to the rest energy of the electron, and to the rest energy of the proton?

SOLUTION

IDENTIFY: In this example we are asked to apply the equipartition principle.

SET UP: We use Eq. (44.20) in each part to determine the target variable T.

EXECUTE: (a) From Eq. (44.20),

$$E = \frac{3}{2}kT = \frac{3}{2}(8.617 \times 10^{-5}\,\text{eV}/\text{K})(290\,\text{K}) = 0.0375\,\text{eV}$$

The temperature at the sun's surface is higher by a factor of $(5800\,\text{K})/(290\,\text{K}) = 20$, so the average kinetic energy there is $20(0.0375\,\text{eV}) = 0.75\,\text{eV}$.

(b) The ionisation energy of hydrogen is 13.6 eV. Using the approximation $E \approx (10^{-4}\,\text{eV}/\text{K})T$, we have

$$T \approx \frac{E}{10^{-4}\,\text{eV}/\text{K}} = \frac{13.6\,\text{eV}}{10^{-4}\,\text{eV}/\text{K}} \approx 10^5\,\text{K}$$

The rest energies of the electron and proton are 0.511 MeV and 938 MeV, respectively. Repeating the calculation for these values gives temperatures of $10^{10}\,\text{K}$, corresponding to the electron rest energy, and $10^{13}\,\text{K}$, corresponding to the proton rest energy.

EVALUATE: Temperatures in excess of $10^5\,\text{K}$ are found in the interior of the sun, so the hydrogen there is predominantly ionised. Temperatures of $10^{10}\,\text{K}$ or $10^{13}\,\text{K}$ are not found anywhere in the solar system; as we will see, temperatures were this high in the very early universe.

Uncoupling of Interactions

The evolution of the universe has been characterised by a continual increase of the scale factor R, which we can think of very roughly as characterising the *size* of the universe, and by a corresponding decrease in average density. As the total gravitational potential energy increased during expansion, there were corresponding *decreases* in temperature and average particle energy. As this happened, the basic interactions became progressively uncoupled.

To understand the uncouplings, recall that the unification of the electromagnetic and weak interactions occurs at energies that are large enough that the differences in mass among the various spin-1 bosons that mediate the interactions become insignificant by comparison. The electromagnetic interaction is mediated by the massless photon, and the weak interaction is mediated by the weak bosons $W^{\pm}$ and Z^0 with masses of the order of $100\,\text{GeV}/c^2$. At energies much *less* than 100 GeV the two interactions seem quite different, but at energies much *greater* than 100 GeV they become part of a single interaction.

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

The grand unified theories (GUTs) provide a similar behaviour for the strong interaction. It becomes unified with the electroweak interaction at energies of the order of 10^{14} GeV, but at lower energies the two appear quite distinct. One of the reasons GUTs are still very speculative is that there is no way to do controlled experiments in this energy range, which is larger by a factor of 10^{11} than energies available with any current accelerator.

Finally, at sufficiently high energies and short distances, it is assumed that gravitation becomes unified with the other three interactions. The distance at which this happens is thought to be of the order of 10^{-35} m. This distance, called the *Planck length* l_P, is determined by the speed of light c and the fundamental constants of quantum mechanics and gravitation, h and G, respectively. The Planck length l_P is defined as

$$l_P = \sqrt{\frac{\hbar G}{c^3}} = 1.616 \times 10^{-35}\ \text{m} \tag{44.21}$$

You should verify that this combination of constants does indeed have units of length. The *Planck time* $t_P = l_P/c$ is the time required for light to travel a distance l_P:

$$t_P = \frac{l_p}{c} = \sqrt{\frac{\hbar G}{c^5}} = 0.539 \times 10^{-43}\ \text{s} \tag{44.22}$$

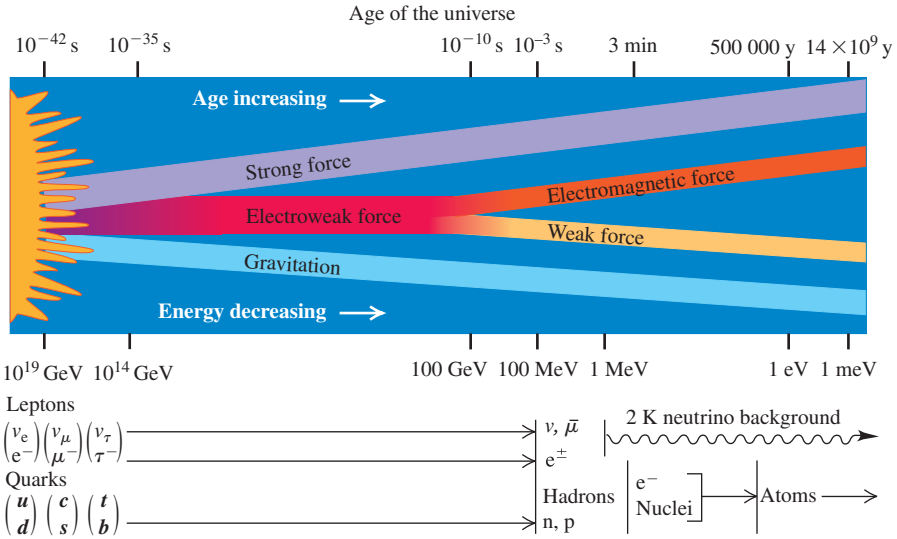
If we mentally go backward in time, we have to stop when we reach $t = 10^{-43}$ s because we have no adequate theory that unifies all four interactions. So as yet we have no way of knowing what happened or how the universe behaved at times earlier than the Planck time or when its size was less than the Planck length.

The Standard Model of the History of the Universe

The description that follows is called the *standard model* of the history of the universe. The title may be slightly optimistic, but it does indicate that there are substantial areas of theory that rest on solid experimental foundations and are quite generally accepted. The figure on pages 1498–1499 is a graphical description of this history, with the characteristic sizes, particle energies and temperatures at various times. Referring to this chart frequently will help you to understand the following discussion.

In this standard model, the temperature of the universe at time $t = 10^{-43}$ s (the Planck time) was about 10^{32} K, and the average energy per particle was approximately

$$E \approx (10^{-13}\ \text{GeV/K})(10^{32}\ \text{K}) = 10^{19}\ \text{GeV}$$



In a totally unified theory this is about the energy below which gravity begins to behave as a separate interaction. This time therefore marked the transition from any proposed TOE to the GUT period.

During the GUT period, roughly $t = 10^{-43}$ to 10^{-35} s, the strong and electroweak forces were still unified, and the universe consisted of a soup of quarks and leptons transforming into each other so freely that there was no distinction between the two families of particles. Other, much more massive particles may also have been freely created and destroyed. One important characteristic of GUTs is that at sufficiently high energies, baryon number is not conserved. (We mentioned earlier the proposed decay of the proton, which has not yet been observed.) Thus by the end of the GUT period the numbers of quarks and antiquarks may have been unequal. This point has important implications; we'll return to it at the end of the section.

By $t = 10^{-35}$ s the temperature had decreased to about 10^{27} K and the average energy to about 10^{14} GeV. At this energy the strong force separated from the electroweak force (Fig. 44.19), and baryon number and lepton numbers began to be separately conserved. In some models, called *inflationary models*, this separation of the strong force was analogous to a *phase change*, such as boiling of a liquid,

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

44.19 Schematic diagram showing the times and energies at which the various interactions are thought to have uncoupled. The energy scale is backward because the average energy decreased as the age of the universe increased.

with an associated heat of vaporisation. Think of it as being similar to boiling a heavy nucleus, pulling the particles apart beyond the short range of the nuclear force. As a result, the inflationary models predict that there was a very rapid expansion. In one model, the scale factor R increased by a factor of 10^{50} in 10^{-32} s.

At $t = 10^{-32}$ s the universe was a mixture of quarks, leptons and the mediating bosons (gluons, photons and the weak bosons $W^{\pm}$ and Z^0). It continued to expand and cool from the inflationary period to $t = 10^{-6}$ s, when the temperature was about 10^{13} K and typical energies were about 1 GeV (comparable to the rest energy of a nucleon; see Example 44.11). At this time the quarks began to bind together to form nucleons and antinucleons. Also there were still enough photons of sufficient energy to produce nucleon–antinucleon pairs to balance the process of nucleon–antinucleon annihilation. However, by about $t = 10^{-2}$ s, most photon energies fell well below the threshold energy for such pair production. There was a slight excess of nucleons over antinucleons; as a result, virtually all of the antinucleons and most of the nucleons annihilated one another. A similar equilibrium occurred later between the production of electron–positron pairs from photons and the annihilation of such pairs. At about $t = 14$ s the average energy dropped to around 1 MeV, below the threshold for e^+e^- pair production. After pair production ceased, virtually all of the remaining positrons were annihilated, leaving the universe with many more protons and electrons than the antiparticles of each.

Up until about $t = 1$ s, neutrons and neutrinos could be produced in the endoergic reaction

$$e^- + p \rightarrow n + \nu_e$$

After this time, most electrons no longer had enough energy for this reaction. The average neutrino energy also decreased, and as the universe expanded, equilibrium reactions that involved *absorption* of neutrinos (which occurred with decreasing probability) became inoperative. At this time, in effect, the flux of neutrinos and antineutrinos throughout the universe uncoupled from the rest of the universe. Because of the extraordinarily low probability for neutrino absorption, most of this flux is still present today, although cooled greatly by expansion. The standard model of the universe predicts a present neutrino temperature of about 2 K, but no one has yet been able to carry out an experiment to test this prediction.

Nucleosynthesis

At about $t = 1$ s, the ratio of protons to neutrons was determined by the Boltzmann distribution factor $e^{-\Delta E/kT}$, where ΔE is the difference between the neutron

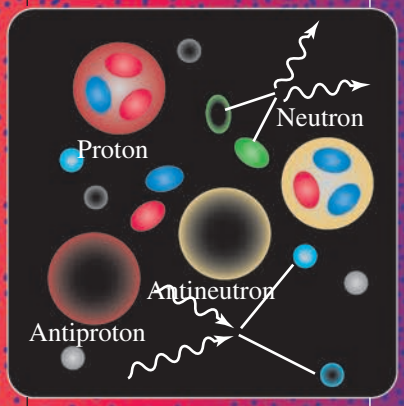
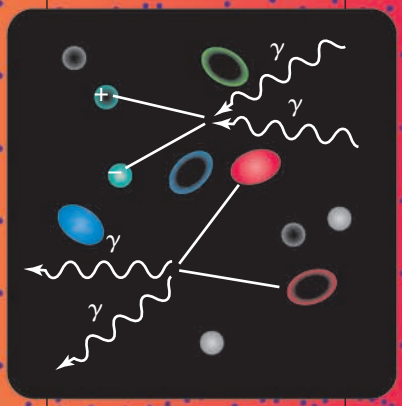
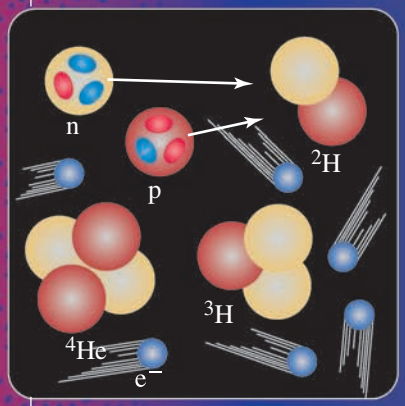
AGE OF QUARKS AND GLUONS (GUT Period)
Dense concentration of matter and antimatter; gravity a separate force; more quarks than antiquarks. Inflationary period (10^{-35} s): rapid expansion, strong force separates from electroweak force.



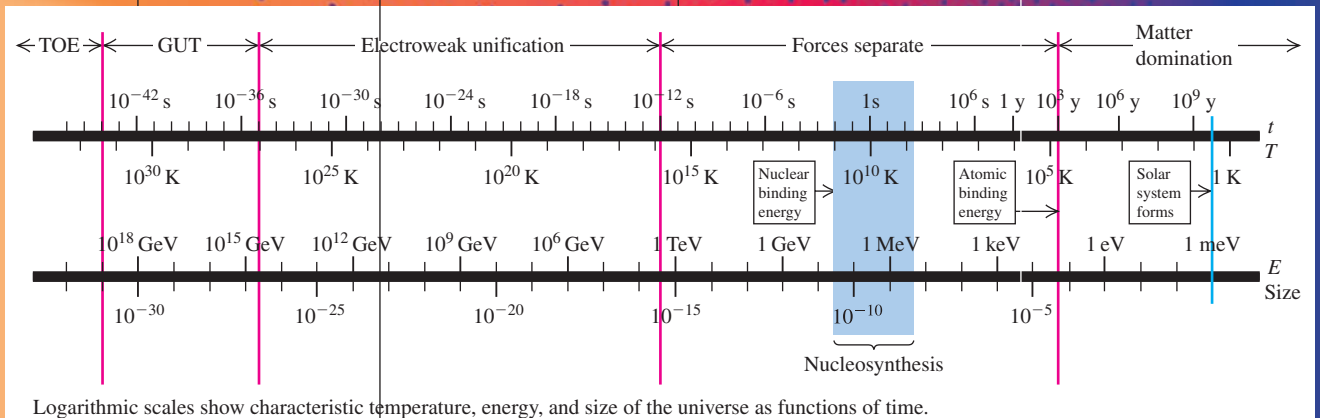
AGE OF LEPTONS
Leptons distinct from quarks; $W^{\pm}$ and Z^0 bosons mediate weak force (10^{-12} s).



AGE OF NUCLEONS AND ANTINUCLEONS
Quarks bind together to form nucleons and antinucleons; energy too low for nucleon–antinucleon pair production at 10^{-2} s.



AGE OF NUCLEOSYNTHESIS
Stable deuterons; matter 74% H, 25% He, 1% heavier nuclei.



BIG BANG 10^{-43} s 10^{-32} s 10^{-6} s 225 s 10^{3} s

Logarithmic scales show characteristic temperature, energy, and size of the universe as functions of time.

and proton rest energies: $\Delta E = 1.294$ MeV. At a temperature of about 10^{10} K, this distribution factor gives about 4.5 times as many protons as neutrons. However, as we have discussed, free neutrons (with a lifetime of 887 s) decay spontaneously to protons. This decay caused the proton–neutron ratio to increase until about $t = 225$ s. At this time, the temperature was about 10^9 K, and the average energy was well below 2 MeV.

This energy distribution was critical because the binding energy of the *deuteron* (a neutron and a proton bound together) is 2.22 MeV (see Section 43.2). A neutron bound in a deuteron does not decay spontaneously. As the average energy decreased, a proton and a neutron could combine to form a deuteron, and there were fewer and fewer photons with 2.22 MeV or more of energy to dissociate the deuterons again. Therefore the combining of protons and neutrons into deuterons halted the decay of free neutrons.

The formation of deuterons starting at about $t = 225$ s marked the beginning of the period of formation of nuclei, or *nucleosynthesis*. At this time, there were about seven protons for each neutron. The deuteron $\left({}^2\text{H}\right)$ can absorb a neutron and form a triton $\left({}^3\text{H}\right)$, or it can absorb a proton and form ^{3}He. Then ^{3}H can absorb a proton, and ^{3}He can absorb a neutron, each yielding ^{4}He (the alpha particle). A few ^{7}Li nuclei may also have been formed by fusion of ^{3}H and ^{4}He nuclei. According to the theory, essentially all the ^{1}H and ^{4}He in the present universe was formed at this time. But then the building of nuclei almost ground to a halt. The reason is that *no* nuclide with mass number $A = 5$ has a half-life greater than 10^{-21} s. Alpha particles simply do not permanently absorb neutrons or protons. The nuclide ^{8}Be that is formed by fusion of two ^{4}He nuclei is unstable, with an extremely short half-life, about 7×10^{-17} s. Note also that at this time, the average energy was still much too large for electrons to be bound to nuclei; there were not yet any atoms.

Conceptual Example 44.12 The relative abundance of hydrogen and helium in the universe

Nearly all of the protons and neutrons in the seven-to-one ratio at $t = 225$ s either formed ^{4}He or remained as ^{1}H. After this time, what was the relative abundance of ^{1}H and ^{4}He by mass?

SOLUTION

The ^{4}He nucleus contains two protons and two neutrons. For every two neutrons we have 14 protons. The two neutrons and two of the 14 protons make up one ^{4}He nucleus, leaving 12 protons (^{1}H nuclei). So at this time there were 12 ^{1}H nuclei for every ^{4}He nucleus. The masses of ^{1}H and ^{4}He are about 1 u and 4 u, respectively, so there were 12 u of ^{1}H for every 4 u of ^{4}He. Therefore the mix, by mass, was 75% ^{1}H and 25% ^{4}He. This result agrees very well with estimates of the present H–He ratio in the universe, an important confirmation of this part of the theory.

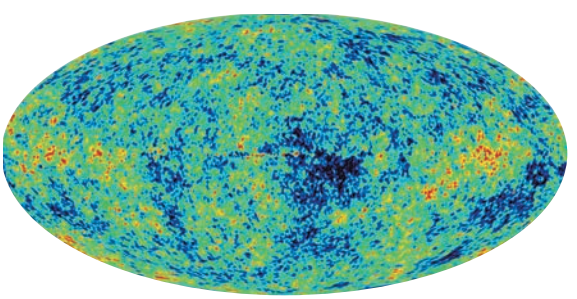
Further nucleosynthesis did not occur until very much later, well after the time $t = 10^{13}$ s (about 380 000 y). At that time, the temperature was about 3000 K, and the average energy was a few tenths of an electron volt. Because the ionisation energies of hydrogen and helium *atoms* are 13.6 eV and 24.5 eV, respectively, almost all the hydrogen and helium was electrically neutral (not ionised). With the electrical repulsions of the nuclei canceled out, gravitational attraction could slowly pull the neutral atoms together to form clouds of gas and eventually stars. Thermonuclear reactions in stars are believed to have produced all of the more massive nuclei. In Section 43.8 we discussed one cycle of thermonuclear reactions in which ^{1}H becomes ^{4}He; this cycle is one of the sources of the energy radiated by stars.

As a star uses up its hydrogen, the inward gravitational pressure exceeds the outward radiation and gas pressure, and the star's core begins to contract. As it does so, the gravitational potential energy decreases, and the kinetic energies of the star's atoms increase. For stars with sufficient mass, there are both enough energy and sufficient density to begin another process, *helium fusion*. First two ^{4}He nuclei fuse to form ^{8}Be. The extremely short lifetime of this unstable nuclide

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

is compensated by the density of the nuclear core and by an usually large probability for absorption of another ^{4}He nucleus with a specific energy, a kind of resonance effect. Thus a reasonable fraction of the ^{8}Be nuclei fuse with ^{4}He to form the stable nuclide ^{12}C. The net result is the fusion of three ^{4}He nuclei to form one ^{12}C, the *triple-alpha process*. Then successive fusions with ^{4}He give ^{16}O, ^{20}Ne, and ^{24}Mg. All these reactions are exoergic. They release energy to heat up the star, and ^{12}C and ^{16}O can fuse to form elements with higher and higher atomic number.

For nuclides that can be created in this manner, the binding energy per nucleon peaks at mass number $A = 56$ with the nuclide ^{56}Fe, so exoergic fusion reactions stop with Fe. But successive neutron captures followed by beta decays can continue the synthesis of more massive nuclei. If the star is massive enough, it may eventually explode as a *supernova*, sending out into space the heavy elements that were produced by the earlier processes (Fig. 44.20; see also Fig. 37.7). In space, the debris and other interstellar matter can gravitationally bunch together to form a new generation of stars and planets. Our own sun is one such 'second-generation' star. This means that the sun's planets and everything on them (including you) contain matter that was long ago blasted into space by an exploding supernova.



44.20 The Veil Nebula in the constellation Cygnus is a remnant of a supernova explosion that occurred more than 20 000 years ago. The gas ejected from the supernova is still moving very rapidly. Collisions between this fast-moving gas and the tenuous material of interstellar space excites the gas and causes it to glow. The portion of the nebula shown here is about 40 ly (12 pc) in

Background Radiation

In 1965 Arno Penzias and Robert Wilson, working at Bell Telephone Laboratories in New Jersey on satellite communications, turned a microwave antenna skyward and found a background signal that had no apparent preferred direction. (This signal produces about 1% of the 'hash' you see on a TV screen when you turn to an unused channel.) Further research has shown that the radiation that is received has a frequency spectrum that fits Planck's blackbody radiation law, Eq. (38.32) (see Section 38.8). The wavelength of peak intensity is 1.063 mm (in the microwave region of the spectrum), with a corresponding absolute temperature $T = 2.725$ K. Penzias and Wilson contacted physicists at nearby Princeton University who had begun the design of an antenna to search for radiation that was a remnant from the early evolution of the universe. We mentioned above that neutral atoms began to form at about $t = 380{,}000$ years when the temperature was 3000 K. With far fewer charged particles present than previously, the universe became transparent at this time to electromagnetic radiation of long wavelength. The 3000 K blackbody radiation therefore survived, cooling to its present 2.725 K temperature as the universe expanded. The *cosmic background radiation* is among the most clear-cut experimental confirmations of the Big Bang theory. Figure 44.21 shows a modern map of the cosmic background radiation.

44.21 This false-colour map shows microwave radiation from the entire sky mapped onto an oval. When this radiation was emitted 380 000 years after the Big Bang, the regions shown in blue were slightly cooler and denser than average. Within these regions formed galaxies, including the Milky Way galaxy of which our solar system, our earth, and ourselves are part.

Example 44.13 Expansion of the universe

By approximately what factor has the universe expanded since $t = 380\,000$ y?

SOLUTION

IDENTIFY: We use the idea that as the universe has expanded, all intergalactic wavelengths have expanded with it.

SET UP: The Wien displacement law, Eq. (38.30), relates the peak wavelength in blackbody radiation to the temperature. Given the temperatures of the cosmic background radiation today and at $t = 380\,000$ y, we can determine the factor by which wavelengths have changed and hence determine the factor by which the universe has expanded.

EXECUTE: We can rewrite Eq. (38.30) to show that the peak wavelength λ_m in blackbody radiation is inversely proportional to absolute temperature:

$$\lambda_m = \frac{2.90 \times 10^{-3}\ \text{m} \cdot \text{K}}{T}$$

As the universe expands, all intergalactic wavelengths (including λ_m) increase in proportion to the scale factor R. The temperature decreased by a factor of $(3000\ \text{K})/(2.7\ \text{K})$, so λ_m and the scale factor must have *increased* by this factor. Thus, between $t = 380\,000$ y and the present, the universe has expanded by a factor of $(3000\ \text{K})/(2.7\ \text{K})$, or about 1100.

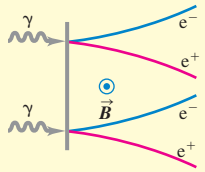
EVALUATE: Our results show that since $t = 380\,000$ y, any particular intergalactic volume has increased by a factor of $(1100)^3 = 1.3 \times 10^9$. They also show that when the cosmic background radiation was emitted, its peak wavelength was $(1.063\ \text{mm})/1100 = 967$ nm, in the infrared region of the spectrum.

Matter and Antimatter

One of the most remarkable features of our universe is the asymmetry between matter and antimatter. One might think that the universe should have equal numbers of protons and antiprotons and of electrons and positrons, but this doesn't appear to be the case. There is no evidence for the existence of substantial amounts of antimatter (matter composed of antiprotons, antineutrons and positrons) anywhere in the universe. Theories of the early universe must explain this imbalance.

We've mentioned that most GUTs include violation of conservation of baryon number at energies at which the strong and electroweak interactions have converged. If particle–antiparticle symmetry is also violated, we have a mechanism for making more quarks than antiquarks, more leptons than antileptons and eventually more matter than antimatter. One serious problem is that any asymmetry that is created in this way during the GUT era might be wiped out by the electroweak interaction after the end of the GUT era. If so, there must be some mechanism that creates particle–antiparticle asymmetry at a much *later* time. The problem of the matter–antimatter asymmetry is still very much an open one.

We hope that this qualitative discussion has given you a hint of the close connections between particle physics and cosmology. There are still many unanswered questions in this active field of research. Is the energy density of the universe precisely equal to $\rho_c c^2$, or are there small but important differences? What is dark energy? Has the density of dark energy remained constant over the history of the universe, or has the density changed? What is dark matter, and why is it so difficult to detect other than by its gravitational influence? What happened during the first 10^{-43} s after the Big Bang? Can we see evidence that the strong and electroweak interactions undergo a grand unification at high energies? The search for the answers to these and many other questions about our physical world continues to be one of the most exciting adventures of the human mind.



Test Your Understanding of Section 44.7 Given a sufficiently powerful telescope, could we detect photons emitted earlier than $t = 380\,000$ y?

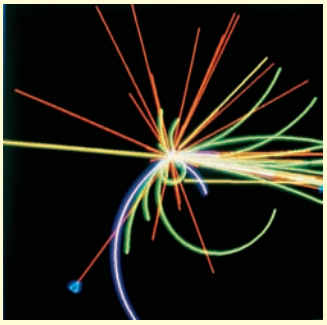
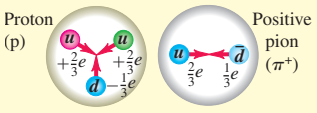
CHAPTER 44 SUMMARY

Fundamental particles: Each particle has an antiparticle; some particles are their own antiparticles. Particles can be created and destroyed, some of them (including electrons and positrons) only in pairs or in conjunction with other particles and antiparticles.

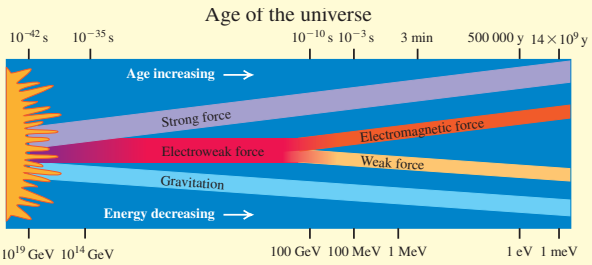
Particles serve as mediators for the fundamental interactions. The photon is the mediator of the electromagnetic interaction. Yukawa proposed the existence of mesons to mediate the nuclear interaction. Mediating particles that can exist only because of the uncertainty principle for energy are called virtual particles. (See Example 44.1.)



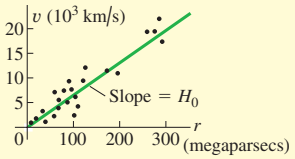
Particle accelerators and detectors: Cyclotrons, synchrotrons and linear accelerators are used to accelerate charged particles to high energies for experiments with particle interactions. Only part of the beam energy is available to cause reactions with targets at rest. This problem is avoided in colliding-beam experiments. (See Examples 44.2–44.4.)



Particles and interactions: Four fundamental interactions are found in nature: the strong, electromagnetic, weak and gravitational interactions. Particles can be described in terms of their interactions and of quantities that are conserved in all or some of the interactions.

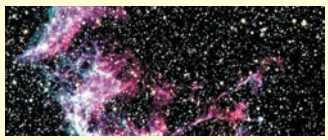


Fermions have half-integer spins; bosons have integer spins. Leptons, which are fermions, have no strong interactions. Strongly interacting particles are called hadrons. They include mesons, which are always bosons, and baryons, which are always fermions. There are conservation laws for three different lepton numbers and for baryon number. Additional quantum numbers, including strangeness and charm, are conserved in some interactions and not in others. (See Examples 44.5–44.7.)



Quarks: Hadrons are composed of quarks. There are thought to be six types of quarks. The interaction between quarks is mediated by gluons. Quarks and gluons have an additional attribute called colour. (See Example 44.8.)

Symmetry and the unification of interactions: Symmetry considerations play a central role in all fundamental-particle theories. The electromagnetic and weak interactions become unified at high energies into the electroweak interaction. In grand unified theories the strong interaction is also unified with these interactions, but at much higher energies.



The expanding universe and its composition: The Hubble law shows that galaxies are receding from each other and that the universe is expanding. Observations show that the rate of expansion is accelerating due to the presence of dark energy, which makes up 74% of the energy in the universe. Only 4% of the energy in the universe is in the form of ordinary matter; the remaining 22% is dark matter, whose nature is poorly understood. (See Examples 44.9 and 44.10.)

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

The history of the universe: In the standard model of the universe, a Big Bang gave rise to the first fundamental particles. They eventually formed into the lightest atoms as the universe expanded and cooled. The cosmic background radiation is a relic of the time when these atoms formed. The heavier elements were manufactured much later by fusion reactions inside stars. (See Examples 44.11–44.13.)

Answer to Chapter Opening Question ?

Only 4% of the mass and energy of the universe is in the form of 'normal' matter. Of the rest, 22% is the poorly understood material called dark matter and 74% is the even more mysterious dark energy.

Answers to Test Your Understanding Questions

44.1 Answer: (i), (iii), (ii), (iv) The more massive the virtual particle, the shorter its lifetime and the shorter the distance that it can travel during its lifetime.

44.2 Answer: no In a head-on collision between an electron and a positron of equal energy, the net momentum is zero. Since both momentum and energy are conserved in the collision, the virtual photon also has momentum $p = 0$ but has energy $E = 90\ \text{GeV} + 90\ \text{GeV} = 180\ \text{GeV}$. Hence the relationship $E = pc$ is definitely *not* true for this virtual photon. In fact, it is a hallmark of virtual particles of all kinds that they need not have the same relationship between energy and momentum that real particles do.

44.3 Answer: no Mesons all have baryon number $B = 0$, while a proton has $B = 1$. The decay of a proton into one or more mesons would require that baryon number *not* be conserved. No violation of this conservation principle has ever been observed, so the proposed decay is impossible. (As discussed in Section 44.5, no evidence has been found suggesting that the proton decays in *any* fashion.)

44.4 Answer: no Only the s quark, with $S = -1$, has nonzero strangeness. For a baryon to have $S = -2$, it must have two s quarks and one quark of a different flavor. Since each s quark has charge $-\frac{1}{3}e$, the nonstrange quark must have charge $+\frac{4}{3}e$ to make the net charge equal to $+e$. But *no* quark has charge $+\frac{4}{3}e$, so the proposed baryon is impossible.

44.5 Answer: (i) If a d quark in a neutron (quark content udd) undergoes the process $d \to u + e^- + \bar{\nu}_e$, the remaining baryon has quark content uud and hence is a proton (see Fig. 44.11). An electron is the same as a β^- particle, so the net result is beta-minus decay: $n \to p + \beta^- + \bar{\nu}_e$. Thus, in the standard model, beta-minus decay of a nucleus is a process whereby a quark within the nucleus undergoes a change in flavor from d to u.

44.6 Answer: yes . . . and no The material of which your body is made is ordinary to us on earth. But from the broader perspective of the universe as a whole, the material of which you are made is quite *extraordinary:* Only 4% of the mass and energy in the universe is in the form of atoms.

44.7 Answer: no Prior to $t = 380\ 000$ the temperature was so high that atoms could not form, so free electrons and protons were plentiful. These charged particles are very effective at scattering photons, so light could not propagate very far and the universe was opaque. The oldest photons that we can detect date from the time $t = 380\ 000$ y when atoms formed and the universe became transparent.

PROBLEMS

For instructor-assigned homework, go to **www.pearson.com.au/masteringphysics** MP

Exercises

Section 44.1 Fundamental Particles—A History

44.1. An electron and a positron are moving towards each other and each has speed $0.500c$ in the lab frame. (a) What is the kinetic energy of each particle? (b) The e^+ and e^- meet head-on and annihilate. What is the energy of each photon that is produced? (c) What is the wavelength of each photon? How does the wavelength compare to the photon wavelength when the initial kinetic energy of the e^+ and e^- is negligibly small (see Example 44.1)?

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

44.2. In Example 44.1, what is the speed of a positron that has kinetic energy 5.00 MeV? Express your result in terms of the speed of light.

44.3. A neutral pion at rest decays into two photons. Find the approximate energy, frequency and wavelength of each photon. In which part of the electromagnetic spectrum does each photon lie? (Use the pion mass given in terms of the electron mass in Section 44.1.)

44.4. Two equal-energy photons collide head-on and annihilate each other, producing a $\mu^+\mu^-$ pair. The muon mass is given in terms of the electron mass in Section 44.1. (a) Calculate the maximum wavelength of the photons for this to occur. If the photons have this wavelength, describe the motion of the μ^+ and μ^- immediately after they are produced. (b) What happens if the photons have shorter wavelength than this maximum but still annihilate and produce a $\mu^+\mu^-$ pair?

44.5. A positive pion at rest decays into a positive muon and a neutrino. (a) Approximately how much energy is released in the decay? (Assume the neutrino has zero rest mass. Use the muon and pion masses given in terms of the electron mass in Section 44.1.) (b) Why can't a positive muon decay into a positive pion?

44.6. A proton and an antiproton annihilate, producing two photons. Find the energy, frequency and wavelength of each photon emitted in the centre-of-momentum reference frame (a) if the initial kinetic energies of the proton and antiproton are negligible and (b) if each particle has an initial kinetic energy of 830 MeV.

44.7. A negative muon at rest decays into an electron–positron pair and two neutrinos. Approximately how much energy is released in the decay? (Assume the neutrino has zero mass.)

44.8. Equations (44.1) and (44.2) describe two nuclear reactions involving neutrons. (a) Are these reactions exoergic or endoergic? (b) How much energy is released (or absorbed) in each of them? (c) Does each of the two reactions have a threshold kinetic energy? (Consult Table 43.2.)

44.9. The starship *Enterprise*, of television and movie fame, is powered by the controlled combination of matter and antimatter. If the entire 400 kg antimatter fuel supply of the *Enterprise* combines with matter, how much energy is released? How does this compare to Australian yearly energy use?

Section 44.2 Particle Accelerators and Detectors

44.10. An electron with a total energy of 20.0 GeV collides with a stationary positron. (a) What is the available energy? (b) If the electron and positron are accelerated in a collider, what total energy corresponds to the same available energy as in part (a)?

44.11. Deuterons in a cyclotron travel in a circle with radius 32.0 cm just before emerging from the dees. The frequency of the applied alternating voltage is 9.00 MHz. Find (a) the magnetic field and (b) the kinetic energy and speed of the deuterons upon emergence.

44.12. The magnetic field in a cyclotron that accelerates protons is 1.30 T. (a) How many times per second should the potential across the dees reverse? (This is twice the frequency of the circulating protons.) (b) The maximum radius of the cyclotron is 0.250 m. What is the maximum speed of the proton? (c) Through what potential difference would the proton have to be accelerated from rest to give it the same speed as calculated in part (b)?

44.13. (a) A high-energy beam of alpha particles collides with a stationary helium gas target. What must the total energy of a beam particle be if the available energy in the collision is 16.0 GeV? (b) If the alpha particles instead interact in a colliding-beam experiment, what must the energy of each beam be to produce the same available energy?

44.14. (a) What is the speed of a proton that has total energy 1000 GeV? (b) What is the angular frequency ω of a proton with the speed calculated in part (a) in a magnetic field of 4.00 T? Use both the nonrelativistic Eq. (44.7) and the correct relativistic expression, and compare the results.

44.15. In Example 44.4 it was shown that a proton beam with an 800 GeV beam energy gives an available energy of 38.7 GeV for collisions with a stationary proton target. (a) You are asked to design an upgrade of the accelerator that will double the available energy in stationary-target collisions. What beam energy is required? (b) In a colliding-beam experiment, what total energy of each beam is needed to give an available energy of $2(38.7\ \text{GeV}) = 77.4\ \text{GeV}$?

44.16. Calculate the minimum beam energy in a proton–proton collider to initiate the $p + p \rightarrow p + p + \eta^0$ reaction. The rest energy of the η^0 is 547.3 MeV (see Table 44.3).

Section 44.3 Particles and Interactions

44.17. What is the mass (in kg) of the Z^0? What is the ratio of the mass of the Z^0 to the mass of the proton?

44.18. Table 44.3 shows that a Σ^0 decays into a Λ^0 and a photon. (a) Calculate the energy of the photon emitted in this decay, if the Λ^0 is at rest. (b) What is the magnitude of the momentum of the photon? Is it reasonable to ignore the final momentum and kinetic energy of the Λ^0? Explain.

44.19. If a Σ^+ at rest decays into a proton and a π^0, what is the total kinetic energy of the decay products?

44.20. The discovery of the Ω^- particle helped confirm Gell-Mann's eightfold way. If an Ω^- decays into a Λ^0 and a K', what is the total kinetic energy of the decay products?

44.21. In which of the following decays are the three lepton numbers conserved? In each case, explain your reasoning. (a) $\mu^- \rightarrow e^- + \nu_e + \bar{\nu}_\mu$; (b) $\tau^- \rightarrow e^- + \bar{\nu}_e + \nu_\tau$; (c) $\pi^+ \rightarrow e^+ + \gamma$; (d) $n \rightarrow p + e^- + \bar{\nu}_e$.

44.22. Which of the following reactions obey the conservation of baryon number? (a) $p + p \rightarrow p + e^+$; (b) $p + n \rightarrow 2e^+ + e^-$; (c) $p \rightarrow n + e^- + \bar{\nu}_e$; (d) $p + \bar{p} \rightarrow 2\gamma$.

44.23. In which of the following reactions or decays is strangeness conserved? In each case, explain your reasoning. (a) $K^+ \rightarrow \mu^+ + \nu_\mu$; (b) $n + K^+ \rightarrow p + \pi^0$; (c) $K^+ + K^- \rightarrow \pi^0 + \pi^0$; (d) $p + K^- \rightarrow \Lambda^0 + \pi^0$.

44.24. (a) Show that the coupling constant for the electromagnetic interaction, $e^2/4\pi\epsilon_0\hbar c$, is dimensionless and has the numerical value $1/137.0$. (b) Show that in the Bohr model (see Section 38.5) the orbital speed of an electron in the $n = 1$ orbit is equal to c times the coupling constant $e^2/4\pi\epsilon_0\hbar c$.

44.25. Show that the nuclear force coupling constant $f^2/\hbar c$ is dimensionless.

Section 44.4 Quarks and the Eightfold Way

44.26. Nine of the spin-$\frac{3}{2}$ baryons are four Δ particles, each with mass 1232 MeV/c^2, strangeness 0 and charges $+2e$, $+e$, 0, and $-e$; three Σ^* particles, each with mass 1385 MeV/c^2, strangeness -1, and charges $+e$, 0, and $-e$; and two Ξ^* particles, each with mass 1530 MeV/c^2, strangeness -2, and charges 0 and $-e$. (a) Place these particles on a plot of S versus Q. Deduce the Q. and S values of the tenth spin-$\frac{3}{2}$ baryon, the Ω^- particle, and place it on your diagram. Also label the particles with their masses. The mass of the Ω^- is 1672 MeV/c^2; is this value consistent with your diagram?

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

(b) Deduce the three-quark combinations (of u, d, and s) that make up each of these ten particles. Redraw the plot of S versus Q from part (a) with each particle labelled by its quark content. What regularities do you see?

44.27. Determine the electric charge, baryon number, strangeness, and charm quantum numbers for the following quark combinations: (a) uds; (b) $c\bar{u}$; (c) ddd; (d) $d\bar{c}$. Explain your reasoning.

44.28. What is the total kinetic energy of the decay products when an upsilon particle at rest decays to $\tau^+ + \tau^-$?

44.29. The quark content of the neutron is udd. (a) What is the quark content of the antineutron? Explain your reasoning. (b) Is the neutron its own antiparticle? Why or why not? (c) The quark content of the ψ is $c\bar{c}$. Is the ψ its own antiparticle? Explain your reasoning.

44.30. Given that each particle contains only combinations of u, d, s, $\bar{u}$, $\bar{d}$, and $\bar{s}$, use the method of Example 44.8 to deduce the quark content of (a) a particle with charge $+e$, baryon number 0 and strangeness $+1$; (b) a particle with charge $+e$, baryon number -1, and strangeness $+1$; (c) a particle with charge 0, baryon number $+1$, and strangeness -2.

44.31. The weak force may change quark flavor in an interaction. Explain how β^+ decay changes quark flavor. If a proton undergoes β^+ decay, determine the decay reaction.

Section 44.6 The Expanding Universe

44.32. The definition of the redshift parameter z is given in Example 44.9. (a) Show that Eq. (44.13) may be written as $1 + z = ([1 + \beta]/[1 - \beta])^{1/2}$, where $\beta = v/c$. (b) The observed redshift parameter for a certain galaxy is $z = 0.500$. Find the speed of the galaxy relative to the earth, if the redshift is due to the Doppler shift. (c) Use the Hubble law to find the distance of this galaxy from the earth.

44.33. The spectrum of the sodium atom is detected in the light from a distant galaxy. (a) If the 590.0 nm line is redshifted to 658.5 nm, at what speed is the galaxy receding from the earth? (b) Use the Hubble law to calculate the distance of the galaxy from the earth.

44.34. (a) According to the Hubble law, what is the distance r from us for galaxies that are receding from us with a speed c? (b) Explain why the distance calculated in part (a) is the size of our observable universe (ignoring any slowing of the expansion of the universe due to gravitational attraction).

44.35. A galaxy in the constellation Pisces is 5210 Mly from the earth. (a) Use the Hubble law to calculate the speed at which this galaxy is receding from earth. (b) What redshifted ratio λ_0/λ_s is expected for light from this galaxy?

44.36. The critical density of the universe is $6.3 \times 10^{-27}\ \text{kg/m}^3$. (a) Assuming that the universe is all hydrogen, express the critical density in the number of H atoms per cubic metre. (b) If the density of the universe is equal to the critical density, how many atoms, on the average, would you expect to find in a room of dimensions 4 m $\times$ 7 m $\times$ 3 m? (c) Compare your answer in part (b) with the number of atoms you would find in the same room under normal conditions on the earth.

Section 44.7 The Beginning of Time

44.37. Calculate the energy released in each reaction: (a) $p + {}^2H \rightarrow {}^3He$; (b) $n + {}^3He \rightarrow {}^4He$.

44.38. Calculate the energy (in MeV) released in the triple-alpha process $3\ {}^4He \rightarrow {}^{12}C$.

44.39. Calculate the reaction energy Q (in MeV) for the reaction $e^- + p \rightarrow n + \nu_e$. Is this reaction endoergic or exoergic?

44.40. Calculate the reaction energy Q (in MeV) for the nucleosynthesis reaction

$$^{12}_{6}C + {}^{4}_{2}He \rightarrow {}^{16}_{8}O$$

Is this reaction endoergic or exoergic?

44.41. The 2.728 K blackbody radiation has its peak wavelength at 1.062 mm. What was the peak wavelength at $t = 700\,000$ y when the temperature was 3000 K?

44.42. (a) Show that the expression for the Planck length, $\sqrt{\hbar G/c^3}$, has dimensions of length. (b) Evaluate the numerical value of $\sqrt{\hbar G/c^3}$, and verify the value given in Eq. (44.21).

Problems

44.43. In the LHC, each proton will be accelerated to a kinetic energy of 7.0 TeV. (a) In the colliding beams, what is the available energy E_a in a collision? (b) In a fixed-target experiment in which a beam of protons is incident on a stationary proton target, what must the total energy (in TeV) of the particles in the beam be to produce the same available energy as in part (a)?

44.44. A proton and an antiproton collide head-on with equal kinetic energies. In the centre-of-momentum frame, two γ rays with wavelengths of 0.780 fm are produced. Calculate the kinetic energy of the incident proton.

44.45. Both the strong and the weak interactions are short-range forces having a range of around 1 fm. If you have two protons separated by this distance, they will be influenced by all four of the fundamental forces (or interactions). (a) Calculate the strengths of the electrical and gravitational interactions that will influence each of these protons. (b) Use the information given about the four forces at the beginning of Section 44.3 to estimate the approximate strengths of the strong interaction and the week interaction on each of these protons. (c) Arrange the four forces in order of strength, starting with the strongest. (d) Express each force as a multiple of the weakest of the four.

44.46. Calculate the threshold kinetic energy for the reaction $\pi^- + p \rightarrow \Sigma^0 + K^0$ if a π^- beam is incident on a stationary proton target. The K^0 has a mass of 497.7 MeV/c^2.

44.47. Calculate the threshold kinetic energy for the reaction $p + p \rightarrow p + p + K^+ + K^-$ if a proton beam is incident on a stationary proton target.

44.48. An η^0 meson at rest decays into three π mesons. (a) What are the allowed combinations of π^0, π^+, and π^- as decay products? (b) Find the total kinetic energy of the π mesons.

44.49. Consider the case where an electron e^- and a positron e^+ annihilate each other and produce photons. Assume that these two particles collide head-on with equal, but slow, speeds. (a) Show that it is not possible for only one photon to be produced. (Hint: Consider the conservation law that must be true in any collision.) (b) Show that if only two photons are produced, they must travel in opposite directions and have equal energy. (c) Calculate the wavelength of each of the photons in part (b). In what part of the electromagnetic spectrum do they lie?

44.50. (a) What energy is released when a negative pion (π^-) at rest decays to stable products (see Tables 44.2 and 44.3 in Section 44.3)? (b) Why do the antineutrinos and neutrino carry away most of this energy?

44.51. Each of the following reactions is missing a single particle. Calculate the baryon number, charge, strangeness and the three lepton numbers (where appropriate) of the missing particle, and from this identify the particle. (a) $p + p \rightarrow p + \Lambda^0 + ?$; (b) $K^- + n \rightarrow \Lambda^0 + ?$; (c) $p + \bar{p} \rightarrow n + ?$; (d) $\bar{\nu}_\mu + p \rightarrow n + ?$

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

44.52. Estimate the energy width (energy uncertainty) of the ψ if its mean lifetime is 7.6×10^{-21} s. What fraction is this of its rest energy?

44.53. The ϕ meson has mass $1019.4\ \text{MeV}/c^2$ and a measured energy width of $4.4\ \text{MeV}/c^2$. Using the uncertainty principle, Eq. (39.13), estimate the lifetime of the ϕ meson.

44.54. A ϕ meson (see Problem 44.53) at rest decays via $\phi \to K^+ + K^-$. It has strangeness 0. (a) Find the kinetic energy of the K^+ meson. (Assume that the two decay products share kinetic energy equally, since their masses are equal.) (b) Suggest a reason the decay $\phi \to K^+ + K^- + \pi^0$ has not been observed. (c) Suggest reasons the decays $\phi \to K^+ + \pi^-$ and $\phi \to K^+ + \mu^-$ have not been observed.

44.55. Proton decay is a feature of some grand unification theories. One possible decay could be $p^+ \to e^+ + \pi^0$, which violates both baryon and lepton number conservation, so the proton lifetime is expected to be very long. Suppose the proton half-life were 1.0×10^{18}y. (a) Calculate the energy deposited per kilogram of body tissue (in rad) due to the decay of the protons in your body in one year. Model your body as consisting entirely of water. Only the two protons in the hydrogen atoms in each H_2O molecule would decay in the manner shown; do you see why? Assume that the π^0 decays to two γ rays, that the positron annihilates with an electron, and that all the energy produced in the primary decay and these secondary decays remains in your body. (b) Calculate the equivalent dose (in rem) assuming a RBE of 1.0 for all the radiation products, and compare with the 0.1 rem due to the natural background and the 5.0 rem guideline for industrial workers. Based on your calculation, can the proton lifetime be as short as 1.0×10^{18}y?

44.56. A Ξ^- particle at rest decays to a Λ^0 and a π^-. (a) Find the total kinetic energy of the decay products. (b) What fraction of the energy is carried off by each particle? (For simplicity, use nonrelativistic momentum and kinetic-energy expressions.)

44.57. Consider the spherical balloon model of a two-dimensional expanding universe (see Fig. 44.16 in Section 44.6). The shortest distance between two points on the surface, measured along the surface, is the arc length r, where $r = R\theta$. As the balloon expands, its radius R increases, but the angle θ between the two points remains constant. (a) Explain why, at any given time, $(dR/dt)/R$ is the same for all points on the balloon. (b) Show that $v = dr/dt$ is directly proportional to r at any instant. (c) From your answer to part (b), what is the expression for the Hubble constant H_0 in terms of R and dR/dt? (d) The expression for H_0 you found in part (c) is constant in space. How would R have to depend on time for H_0 to be constant in time? (e) Is your answer to part (d) consistent with the gravitational attraction of matter in the universe?

44.58. Suppose all the conditions are the same as in Problem 44.57, except that $v = dr/dt$ is constant for a given θ, rather than H_0 being constant in time. Show that the Hubble constant is $H_0 = 1/t$ and, hence, that the current value is $1/T$, where T is the age of the universe.

Challenge Problems

44.59. Consider a collision in which a stationary particle with mass M is bombarded by a particle with mass m, speed v_0, and total energy (including rest energy) E_m. (a) Use the Lorentz transformation to write the velocities v_m and v_M of particles m and M in terms of the speed v_{cm} of the centre of momentum. (b) Use the fact that the total momentum in the centre-of-momentum frame is zero to obtain an expression for v_{cm} in terms of m, M, and v_0. (c) Combine the results of parts (a) and (b) to obtain Eq. (44.9) for the total energy in the centre-of-momentum frame.

44.60. A Λ^0 hyperon at rest decays into a neutron and a π^0. (a) Find the total kinetic energy of the decay products. (b) What fraction of the total kinetic energy is carried off by each particle? (*Hint:* Use the relativistic expressions for momentum and kinetic energy.)

APPENDIX A

THE INTERNATIONAL SYSTEM OF UNITS

The Système International d'Unités, abbreviated SI, is the system developed by the General Conference on Weights and Measures and adopted by nearly all the industrial nations of the world. The following material is adapted from B. N. Taylor, ed., National Institute of Standards and Technology Spec. Pub. 811 (U.S. Govt. Printing Office, Washington, DC, 1995). See also **http://physics.nist.gov/cuu**; **http://www.bipm.org**; **http://www.measurement.gov.au**.

Quantity	Name of unit	Symbol

solid angle	steradian	sr	

Definitions of SI Units

metre (m) The *metre* is the length equal to the distance travelled by light, in vacuum, in a time of 1/299 792 458 second.

kilogram (kg) The *kilogram* is the unit of mass; it is equal to the mass of the international prototype of the kilogram. (The international prototype of the kilogram is a particular cylinder of platinum-iridium alloy that is preserved in a vault at Sévres, France, by the International Bureau of Weights and Measures.)

second (s) The *second* is the duration of 9 192 631 770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom.

ampere (A) The *ampere* is that constant current that, if maintained in two straight parallel conductors of infinite length, of negligible circular cross-section, and placed 1 metre apart in vacuum, would produce between these conductors a force equal to 2×10^{-7} newton per metre of length.

kelvin (K) The *kelvin*, unit of thermodynamic temperature, is the fraction 1/273.16 of the thermodynamic temperature of the triple point of water.

ohm (Ω) The *ohm* is the electric resistance between two points of a conductor when a constant difference of potential of 1 volt, applied between these two points, produces in this conductor a current of 1 ampere, this conductor not being the source of any electromotive force.

coulomb (C) The *coulomb* is the quantity of electricity transported in 1 second by a current of 1 ampere.

candela (cd) The *candela* is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} hertz and that has a radiant intensity in that direction of 1/683 watt per steradian.

mole (mol) The *mole* is the amount of substance of a system that contains as many elementary entities as there are carbon atoms in 0.012 kg of carbon 12. The elementary entities must be specified and may be atoms, molecules, ions, electrons, other particles or specified groups of such particles.

newton (N) The *newton* is that force that gives to a mass of 1 kilogram an acceleration of 1 metre per second per second.

joule (J) The *joule* is the work done when the point of application of a constant force of 1 newton is displaced a distance of 1 metre in the direction of the force.

watt (W) The *watt* is the power that gives rise to the production of energy at the rate of 1 joule per second.

volt (V) The *volt* is the difference of electric potential between two points of a conducting wire carrying a constant current of 1 ampere, when the power dissipated between these points is equal to 1 watt.

weber (Wb) The *weber* is the magnetic flux that, linking a circuit of one turn, produces in it an electromotive force of 1 volt as it is reduced to zero at a uniform rate in 1 second.

lumen (lm) The *lumen* is the luminous flux emitted in a solid angle of 1 steradian by a uniform point source having an intensity of 1 candela.

farad (F) The *farad* is the capacitance of a capacitor between the plates of which there appears a difference of potential of 1 volt when it is charged by a quantity of electricity equal to 1 coulomb.

henry (H) The *henry* is the inductance of a closed circuit in which an electromotive force of 1 volt is produced when the electric current in the circuit varies uniformly at a rate of 1 ampere per second.

radian (rad) The *radian* is the plane angle between two radii of a circle that cut off on the circumference an arc equal in length to the radius.

steradian (sr) The *steradian* is the solid angle that, having its vertex in the centre of a sphere, cuts off an area of the surface of the sphere equal to that of a square with sides of length equal to the radius of the sphere.

SI Prefixes The names of multiples and submultiples of SI units may be formed by application of the prefixes listed in Appendix F.

APPENDIX B

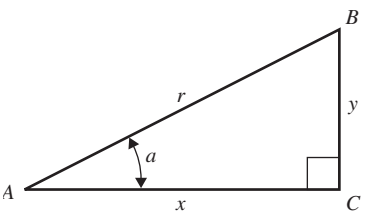
USEFUL MATHEMATICAL RELATIONS

Algebra

$$a^{-x} = \frac{1}{a^x} \qquad a^{(x+y)} = a^x a^y \qquad a^{(x-y)} = \frac{a^x}{a^y}$$

Logarithms: If $\log a = x$, then $a = 10^x$. $\log a + \log b = \log(ab)$ $\log a - \log b = \log(a/b)$ $\log(a^n) = n\log a$

If $\ln a = x$, then $a = e^x$. $\ln a + \ln b = \ln(ab)$ $\ln a - \ln b = \ln(a/b)$ $\ln(a^n) = n\ln a$



Quadratic formula: If $ax^2 + bx + c = 0$, $\quad x = \dfrac{-b \pm \sqrt{b^2 - 4ac}}{2a}$.

Binomial Theorem

$$(a+b)^n = a^n + na^{n-1}b + \frac{n(n-1)a^{n-2}b^2}{2!} + \frac{n(n-1)(n-2)a^{n-3}b^3}{3!} + \cdots$$

Trigonometry

In the right triangle ABC, $x^2 + y^2 = r^2$.

Definitions of the trigonometric functions: $\sin a = y/r$ $\cos a = x/r$ $\tan a = y/x$

Identities:

$$\sin^2 a + \cos^2 a = 1 \qquad \tan a = \frac{\sin a}{\cos a}$$

$$\sin 2a = 2\sin a \cos a \qquad \cos 2a = \cos^2 a - \sin^2 a = 2\cos^2 a - 1 = 1 - 2\sin^2 a$$

$$\sin\tfrac{1}{2}a = \sqrt{\frac{1-\cos a}{2}} \qquad \cos\tfrac{1}{2}a = \sqrt{\frac{1+\cos a}{2}}$$

$$\sin(-a) = -\sin a \qquad \sin(a \pm b) = \sin a\cos b \pm \cos a \sin b$$

$$\cos(-a) = \cos a \qquad \cos(a \pm b) = \cos a\cos b \mp \sin a \sin b$$

$$\sin(a \pm \pi/2) = \pm\cos a \qquad \sin a + \sin b = 2\sin\tfrac{1}{2}(a+b)\cos\tfrac{1}{2}(a-b)$$

$$\cos(a \pm \pi/2) = \mp\sin a \qquad \cos a + \cos b = 2\cos\tfrac{1}{2}(a+b)\cos\tfrac{1}{2}(a-b)$$

Geometry

Circumference of circle of radius r:	$C = 2\pi r$
Area of circle of radius r:	$A = \pi r^2$
Volume of sphere of radius r:	$V = 4\pi r^3/3$
Surface area of sphere of radius r:	$A = 4\pi r^2$
Volume of cylinder of radius r and height h:	$V = \pi r^2 h$

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

Calculus

Derivatives:

$$\frac{d}{dx}x^n = nx^{n-1}$$

$$\frac{d}{dx}\sin ax = a\cos ax$$

$$\frac{d}{dx}\cos ax = -a\sin ax$$

$$\frac{d}{dx}e^{ax} = ae^{ax}$$

$$\frac{d}{dx}\ln ax = \frac{1}{x}$$

Integrals:

$$\int x^n dx = \frac{x^{n+1}}{n+1} \quad (n \neq -1)$$

$$\int \frac{dx}{x} = \ln x$$

$$\int \sin ax\,dx = -\frac{1}{a}\cos ax$$

$$\int \cos ax\,dx = \frac{1}{a}$$

$$\int e^{ax}dx = \frac{1}{a}e^{ax}$$

$$\int \frac{dx}{\sqrt{a^2 - x^2}} = \arcsin\frac{x}{a}$$

$$\int \frac{dx}{\sqrt{x^2 + a^2}} = \ln\left(x + \sqrt{x^2 + a^2}\right)$$

$$\int \frac{dx}{x^2 + a^2} = \frac{1}{a}\arctan\frac{x}{a}$$

$$\int \frac{dx}{(x^2 + a^2)^{3/2}} = \frac{1}{a^2}\frac{x}{\sqrt{x^2 + a^2}}$$

$$\int \frac{x\,dx}{(x^2 + a^2)^{3/2}} = -\frac{1}{\sqrt{x^2 + a^2}}$$

Power series (convergent for range of x shown):

$$(1+x)^n = 1 + nx + \frac{n(n-1)x^2}{2!} + \frac{n(n-1)(n-2)}{3!}x^3 + \cdots \quad (|x| < 1)$$

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \cdots \quad (\text{all } x)$$

$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \cdots \quad (\text{all } x)$$

$$\tan x = x + \frac{x^3}{3} + \frac{2x^2}{15} + \frac{17x^7}{315} + \cdots \quad (|x| < \pi/2)$$

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \cdots \quad (\text{all } x)$$

$$\ln(1+x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4} + \cdots \quad (|x| < 1)$$

For each element the average atomic mass of the mixture of isotopes occurring in nature is shown. For elements having no stable isotope, the approximate atomic mass of the longest-lived isotope is shown in parentheses. For elements that have been predicted but not yet detected, no atomic mass is given. All atomic masses are expressed in atomic mass units ($1\ \text{u} = 1.66053886(28) \times 10^{-27}$ kg), equivalent to grams per mole (g/mol).

UNIT CONVERSION FACTORS

Length
1 m = 100 cm = 1000 mm = 10^6 μm = 10^9 nm
1 km = 1000 m = 0.6214 mi
1 m = 3.281 ft = 39.37 in.
1 cm = 0.3937 in.
1 in. = 2.540 cm
1 ft = 30.48 cm
1 yd = 91.44 cm
1 mi = 5280 ft = 1.609 km
1 Å = 10^{-10} m = 10^{-8} cm = 10^{-1} nm
1 nautical mile = 6080 ft
1 light year = 9.461×10^{15} m

Area
1 cm^2 = 0.155 $in.^2$
1 m^2 = 10^4 cm^2 = 10.76 ft^2
1 $in.^2$ = 6.452 cm^2
1 ft = 144 $in.^2$ = 0.0929 m^2

Volume
1 litre = 1000 cm^3 = $10^{-3}$$m^3$ = 0.03531 ft^3 = 61.02 $in.^3$
1 ft^3 = 0.02832 m^3 = 28.32 litres = 7.477 gallons
1 gallon = 3.788 litres

Time
1 min = 60 s
1 h = 3600 s
1 d = 86,400 s
1 y = 365.24 d = 3.156×10^7 s

Angle
1 rad = 57.30° = 180°/π
1° = 0.01745 rad = π/180 rad
1 revolution = 360° = 2π rad
1 rev/min (rpm) = 0.1047 rad/s

Speed
1 m/s = 3.281 ft/s
1 ft/s = 0.3048 m/s
1 mi/min = 60 mi/h = 88 ft/s
1 km/h = 0.2778 m/s = 0.6214 mi/h
1 mi/h = 1.466 ft/s = 0.4470 m/s = 1.609 km/h
1 furlong/fortnight = 1.662×10^{-4} m/s

Acceleration
1 m/s^2 = 100 cm/s^2 = 3.281 ft/s^2
1 cm/s^2 = 0.01 m/s^2 = 0.03281 ft/s^2
1 ft/s^2 = 0.3048 m/s^2 = 30.48 cm/s^2
1 mi/h · s = 1.467 ft/s^2

Mass
1 kg = 10^3 g = 0.0685 slug
1 g = 6.85×10^{-5} slug
1 slug = 14.59 kg
1 u = 1.661×10^{-27} kg
1 kg has a weight of 2.205 lb when g = 9.80 m/s^2

Force
1 N = 10^5 dyn = 0.2248 lb
1 lb = 4.448 N = 4.448×10^5 dyn

Pressure
1 Pa = 1 N/m^2 = $1.450 \times 10^{-4}$$lb/in.^2$ = 0.209 lb/ft^2
1 bar = 10^5 Pa
1 $lb/in.^2$ = 6895 Pa
1 lb/ft^2 = 47.88 Pa
1 atm = 1.013×10^5 Pa = 1.013 bar
= 14.7 $lb/in.^2$ = 2117 lb/ft^2
1 mm Hg = 1 torr = 133.3 Pa

Energy
1 J = 10^7ergs = 0.239 cal
1 cal = 4.186 J (based on 15° calorie)
1 ft · lb = 1.356 J
1 Btu = 1055 J = 252 cal = 778 ft · lb
1 eV = 1.602×10^{-19} J
1 kWh = 3.600×10^6 J

Mass–Energy Equivalence
1 kg ↔ 8.988×10^{16} J
1 u ↔ 931.5 MeV
1 eV ↔ 1.074×10^{-9} u

Power
1 W = 1 J/s
1 hp = 746 W = 550 ft · lb/s
1 Btu/h = 0.293 W

APPENDIX F

NUMERICAL CONSTANTS

Fundamental Physical Constants*

Name	Symbol	Value
Speed of light	c	2.99792458×10^{8} m/s
Magnitude of charge of electron	e	$1.60217653(14) \times 10^{-19}$ C
Gravitational constant	G	$6.6742(10) \times 10^{-11}$ N · m^2/kg^2
Planck's constant	h	$6.6260693(11) \times 10^{-34}$ J · s
Boltzmann constant	k	$1.3806505(24) \times 10^{-23}$ J/K
Avogadro's number	N_A	$6.0221415(10) \times 10^{23}$ molecules/mol
Gas constant	R	8.314472(15) J/mol · K
Mass of electron	m_e	$9.1093826(16) \times 10^{-31}$ kg
Mass of proton	m_p	$1.67262171(29) \times 10^{-27}$ kg
Mass of neutron	m_n	$1.67492728(29) \times 10^{-27}$ kg
Permeability of free space	μ_0	$4\pi \times 10^{-7}$ Wb/A · m
Permittivity of free space	$\epsilon_0 = 1/\mu_0 c^2$	$8.854187817\ldots \times 10^{-12}$ C^2/N · m^2
	$1/4\pi\epsilon_0$	$8.987551787\ldots \times 10^{9}$ N · m^2/C^2

Other Useful Constants*

Mechanical equivalent of heat		4.186 J/cal (15° calorie)
Standard atmospheric pressure	1 atm	1.01325×10^{5} Pa
Absolute zero	0 K	−273.15°C
Electron volt	1 eV	$1.60217653(14) \times 10^{-19}$ J
Atomic mass unit	1 u	$1.66053886(28) \times 10^{-27}$ kg
Electron rest energy	$m_e c^2$	0.510998918(44) MeV
Volume of ideal gas (0°C and 1 atm)		22.413996(39) litre/mol
Acceleration due to gravity (standard)	g	9.80665 m/s^2

*Source: National Institute of Standards and Technology (**http://physics.nist.gov/cuu**). Numbers in parentheses show the uncertainty in the final digits of the main number; for example, the number 1.6454(21) means 1.6454 ± 0.0021. Values shown without uncertainties are exact.

Astronomical Data[†]

Body	Mass (kg)	Radius (m)	Orbit radius (m)	Orbit period
Sun	1.99×10^{30}	6.96×10^{8}	—	—
Moon	7.35×10^{22}	1.74×10^{6}	3.84×10^{8}	27.3 d
Mercury	3.30×10^{23}	2.44×10^{6}	5.79×10^{10}	88.0 d
Venus	4.87×10^{24}	6.05×10^{6}	1.08×10^{11}	224.7 d
Earth	5.97×10^{24}	6.38×10^{6}	1.50×10^{11}	365.3 d
Mars	6.42×10^{23}	3.40×10^{6}	2.28×10^{11}	687.0 d
Jupiter	1.90×10^{27}	6.91×10^{7}	7.78×10^{11}	11.86 y
Saturn	5.68×10^{26}	6.03×10^{7}	1.43×10^{12}	29.45 y
Uranus	8.68×10^{25}	2.56×10^{7}	2.87×10^{12}	84.02 y
Neptune	1.02×10^{26}	2.48×10^{7}	4.50×10^{12}	164.8 y
Pluto[‡]	1.31×10^{22}	1.15×10^{6}	5.91×10^{12}	247.9 y

[†]*Source:* NASA Jet Propulsion Laboratory Solar System Dynamics Group (**http://ssd.jpl.nasa.gov**), and P. Kenneth Seidelmann, ed., ***Explanatory Supplement to the Astronomical Almanac*** (University Science Books, Mill Valley, CA, 1992), pp. 704–706. For each body, 'radius' is its radius at its equator and 'orbit radius' is its average distance from the sun (for the planets) or from the earth (for the moon).

[‡]In August 2006, the International Astronomical Union reclassified Pluto and other small objects that orbit the sun as 'dwarf planets.'

Prefixes for Powers of 10

Power of ten	Prefix	Abbreviation	Pronunciation
10^{-24}	yocto-	y	*yoc*-toe
10^{-21}	zepto-	z	*zep*-toe
10^{-18}	atto-	a	*at*-toe
10^{-15}	femto-	f	*fem*-toe
10^{-12}	pico-	p	*pee*-koe
10^{-9}	nano-	n	*nan*-oe
10^{-6}	micro-	μ	*my*-crow
10^{-3}	milli-	m	*mil*-i
10^{-2}	centi-	c	*cen*-ti
10^{3}	kilo-	k	*kil*-oe
10^{6}	mega-	M	*meg*-a
10^{9}	giga-	G	*jig*-a or *gig*-a
10^{12}	tera-	T	*ter*-a
10^{15}	peta-	P	*pet*-a
10^{18}	exa-	E	*ex*-a
10^{21}	zetta-	Z	*zet*-a
10^{24}	yotta-	Y	*yot*-a

Examples:

1 femtometre = 1 fm = 10^{-15} m

1 picosecond = 1 ps = 10^{-12} s

1 nanocoulomb = 1 nC = 10^{-9} C

1 microkelvin = 1 μK = 10^{-6} K

1 millivolt = 1 mV = 10^{-3} V

1 kilopascal = 1 kPa = 10^{3} Pa

1 megawatt = 1 MW = 10^{6} W

1 gigahertz = 1 GHz = 10^{9} Hz

ANSWERS TO ODD-NUMBERED PROBLEMS

Chapter 1

1.1 $473\ \text{cm}^3$
1.3 $1.13 \times 10^4\ \text{kg/m}^3$
1.5 $5.49 \times 10^3\ \text{kg/m}^3$
1.7 $1.19 \times 10^4\ \text{kg/m}^3$
1.9 63.42 s older
1.11 $8 \times 10^9\ \text{mm}^2$
1.13 a) $1.1 \times 10^{-3}\%$ b) no
1.15 a) 0.1% b) 0.008% c) 0.03%
1.17 a) $2.8 \pm 0.3\ \text{cm}^3$ b) 170 ± 20
1.19 a) no b) no c) no d) no e) no
1.21 10^6
1.23 10^9
1.25 \$70 million
1.29 $\$8.5 \times 10^{11}$; about $\$4 \times 10^4$
1.31 7.8 km, 38° north of east
1.33 144 m, 41° south of west
1.35 $A_x = 0$, $A_y = -8.00$ m; $B_x = 7.50$ m, $B_y = 13.0$ m; $C_x = -10.9$ m, $C_y = -5.07$ m; $D_x = -7.99$ m, $D_y = 6.02$ m
1.37 1190 N; 13.4° above forward direction
1.39 a) 9.01 m, 33.7° b) 9.01 m, 33.7° c) 22.3 m, 250.3° d) 22.3 m, 70.3°
1.41 5.06 km, 20.2° north of west
1.43 a) 2.48 cm, 18.3° b) 4.10 cm, 83.7° c) 4.10 cm, 263.7°
1.45 781 N, 166°
1.47 $\vec{A} = -(8.00\ \text{m})\hat{j}$; $\vec{B} = (7.50\ \text{m})\hat{i} + (13.0\ \text{m})\hat{j}$; $\vec{C} = -(10.9\ \text{m})\hat{i} + (-5.07\ \text{m})\hat{j}$; $\vec{D} = (-7.99\ \text{m})\hat{i} + (6.02\ \text{m})\hat{j}$
1.49 a) $\vec{A} = (1.23\ \text{m})\hat{i} + (3.38\ \text{m})\hat{j}$; $\vec{B} = (-2.08\ \text{m})\hat{i} + (-1.20\ \text{m})\hat{j}$ b) $\vec{C} = (12.01\ \text{m})\hat{i} + (14.94\ \text{m})\hat{j}$ c) 19.17 m; 51.2°
1.51 a) no b) no; yes c) ± 0.20
1.53 a) $-104\ \text{m}^2$ b) $-148\ \text{m}^2$ c) $40.6\ \text{m}^2$
1.55 a) 165° b) 28° c) 90°
1.57 a) $63.9\ \text{m}^2$; $-\hat{k}$ b) $63.9\ \text{m}^2$; $+\hat{k}$
1.59 a) $4.61\ \text{cm}^2$; $-z$ b) $4.61\ \text{cm}^2$; $+z$
1.61 a) 1.65×10^4 km b) 2.6 earth radii
1.63 10^{28}
1.65 a) 2.94 cm b) 1.82 cm
1.67 a) 10^{50} b) 10^{57} c) 10^{79}
1.69 149 N; 32.2° north of east
1.71 b) $A_x = 3.03$ cm, $A_y = 8.10$ cm c) 8.65 cm; 69.5° from the $+x$-axis toward the $+y$-axis
1.73 144 m, 41° south of west
1.75 a) 46 N, 139°
1.77 a) (87, 258) b) 136 pixels, 25° below straight left
1.79 380 km, 28.8° south of east
1.81 160 N, 13° below horizontal
1.83 a) 911 m; 8.9° west of south
1.87 b) 90°
1.89 a) $A = 5.39$, $B = 4.36$ b) $-5.00\hat{i} + 2.00\hat{j} + 7.00\hat{k}$ c) 8.83; yes
1.93 a) 54.7° b) 35.3°
1.95 $C_x = 8.0$, $C_y = 6.1$
1.97 b) 72.2
1.99 b) (i) 0.9857 AU (ii) 1.3820 AU (iii) 1.695 c) 54.6° d) no not visible at midnight because the Sun-Mars angle is less than 90°
1.101 If $Ax + By + Cz = 0$, then $\mathbf{r}.\mathbf{S} = 0$. All points $\mathbf{r}$ are perpendicular to $\mathbf{S}$.

Chapter 2

2.1 a) 197 m/s b) 169 m/s
2.3 1 h 10 min
2.5 a) 17.1 s b) faster: 106 m; slower: 94 m
2.7 250 km
2.9 a) 12.0 m/s b) 0 m/s, 15.0 m/s, 12.0 m/s c) 13.3 s
2.11 a) 2.3 m/s, 2.3 m/s b) 2.3 m/s, 0.33 m/s
2.13 a) no b) (i) $12.8\ \text{m/s}^2$ (ii) $3.5\ \text{m/s}^2$ (iii) $0.72\ \text{m/s}^2$; yes
2.15 a) 2.00 cm/s, 50.0 cm, $-0.125\ \text{cm/s}^2$ b) 16.0 s c) 32.0 s d) 6.20 s, 1.22 cm/s; 25.8 s, -1.22 cm/s; 36.4 s, -2.55 cm/s
2.17 a) $2.8\ \text{m/s}^2$ assume 10s to accelerate b) $-6.9\ \text{m/s}^2$ assume 4s to break
2.21 a) 5.0 m/s b) $1.43\ \text{m/s}^2$
2.23 a) $675\ \text{m/s}^2$ b) 0.067 s
2.25 1.70 m
2.27 a) (i) $5.59\ \text{m/s}^2$ (ii) $7.74\ \text{m/s}^2$ b) (i) 179 m (ii) 12,800 m
2.29 a) +2.7 cm/s, −1.3 cm/s b) $-1.3\ \text{cm/s}^2$ c) 22.5 cm; 25.5 cm
2.31 a) 0, $6.3\ \text{m/s}^2$, $-11.2\ \text{m/s}^2$ b) 100 m, 230 m, 320 m
2.33 a) 1.80×10^4 m/s b) 0.957 c) 6 h 11 min
2.35 b) 1 s, 3 s d) 2 s e) 3 s f) 1 s
2.37 a) *A:* 20.5 m/s^2; *B:* 3.8 m/s^2; *C:* 53 m/s^2 b) 721 km
2.39 a) 2.94 m/s b) 0.599 s
2.41 a) $t = \sqrt{2d/g}$ b) 0.190 s
2.43 a) 646 m b) 16.4 s, 112 m/s
2.45 a) 25.6 m/s b) 31.6 m c) 15.2 m/s
2.47 a) $249\ \text{m/s}^2$ b) 25.4 c) 101 m d) no
2.49 $0.0868\ \text{m/s}^2$
2.51 a) $x(t) = (0.250\ \text{m/s}^3)t^3 - (0.0100\ \text{m/s}^4)t^4$; $v_x(t) = (0.750\ \text{m/s}^3)t^2 - (0.0400\ \text{m/s}^4)t^3$ b) 39.1 m/s
2.53 a) 30.0 cm/s
2.55 b) 0.627 s, 1.60 s c) negative at 0.627 s, positive at 1.60 s d) 1.11 s e) 2.45 m f) 2.00 s, 0 s
2.57 a) 73.8 km/h b) 24 km/h
2.59 a) $3.5\ \text{m/s}^2$ b) 0 c) $1.5\ \text{m/s}^2$
2.61 a) 92.0 m b) 92.0 m
2.63 a) 464 m/s b) 2.99×10^4 m/s c) 7.48
2.65 50.0 m
2.67 $4.6\ \text{m/s}^2$
2.69 a) 6.17 s b) 24.8 m c) $v_{\text{truck}} = 13.0$ m/s, $v_{\text{auto}} = 21.0$ m/s
2.71 a) 7.85 cm/s b) 5.00 cm/s, horizontal from the initial to final position
2.73 a) 15.9 s b) 393 m c) 29.5 m/s
2.75 a) −4.00 m/s b) 12.0 m/s
2.77 a) $2.64H$ b) $2.64T$
2.79 a) no b) yes; 14.4 m/s; not physically attainable
2.81 a) $6.79 \times 10^4 g$ b) 1.45 m/s c) $H/4$
2.83 a) 7.59 m/s b) 5.14 m c) 1.60 s
2.85 a) 7.7 m/s b) 0.78 s c) 0.59 s d) 1.3 m
2.87 270 m
2.89 a) 20.5 m/s b) yes
2.91 a) 947 m b) 393 m
2.93 a) A b) 2.27 s, 5.73 s c) 1.00 s, 4.33 s d) 2.67 s
2.95 a) 9.55 s, 47.8 m b) 1.62 m/s d) 8.38 m/s e) no f) 3.69 m/s, 21.7 s, 80.0 m
2.97 a) 8.18 m/s b) (i) 0.411 m (ii) 1.15 km c) 9.80 m/s d) 4.90 m/s

Chapter 3

3.1 a) $v_{\text{av-}x} = 1.4$ m/s, $v_{\text{av-}y} = -1.3$ m/s b) 1.9 m/s, −43°
3.3 a) 7.1 cm/s, 45° b) 5.0 cm/s, 90°; 7.1 cm/s; 45°; 11 cm/s, 27°
3.5 b) $a_{\text{av-}x} = -8.67\ \text{m/s}^2$, $a_{\text{av-}y} = -2.33\ \text{m/s}^2$ c) $8.98\ \text{m/s}^2$, 195°
3.7 b) $\vec{v} = \alpha\hat{i} + (-2t)\hat{j}$; $\vec{a} = -2\beta\hat{j}$ c) $v = 5.4$ m/s, −63°; $a = 2.4\ \text{m/s}^2$, −90° d) speeding up and turning right
3.9 a) 0.600 m b) 0.385 m c) $v_x = 1.10$ m/s, $v_y = -3.43$ m/s; $v = 3.60$ m/s, 72.2° below the horizontal
3.11 3.32 m
3.13 a) 30.6 m/s b) 36.3 m/s
3.15 $1.29\ \text{m/s}^2$
3.17 a) 40.0 m/s, 69.3 m/s b) 7.07 s c) 245 m d) 565 m e) $a_x = 0$, $a_y = -9.80\ \text{m/s}^2$; $v_x = 40.0$ m/s, $v_y = 0$
3.19 a) 0.682 s, 2.99 s b) 24.0 m/s, 11.3 m/s; 24.0 m/s, −11.3 m/s c) 30.0 m/s, −36.9°
3.21 a) 1.5 m b) −0.89 m/s
3.23 a) 13.6 m b) 34.6 m/s c) 103 m
3.25 a) 296 m b) 176 m c) 198 m (i) horizontal: 15 m/s; vertical: 58.8 m/s (ii) horizontal: 15 m/s; vertical: 78.8 m/s
3.27 795 m
3.29 a) $0.034\ \text{m/s}^2$, $0.0034g$ b) 1.4 h
3.31 a) 3.07 s b) 1.68 s
3.33 a) $3.50\ \text{m/s}^2$, upward b) $3.50\ \text{m/s}^2$, downward c) 12.6 s
3.35 a) 32.9 m/s b) $27.7\ \text{m/s}^2$ c) 35.5 rpm
3.37 a) 14 s b) 70 s
3.39 0.36 m/s, 38° west of south
3.41 a) 4.7 m/s, 25° south of east b) 190 s c) 380 m
3.43 b) −7.1 m/s, −42 m/s c) 43 m/s, 9.5° west of south
3.45 a) $A = 0$, $B = 2.00\ \text{m/s}^2$, $C = 50.0$ m, $D = 0.50\ \text{m/s}^3$ b) $\vec{a} = (4.00\ \text{m/s}^2)\hat{i}$, $v = 0$ c) $v_x = 40.0$ m/s, $v_y = 150$ m/s, $v = 155$ m/s c) $\vec{r} = (200\ \text{m})\hat{i} + (550\ \text{m})\hat{j}$
3.47 a) 124 m b) 280 m
3.49 22 m/s
3.51 40 m/s
3.53 274 m
3.55 a) 42.8 m/s b) 42.0 m
3.57 a) $\sqrt{2gh}$ b) 30.0° c) $6.93h$
3.59 c) less than 45°
3.61 b) 15°, 75°
3.63 a) 17.8 m/s b) in river, 28.4 m from the near bank
3.65 a) 81.6 m b) in cart c) 245 m d) 53.1°
3.67 a) 49 m/s b) 50 m
3.69 a) 2000 m b) 2180 m

14.75 risen by 5.57×10^{-4} m
14.77 a) $1 - \rho_B/\rho_L$ b) $(\rho_L - \rho_B)L/(\rho_L - \rho_W)$ c) 4.60 cm
14.79 a) la/g b) $\omega^2 l^2/2g$
14.83 a) $2\sqrt{h(H-h)}$ b) h
14.85 a) 0.200 m^3/s b) 6.97×10^4 Pa
14.87 $3h_1$
14.89 a) $r = r_0(1 + 2gy/v_0^2)^{-1/4}$ b) 1.10 m
14.91 a) 80.4 N
14.93 a) $\sqrt{2gh}$ b) $(p_a/\rho g) - h$

Chapter 15

15.1 a) 0.439 m; 1.28 ms b) 0.219 m
15.3 220 m/s = 800 km/h
15.5 a) 4.3×10^{14} Hz to 7.5×10^{14} Hz; 1.3×10^{-15} s to 2.3×10^{-15} s b) no
15.7 a) $f = 25.0$ Hz, $T = 0.0400$ s, $k = 19.6$ rad/m b) $y(x,t) = (0.0700\text{ m})\cos 2\pi\left(\dfrac{x}{0.320\text{ m}} + \dfrac{t}{0.0400\text{ s}}\right)$ c) +0.0495 m d) 0.0050 s
15.9 a) yes b) no c) no d) $v_y(x,t) = \omega A\cos(kx + \omega t)$, $a_y(x,t) = -\omega^2 A\sin(kx + \omega t)$
15.11 a) 4.0 mm b) 0.040 s c) 0.14 m, 3.6 m/s d) 0.24 m, 6.0 m/s e) no
15.13 b) $+x$-direction
15.15 a) 16.3 m/s b) 0.136 m c) both increase by factor of $\sqrt{2}$
15.17 a) 18.6 N b) 29.1 m/s
15.19 a) 10.0 m/s b) 0.250 m c) $y(x,t) = (3.00\text{ cm})\cos[(8.00\pi\text{ rad/m})x - (80.0\pi\text{ rad/s})t]$ d) 1890 m/s^2 e) yes
15.21 a) 95 km b) 2.5×10^{-7} W/m^2 c) 1.1×10^5 W
15.23 a) 0.050 W/m^2 b) 2.2×10^4 J
15.25 707 W
15.33 a) $(1.33\text{ m})n$, $n = 0, 1, 2, 3, \ldots$ b) $(1.33\text{ m})(n + \frac{1}{2})$, $n = 0, 1, 2, 3, \ldots$
15.39 a) 96.0 m/s b) 461 N c) 1.13 m/s, 426 m/s^2
15.41 b) 2.80 cm c) 277 cm d) 185 cm, 7.96 Hz 0.126 s, 1470 cm/s e) 280 cm/s f) $y(x,t) = (5.60\text{ cm})\sin[(0.0907\text{ rad/cm})x]\sin([133\text{ rad/s}]t)$
15.43 a) $y(x,t) = (4.60\text{ mm})\sin[(6.98\text{ rad/m})x]\sin([742\text{ rad/s}]t)$ b) 3rd c) 39.4 Hz
15.45 a) 45.0 cm b) no
15.47 a) 311 m/s b) 246 Hz c) 245 Hz, 1.40 m
15.49 a) 20.0 Hz, 126 rad/s, 3.49 rad/m b) $y(x,t) = (2.50\text{ mm})\cos[(3.49\text{ rad/m})x - (126\text{ rad/s})t]$ c) $y(t) = (2.50\text{ mm})\cos[(126\text{ rad/s})t]$ d) $y(t) = (2.50\text{ mm})\cos[3\pi/2 - (126\text{ rad/s})t]$ e) 0.314 m/s f) -2.50 mm, 0
15.51 a) $(7L/2)\sqrt{\mu_1/F}$ b) no
15.53 a) $(2\pi A/\lambda)\sqrt{FL/M}$ b) increase by a factor of 4
15.55 a) $4\pi^2 F\Delta x/\lambda^2$
15.57 a) 1, 0; 2, +; 3, −; 4, 0; 5, −; 6, + b) 1, −; 2, +; 3, −; 4, +; 5, −; 6, 0 c) (a): answers would reverse sign; (b): no change
15.61 c) C/B
15.63 b) k decreases by a factor of $2\sqrt{2}$; ω decreases by a factor of $\sqrt{2}$
15.65 a) 7.07 cm b) 400.0 W
15.67 $\alpha = (v_1^2 - v_2^2)\rho/Y\Delta T$
15.69 $n(0.800\text{ Hz})$, $n = 1, 2, 3, \ldots$
15.71 b) yes
15.73 c) $2A$, $2A\omega$, $2A\omega^2$
15.75 230 N
15.77 a) 0, L b) 0, $L/2$, L d) no
15.79 a) 148 N b) 26%
15.81 b) $\frac{1}{2}\mu\omega^2 A^2\sin^2(kx - \omega t)$ e) $\frac{1}{2}Fk^2A^2\sin^2(kx - \omega t)$
15.83 $\pi/\omega\sqrt{2}$
15.85 a) 99.4 N c) −4.25 Hz, falls

Chapter 16

16.1 a) 0.344 m b) 1.2×10^{-5} m c) 6.9 m, 50 Hz
16.3 a) 7.78 Pa b) 77.8 Pa c) 778 Pa
16.5 a) 1.33×10^{10} Pa b) 9.47×10^{10} Pa
16.7 90.8 m
16.9 81.5°C
16.11 0.208 s
16.13 $Y/900$
16.15 a) 9.44×10^{-11} m; 0.434 m b) 5.66×10^{-9} m; 0.101 m c) air; $A_{\text{air}}/A_{\text{water}} = 60.0$
16.17 a) 1.94 Pa b) 4.58×10^{-3} W/m^2 c) 96.6 dB
16.19 a) 4.4×10^{-12} W/m^2 b) 6.39 dB c) 5.8×10^{-11} m
16.21 14.0 dB
16.23 a) 20.0
16.25 a) *fundamental:* displacement node at 0.60 m, pressure nodes at 0 and 1.20 m; *first overtone:* displacement nodes at 0.30 m and 0.90 m, pressure nodes at 0. 0.60 m, and 1.20 m; *second overtone:* displacement nodes at 0.20 m, 0.60 m, and 1.00 m, pressure nodes at 0, 0.40 m, 0.80 m, and 1.20 m b) *fundamental:* displacement node at 0, pressure node at 1.20 m; *first overtone:* displacement nodes at 0 and 0.80 m, pressure nodes at 0.40m and 1.20 m, and; *second overtone:* displacement nodes at 0, 0.48 m, and 0.96 m, pressure nodes at 0.24 m, 0.72 m, 1.20 m
16.27 506 Hz, 1520 Hz, 2530 Hz
16.29 a) 767 Hz b) no
16.31 a) 614 Hz b) 1.23 kHz
16.33 a) 172 Hz b) 86 Hz
16.35 0.125 m
16.37 destructive
16.39 1.3 Hz
16.41 780 m/s
16.43 a) 375 Hz b) 371 Hz c) 4 Hz
16.45 a) 0.25 m/s b) 0.91 m
16.47 19.8 m/s
16.49 26.8 Hz
16.51 0.095c; toward us
16.53 a) 36.0° b) 2.23 s
16.55 a) 1.00 b) 8.00 c) 47.3 nm
16.57 b) $3f_0$ c) $v = 4Lf_0$
16.59 flute harmonic $3N$($N = 1, 3, \ldots$) resonates with string harmonic $4N$
16.61 a) stopped b) $n = 7$, $n = 9$ c) 43.9 cm
16.63 a) $v/(2L)$, v/L, $3v/(2L)$
16.65 a) 375 m/s b) 1.39 c) 0.8 cm
16.67 a) $n(77.3\text{ Hz})$, $n = 1, 2, 3, \ldots$
16.69 1.27
16.71 a) 548 Hz b) 652 Hz
16.73 a) $I = 2\pi^2\sqrt{\rho B f^2}(\Delta R)^2$ b) $P = 8\pi^3\sqrt{\rho B f^2 R^2}(\Delta R)^2$ c) $A = (R/d)\Delta R$, $p_{\max} = 2\pi\sqrt{\rho B}(Rf/d)\Delta R$, $I = 2\pi^2\sqrt{\rho B}(fR/d)^2(\Delta R)^2$
16.75 a) 6.74 cm b) 147 Hz
16.77 b) 2.0 m/s
16.79 a) 1.2×10^6 m/s b) 3.6×10^{16} m = 3.8 ly c) 5.2×10^3 ly; 4100 BCE
16.81 a) $f_0\left(\dfrac{2v_W}{v - v_W}\right)$ b) $f_0\left(\dfrac{2v_W}{v + v_W}\right)$
16.83 d) 9.69 cm/s; 6.67×10^2 m/s^2

Chapter 17

17.1 21 K
17.3 −10.0 C°
17.5 a) 313.35 K; yes b) 285.15 K
17.7 63 K
17.9 a) −282°C b) no, 4.76×10^4 Pa
17.11 0.39 m

18.59 1.92 atm
18.61 a) 31 b) 8.41×10^3 N c) 7.8×10^3 N
18.63 a) 26.2 m/s b) 16.1 m/s, 5.44 m/s
c) 1.74 m
18.65 5.0×10^{27}
18.67 a) same translational kinetic energy; A has greater rms speed b) B c) 4250°C d) B
18.69 b) 303 mol/m^3 c) van der Waals
18.71 a) 4.65×10^{-26} kg b) 6.11×10^{-21} J
c) 2.04×10^{24} molecules d) 1.24×10^4 J
18.73 b) r_2 c) $r_1 = R_0/2^{1/6}$, $r_2 = R_0$, $r_1/r_2 = 2^{-1/6}$
d) U_0
18.75 a) 517 m/s b) 299 m/s
18.77 b) 1.40×10^5 K, 1.01×10^4 K
c) 6.37×10^3 K, 4.59×10^2 K
18.79 a) 1.24×10^{-14} kg b) 4.16×10^{11}
c) 2.95×10^{-6} m, no
18.81 a) $2R = 16.6$ J/mol · K b) less
18.83 CO_2: 20.79 J/mol · K, 0.270; SO_2: 24.94 J/mol · K, 0.205; H_2S: 24.94 J/mol · K, 0.039
18.87 b) $0.0420N$ c) $(2.94 \times 10^{-21})N$
d) $0.0297N$, $(2.08 \times 10^{-21})N$ e) $0.0595N$, $(4.15 \times 10^{-21})N$
18.89 42.6%
18.91 a) 4.5×10^{11} m b) 703 m/s, 6.4×10^8 s (about 20 y). no c) 1.4×10^{-14} Pa
d) about 650 m/s; evaporate
f) 2×10^5 K; no

Chapter 19

19.1 b) 1330 J
19.3 b) −6540 J
19.5 a) 0.88 atm
19.7 a) $(p_1 - p_2)(V_2 - V_1)$ b) negative of work done in reverse direction
19.9 a) 3.78×10^4 J b) 7.72×10^4 J c) no
19.11 a) 410 J b) rises
19.13 a) 16.4 min b) 139 m/s = 501 km/h
19.15 a) zero b) $T_b = 2T_a$ c) $U_b = U_a + 400$ J
19.17 a) positive b) I: positive; II: negative
c) into d) I: into; II: out of
19.19 a) 1.67×10^5 J b) 2.03×10^6 J
19.21 b) 208 J c) on the piston d) 712 J
e) 920 J f) 208 J
19.23 a) 948 K b) 900 K
19.25 2/5
19.27 a) 25.0 C° b) 17.9 C° c) a
19.29 a) −605 J b) 0 c) yes, 605 J, liberates
19.31 a) 747 J b) 1.30
19.33 a) 4.76×10^5 Pa b) -1.06×10^4 J
c) 1.59; heated
19.35 5.1×10^3 J; increases; increases
19.37 b) 224 J c) −224 J
19.39 11.6°C
19.41 a) increases b) 4800 J
19.43 a) 45.0 J b) liberates 65.0 J
c) $Q_{ad} = 23.0$ J, $Q_{ab} = 22.0$ J
19.45 a) same b) absorbs 4000 J
c) absorbs 8000 J
19.47 b) −2460 J
19.49 a) 1173 K b) 1.22×10^4 J
c) 4.26×10^4 J d) 4.57×10^4 J
19.51 −0.226 m^3
19.53 a) 4.32×10^{-4} m^3 b) 648 J
c) 7.15×10^5 J d) 7.15×10^5 J
e) no substantial difference
19.55 3.4×10^5 J/kg
19.57 b) $W = p_0V_0[1 + \frac{C_V}{R}(2 - 2^{2-\gamma})]$
c) $T_3 = T_0(2)^{2-\gamma}$.
d) $Q = p_0V_0(\frac{C_V}{R} + 1)$ heat flows into the gas, $Q > 0$.
19.59 b) $m = 1.02 \times 10^{-3}$ kg, 44%
c) $m = 9.16 \times 10^{-4}$ kg, 30%
19.61 a) $W = 738$ J, $Q = 2588$ J, $\Delta U = 1850$ J
b) $W = 0$, $Q = -1850$ J, $\Delta U = -1850$ J
c) 0
19.63 a) $W = -187$ J, $Q = -654$ J, $\Delta U = -467$ J
b) $W = 113$ J, $Q = 0$, $\Delta U = -113$ J
c) $W = 0$, $Q = 580$ J, $\Delta U = 580$ J
19.65 a) 360 K, 2.67×10^5 Pa b) 1.14 L

Chapter 20

20.1 a) 6500 J b) 34%
20.3 a) 23% b) 12,400 J c) 0.350 g
d) 222 kW = 298 hp
20.5 a) 25% b) 970 MW
20.7 13.8
20.9 a) 1.62×10^4 J b) 5.02×10^4 J
20.11 a) 767 W b) 7.27
20.13 a) 215 J b) 378 K c) 39.1%
20.15 a) 4.2×10^4 J b) 715 K
20.17 a) 492 J b) 212 W c) 5.4
20.19 a) 400 W b) 10.7 c) 36.9 kg
20.21 4500 J
20.23 37.1 hp
20.25 a) 428 J/K b) −392 J/K c) 36 J/K
20.27 a) irreversible b) $+1.25 \times 10^4$ J/K; it is consistent
20.29 −6.31 J/K
20.31 a) 6.05×10^3 J/K b) five time greater for vaporization
20.33 gallium: +6.63 J/K; hand: −6.48 J/K; greater for gallium
20.35 a) no b) 18.3 J/K c) 18.3 J/K
20.37 a) 0.200 b) 8000 J
20.39 a) 27.8 C° b) 15.3 C°
20.41 b) absorbed: *bc;* rejected: *ab, ca*
c) $T_a = T_b = 241$ K, $T_c = 481$ K
d) $Q_{net} = W_{net} = 610$ J e) 8.7%
20.43 a) enters: 2.10×10^4 J; leaves: 1.66×10^4J
b) 4.4×10^3 J; 21% c) maximum is $e = 67\%$
20.45 a) 7.0% b) 3.0×10^6 J/s; 2.8×10^6 J/s
c) 6×10^5 kg/h = 6×10^5 L/h
20.47 a) $p_1 = 2.00$ atm, $V_1 = 4.00$ L; $p_2 = 2.00$ atm, $V_2 = 6.00$ L; $p_3 = 1.11$ atm, $V_3 = 6.00$ L; $p_4 = 1.67$ atm, $V_4 = 4.00$ L
b) (i) $Q = 1422$ J, $W = 405$ J
(ii) $Q = -1355$ J, $W = 0$
(iii) $Q = W = -274$ J (iv) $Q = 339$ J, $W = 0$ c) 131 J d) 7.5%; $e_{Carnot} = 44\%$
20.49 a) $a \to b$: $Q = 2.25 \times 10^5$ J, $W = 0.90 \times 10^5$ J, $\Delta U = 1.35 \times 10^5$ J; $b \to c$: $Q = -2.40 \times 10^5$ J, $W = 0$, $\Delta U = -2.40 \times 10^5$ J; $c \to a$: $Q = 0.45 \times 10^5$ J, $W = -0.60 \times 10^5$ J, $\Delta U = 1.05 \times 10^5$ J b) $Q = W = 0.30 \times 10^5$ J, $\Delta U = 0$ c) 11.1%
20.51 $1 - T_C/T_H$; same
20.53 a) 122 J, 78 J b) 5.10×10^{-4} m^3
c) $p_b = 2.32 \times 10^6$ Pa, $V_b = 4.81 \times 10^{-5}$ m^3, $T_b = 771$ K; $p_c = 4.00 \times 10^6$ Pa, $V_c = 4.81 \times 10^{-5}$ m^3, $T_c = 1333$ K; $p_d = 1.47 \times 10^5$ Pa, $V_d = 5.10 \times 10^{-4}$ m^3, $T_d = 518$ K d) $e = 61.1\%$; $e_{Carnot} = 77.5\%$
20.55 b) 6.20×10^4 J c) 3.42×10^4 J
d) before: 6.20×10^4J; after: 3.42×10^4 J
20.57 a) 88.5 J b) 17.7 J
20.59 a) $b \to c$: $nC_V \ln(T_c/T_b)$; $d \to a$: $nC_V \ln(T_a/T_d)$
b) zero
20.61 a) −143 J/K b) +196 J/K c) zero
d) +53 J/K

Chapter 21

21.1 a) 2.0×10^{10} b) 8.58×10^{-13}
21.3 2.10×10^{28} electrons, 3.35×10^9 C
21.5 3.71×10^3 m
21.7 a) 7.42×10^{-7} C on each sphere
b) 3.71×10^{-7} C on one and 1.48×10^{-6} C on the other
21.9 1.43×10^{13}, away from each other
21.11 a) 2.20×10^4 m/s
21.13 +0.750 nC
21.15 1.8×10^{-4} N, +x-direction
21.17 $x = -0.144$ m
21.19 2.58×10^{-6} N, −y-direction
21.21 b) $F_x = 0$, $F_y = +2kqQa/(a^2 + x^2)^{3/2}$
c) $2kqQ/a^2$, +y-direction
21.23 b) $kq^2(1 + 2\sqrt{2})/2L^2$
21.25 a) 4.40×10^{-16} N b) 2.63×10^{11} m/s^2
c) 2.63×10^5 m/s
21.27 a) 3.31×10^6 N/C, to the left
b) 1.42×10^{-8} s c) 1.80×10^3 N/C, to the right
21.29 a) $-21.9\mu C$ b) 1.02×10^{-7} N/C
21.31 a) 8.75×10^3 N/C,to the right
b) 6.54×10^3 N/C,to the right
c) 1.40×10^{-15} N,to the right
21.33 a) 364 N/C b) no, 2.73 μm downward
21.35 1.79×10^6 m/s

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

21.37 a) $mg = 8.93 \times 10^{-30}$ N; $F_e = 1.60 \times 10^{-15}$ N; yes
b) 1.63×10^{-16} kg $= 1.79 \times 10^{14} m_e$ c) no
21.39 a) $-\hat{j}$ b) $(\hat{i} + \hat{j})/\sqrt{2}$ c) $-0.390\hat{i} + 0.921\hat{j}$
21.41 a) 6.33×10^5 m/s b) 1.59×10^4 m/s
21.43 a) 0 b) $E_x = -2kq(x^2 + a^2)/(x^2 - a^2)^2$, for $x < -a$; $E_x = +2kq(x^2 + a^2)/(x^2 - a^2)^2$, for $x > +a$
21.45 a) (i) 574 N/C, $+x$-direction
(ii) 268 N/C, $-x$-direction
(iii) 404 N/C, $-x$-direction
b) (i) 9.20×10^{-17} N, $-x$-direction
(ii) 4.30×10^{-17} N, $+x$-direction
(iii) 6.48×10^{-17} N, $+x$-direction
21.47 1.04×10^7 N/C, to the left
21.49 a) $E_x = E_y = E = 0$
b) $E_x = +2.66 \times 10^3$ N/C, $E_y = 0$; $E = 2.66 \times 10^3$ N/C, $+x$-direction
c) $E_x = +129$ N/C, $E_y = -510$ N/C; $E = 526$ N/C, 284° clockwise from $+x$-axis
d) $E_x = 0$, $E_y = E = +1.38 \times 10^3$ N/C, $+y$-direction
21.51 a) $E_x = -4.79 \times 10^3$ N/C, $E_y = 0$; $E = 4.79 \times 10^3$ N/C, $-x$-direction
b) $E_x = +2.13 \times 10^3$ N/C, $E_y = 0$; $E = 2.13 \times 10^3$ N/C, $+x$-direction
21.53 a) $\vec{E} = \dfrac{2k\lambda}{x\sqrt{x^2/a^2 + 1}}\hat{i}$ b) $\vec{E} = \dfrac{2k\lambda}{x}\hat{i}$
21.55 a) $(7.0\text{ N/C})\hat{i}$ b) $(1.75 \times 10^{-5}\text{ N})\hat{i}$
21.57 a) 0 b) 0 c) σ/ϵ_0 directed downward
21.59 a) yes b) no
21.61 An infinite line of charge has a radial field in the plane through the wire, and constant in the plane of the wire, mirror-imaged about the wire
21.63 a) 1.4×10^{-11} C · m from q_1 toward q_2
b) 860 N/C
21.65 b) This also gives the correct expression for E_y since y appears in the full expression's denominator squared, so the signs carry through correctly.
21.67 b) Opposite charges are closest so the dipoles attract.
21.69 a) The torque is zero when $\vec{p}$ is aligned either in the *same* direction as $\vec{E}$ or in the *opposite* directions
b) The stable orientation is when $\vec{p}$ is aligned in the *same* direction as $\vec{E}$
21.71 1680 N, from $+5.00\ \mu$C charge toward $-5.00\ \mu$C charge
b) 22.3 N · m, clockwise
21.73 a) $\sqrt{\dfrac{kqQ}{m\pi^2 a^3}}$ b) accelerating along the y-axis away from origin
21.75 b) 2.80×10^{-6}C c) 39.5°
21.77 a) 2.09×10^{21} N b) 5.90×10^{23} m/s^2 c) no
21.79 a) $6kq^2/L^2$, away from vacant corner
b) $(3kq^2/2L^2)(1 + 2\sqrt{2})$, toward center of square
21.81 a) 6.0×10^{23}
b) $F_g = 4.1 \times 10^{-31}$ N, $F_e = 5.1 \times 10^5$ N
c) yes for F_e and no for F_g
21.83 a) $(2kq/x^2)[1 - (1 + a^2/x^2)^{-3/2}]$, $-x$-direction
b) $3kqa^2/x^4$
21.85 a) 3.5×10^{20} b) 1.6 C; 2.4×10^{10} N
21.87 a) $(mv_0^2 \sin^2\alpha)/2eE$ b) $(mv_0^2 \sin^2 2\alpha)/eE$
c) $h_{max} = 0.418$ m, $d = 2.89$ m
21.89 a) $E_x = \dfrac{kQ}{a}\left(\dfrac{1}{r} - \dfrac{1}{a + r}\right)$, $E_y = 0$
b) $\dfrac{kqQ}{a}\left(\dfrac{1}{x - a} - \dfrac{1}{x}\right)\hat{i}$
21.91 a) $-(7850\text{ N/C})\hat{i}$ b) smaller c) 18 cm
21.93 a) $+(0.89\text{ N/C})\hat{i}$ b) smaller c) (i) 1.2% (ii) 4.5%
21.95 a) $F = \dfrac{2kqQ}{a}\left(\dfrac{1}{y} - \dfrac{1}{\sqrt{a^2 + y^2}}\right)$, $-x$-direction
b) $F = \dfrac{kqQ}{a}\left(\dfrac{1}{x - a} - \dfrac{1}{x + a} - \dfrac{2}{x}\right)$, $+x$-direction
21.97 $E_x = E_y = 2kQ/a^2$
21.99 a) 6.25×10^4 N/C, 225° measured counterclockwise from $+x$-axis
b) 1.00×10^{-14} N, 45° measured counterclockwise from $+x$-axis
21.101 a) 1.19×10^6 N/C, to the left
b) 1.19×10^5 N/C, to the left
c) 1.19×10^5 N/C, to the right
21.103 $\vec{E} = \dfrac{\sigma}{2\epsilon_0}\left[-\dfrac{x}{|x|}\hat{i} + \dfrac{z}{|z|}\hat{k}\right]$
21.105 b) $q_1 < 0$, $q_2 > 0$ c) 0.844 μC d) 56.2 N
21.107 a) $\dfrac{kQ}{L}\left[\dfrac{1}{x + a/2} - \dfrac{1}{x + L + a/2}\right]$

Chapter 22

22.1 a) 1.75 N · m^2/C b) no c) i) 0 ii) 90°
22.3 a) 3.53×10^5 N · m^2/C b) 3.13×10^{-6} C
22.5 $\Phi = E\pi r^2$
22.7 a) 2.71×10^5 N · m^2/C
b) 2.71×10^5 N · m^2/C
c) 5.42×10^5 N · m^2/C
22.9 a) zero b) 3.75×10^7 N/C radially inward
c) 1.11×10^7 N/C radially inward
22.11 b) no
22.13 a) 1.81×10^5 N · m^2/C b) no change
22.15 a) 4.50×10^4 N/C b) 9.18×10^2 N/C
22.17 a) 3.00×10^{-7} C b) 1.20×10^5 N/C
22.19 a) $q = 3.27 \times 10^{-9}$ C b) $n_e = 2.04 \times 10^{10}$
22.21 8.06×10^5 N/C, toward negatively charged sphere
22.23 a) 5.73×10^{-6} C/m^2 b) 6.48×10^5 N/C
c) -5.65×10^4 N · m^2/C
22.25 a) 2.59×10^{-7} C/m^3 b) 1.96×10^3 N/C
22.27 a) $E = \sigma/\epsilon_0$ b) 0
22.29 a) $\lambda = 2\pi r\sigma$ b) $\sigma R/r\epsilon_0$
22.31 a) yes; $+Q$ b) no c) yes d) no; no e) no; yes; no
22.33 a) 750 N · m^2/C b) 0 c) 577 N/C
22.35 a) -5.98×10^{-10} C
22.37 a) $\lambda/2\pi\epsilon_0 r$, radially outward
b) $\lambda/2\pi\epsilon_0 r$, radially outward
d) inner: $-\lambda$; outer: $+\lambda$
22.39 a) i) $\alpha/2\pi\epsilon_0 r$, radially outward ii) 0 iii) 0
b) i) $-\alpha$ ii) 0
22.41 $\theta = 19.8°$
22.43 a) $0 < r < R$, $E = 0$
$R < r < 2R$, $E = Q/4\pi\epsilon_0 r^2$, radially outward;
$r > 2R$, $E = 2Q/4\pi\epsilon_0 r^2$, radially outward
22.45 a) i) 0 ii) 0 iii) $q/2\pi\epsilon_0 r^2$, radially outward iv) 0 v) $3q/2\pi\epsilon_0 r^2$, radially outward b) i) 0 ii) $+2q$ iii) $-2q$ iv) $+6q$
22.47 a) i) 0 ii) 0 iii) $q/2\pi\epsilon_0 r^2$, radially outward iv) 0 v) $q/2\pi\epsilon_0 r^2$, radially inward b) i) 0 ii) $+2q$ iii) $-2q$ iv) $-2q$
22.49 a) $Qq/4\pi\epsilon_0 r^2$, toward the center of the shell
b) 0
22.51 a) The given σ is on both sides, so E is twice as great b) $\Phi = (\sigma A)/\epsilon_0$, but $E_{out} = \sigma/\epsilon_0$, so $E_{in} = 0$
22.53 $d = R/2$
22.55 b) for $|x| \le d$: $\vec{E} = (\rho_0 x^3/3\epsilon_0 d^2)\hat{i}$;
for $|x| \ge d$: $\vec{E} = (\rho_0 d/3\epsilon_0)(x/|x|)\hat{i}$
22.57 c) $E(r) = \dfrac{Q}{\pi\epsilon_0 R}\left(\dfrac{r}{R} - \dfrac{3r^2}{4R^2}\right)$
e) $E_{max} = Q/3\pi\epsilon_0 R^2$ at $r = 2R/3$
22.59 a) $\Phi = 4\pi GMm$ b) $\Phi = -4\pi GM_{encl}$
22.61 $\rho\vec{b}/3\epsilon_0$
22.63 a) $-(Q/16\pi\epsilon_0 R^2)\hat{i}$ b) $(Q/72\pi\epsilon_0 R^2)\hat{i}$
22.65 a) $Q(r) = Qe^{-2r/a_0}[2(r/a_0)^2 + 2(r/a_0) + 1]$
b) $E = \dfrac{kQe^{-2r/a_0}}{r^2}[2(r/a_0)^2 + 2(r/a_0) + 1]$
22.67 c) 0.807

Chapter 23

23.3 3.46×10^{-13} J
23.5 a) 12.5 m/s b) 0.323 m
23.7 a) 0.198 J b) i) 26.6 m/s ii) 36.7 m/s iii) 37.6 m/s
23.9 a) -3.60×10^{-7} J b) $x = 0.0743$ m
23.11 $-q/2$
23.13 B: larger C: smaller D: same
23.15 7.42 m/s; faster
23.17 a) 0 b) $+7.50 \times 10^{-4}$ J
c) -2.06×10^{-3} J
23.19 a) 2.50 mm b) 7.49 mm
23.21 a) -737 V b) -704 V c) $+8.2 \times 10^{-8}$ J
23.23 b) 0 d) 0
23.25 b) $V = \dfrac{q}{4\pi\epsilon_0}\left(\dfrac{1}{|x|} - \dfrac{2}{|x - a|}\right)$
23.27 1.02×10^7 m/s
23.29 a) b b) 800 V/m c) -4.8×10^{-5} J
23.31 a) increase of 156 V b) decrease of 182 V
23.33 a) oscillatory b) 1.67×10^7 m/s
23.35 a) $\lambda = 9.51$ C/m b) no. less.
V decreases in direction of $\vec{E}$.
$\lambda > 0$: V inversely proportional to r
c) 0
23.37 a) 7.81×10^4 V b) 0
23.41 a) 8.00 kV/m b) 1.92×10^{-7} N
c) 8.64×10^{-7} J d) -8.64×10^{-7} J
23.43 b) -20 nC c) no
23.47 a) $E_x = -Ay + 2Bx$, $E_y = -Ax - C$, $E_z = 0$
b) $x = -C/A$, $y = -2BC/A^2$, any value of z
23.49 a) i) for $r < r_a$, $V = \dfrac{q}{4\pi\epsilon_0}\left(\dfrac{1}{r_a} - \dfrac{1}{r_b}\right)$
ii) for $r_a < r < r_b$, $V = \dfrac{q}{4\pi\epsilon_0}\left(\dfrac{1}{r} - \dfrac{1}{r_b}\right)$
iii) for $r > r_b$, $V = 0$
b) $V_{ab} = \dfrac{q}{4\pi\epsilon_0}\left(\dfrac{1}{r_a} - \dfrac{1}{r_b}\right)$
c) for $r_a < r < r_b$, $E = \dfrac{V_{ab}}{\left(\frac{1}{r_a} - \frac{1}{r_b}\right)}\dfrac{1}{r^2}$
d) $E = 0$
23.51 a) concentric cylinders
b) 10 V: 2.90×10^{-2} m; 20 V: 4.20×10^{-2} m
23.53 a) -2.15×10^{-5} J b) $W_E = +2829$ V
c) $E = 3.54 \times 10^4$ V/m
23.55 a) 7.85 × 10^4 V/m$^{4/3}$
b) $\vec{E} = (-1.0 \times 10^5\text{ V/m}^{4/3})x^{1/3}\hat{i}$
c) $\vec{F} = (3.13 \times 10^{-15}\text{ N})\hat{i}$
23.57 a) $-1.46q^2/\pi\epsilon_0 d$
23.59 a) -8.62×10^{-18} J b) 2.87×10^{-11} m
23.61 a) i) $V = (\lambda/2\pi\epsilon_0)\ln(b/a)$
ii) $V = (\lambda/2\pi\epsilon_0)\ln(b/r)$ iii) $V = 0$
d) $(\lambda/2\pi\epsilon_0)\ln(b/a)$
23.63 a) 1.76×10^{-16} N, downward
b) 1.93×10^{14} m/s, downward c) 8.24 mm
d) 15.4° e) 4.12 cm
23.65 a) 9.71×10^4 V/m b) 3.03×10^{-11} C
23.67 a) $r \le R$: $V = \left(\dfrac{\lambda}{4\pi\epsilon_0}\right)[1 - (r/R)^2]$;
$r \ge R$: $V = -\left(\dfrac{\lambda}{2\pi\epsilon_0}\right)\ln(r/R)$
23.69 $Q/4\pi\epsilon_0\sqrt{x^2 + a^2}$
23.71 $Q^2/8\pi\epsilon_0 R$
23.73 a) $Q/8\pi\epsilon_0 R$ b) i) center c) ii) surface
23.75 b) yes c) no
23.77 $Q/8\pi\epsilon_0 R$
23.79 a) $(Q/4\pi\epsilon_0 a)\ln[1 + (a/x)]$
b) $(Q/4\pi\epsilon_0 a)\ln[(a/y) + \sqrt{1 + (a/y)^2}]$
c) in (a), $(Q/4\pi\epsilon_0 x)$ in (b), $(Q/4\pi\epsilon_0 y)$
23.81 a) 1/3 b) 3
23.83 a) $E = Q_1/4\pi\epsilon_0 R_1^2$; $V = Q_1/4\pi\epsilon_0 R_1$
b) sphere 1: $Q_1 R_1/(R_1 + R_2)$;
sphere 2: $Q_1 R_2/(R_1 + R_2)$
c) $V = Q_1/4\pi\epsilon_0(R_1 + R_2)$ for either sphere
d) sphere 1: $E = Q_1/4\pi\epsilon_0 R_1(R_1 + R_2)$;
sphere 2: $E = Q_1/4\pi\epsilon_0 R_2(R_1 + R_2)$
23.85 a) 7.6×10^6 m/s b) 7.3×10^6 m/s
c) 2.3 × 10^9 K; 6.9 × 10^9 K
23.87 a) 5.9×10^{-15} m b) 4.14×10^{-11} J
c) 2.55×10^{25} nuclei
23.89 a) 1.01×10^{-12} m, 1.11×10^{-13} m, 2.54×10^{-14} m
23.91 c) 3 electrons, 0.507 μm

Chapter 24

24.1 1.82×10^{-4} C
24.3 a) 604 V b) 9.1×10^{-3} m^2 c) 1.84×10^{6} V/m d) 1.63×10^{-5} C/m^2
24.5 a) 120 μC b) $C = \epsilon_0 A/d$ c) 480 μC
24.7 2.8 mm
24.9 a) 4.35×10^{-12} F b) 2.30 V
24.11 a) 6.56×10^{-11} F/m b) 6.43×10^{-11} C
24.13 a) 1.50×10^{-11} F b) 3.08 cm c) 3.13×10^{4} N/C
24.15 a) $C_{eq} = 2.40\ \mu$F; $Q_{total} = 6.72 \times 10^{-5}$ C; $Q_{12} = 2.24 \times 10^{-5}$C; $Q_3 = 4.48 \times 10^{-5}$ C; $Q_1 = Q_2 = Q_{12} = 2.24 \times 10^{-5}$ C
24.17 a) $Q_1 = 1.56 \times 10^{-5}$ C; $Q_1 = 2.6 \times 10^{-4}$ C b) 52.0 V
24.19 $V_2 = 50$ V; $V_3 = 70$ V
24.21 $C_{eq} = \dfrac{\epsilon_0 A}{d_1 + d_2}$
24.23 57 μF
24.25 0.0283 J/m^3
24.27 19.6 J
24.29 a) $Q^2x/2\epsilon_0 A$ b) $(Q^2/2\epsilon_0 A)dx$ c) $Q^2/2\epsilon_0 A$
24.31 b) yes c) flat sheets parallel to the plates
24.33 a) 24.2 μC b) $V = 220$ V: $Q_{35} = 7.7\ \mu$C, $Q_{75} = 16.5\ \mu$C c) 2.66 mJ d) 35 nF: 0.85 mJ; 75 nF: 1.81 mJ e) 220V for each capacitor
24.35 a) 1.60 nC b) 8.0
24.37 a) $U_{parallel} = 4U_{series}$ b) $Q_{parallel} = 2Q_{series}$ c) $E_{parallel} = 2E_{series}$
24.39 a) 6.20×10^{-7} C/m^2 b) 1.28
24.41 0.0135 m^2
24.43 a) 2.3×10^{-11} C^2/N$\cdot$m^2 b) 40 kV c) $\sigma = 4.6 \times 10^{-4}$ C/m^2, $\sigma_i = 2.8 \times 10^{-4}$ C/m^2
24.45 a) 10.1 V b) 2.25
24.47 a) 3.6 mJ; 13.5 mJ b) increased by 9.9 mJ
24.49 a) $Q/k\epsilon_0 A$ b) $Qd/k\epsilon_0 A$ c) $k\epsilon_0 A/d$
24.51 a) 2.4×10^{-11} F b) 2.9×10^{-10} C c) 1.3×10^{3} d) 1.7×10^{-9} J
24.53 a) 421 J b) 5.39×10^{-9} F
24.55 for $d \ll r_a$: $C \approx \dfrac{\epsilon_0 A}{d}$
24.57 a) $U_{tot} = 158\ \mu$J b) $U_{4.5} = 72.1\ \mu$J
24.59 a) 2.5 μF b) $Q_1 = 5.5 \times 10^{-4}$ C, $V_1 = 66$ V; $Q_2 = 3.7 \times 10^{-4}$ C, $V_2 = 88$ V; $Q_3 = 1.8 \times 10^{-4}$ C, $V_3 = 44$ V; $Q_4 = 1.8 \times 10^{-4}$ C, $V_4 = 44$ V; $Q_5 = 5.5 \times 10^{-4}$ C, $V_5 = 66$ V
24.61 a) 76 μC b) 1.4×10^{-3} J c) 11 V d) 1.2×10^{-3} J
24.63 a) 2.3 μF b) $C_1 = 9.7 \times 10^{-4}$ C; $C_2 = 6.4 \times 10^{-4}$ C c) 47 V
24.65 a) 3.91 b) 22.8 V
24.67 c) 710 μF
24.69 a) 6.5×10^{-2} F b) $Q = 2.3 \times 10^{4}$ C c) 4.0×10^{9} J
24.71 $C_{eq} = \dfrac{2\epsilon_0 A}{d}\left(\dfrac{K_1 K_2}{K_1 + K_2}\right)$
24.73 b) 14 μF c) 72.0 μF: 505 μC, 7.02 V; 28.0 μF: 259 μC, 9.24 V; 18.0 μF: 229 μC, 12.7 V; 27.0 μF: 276 μC, 10.2 V; 6.0 μF: 14.9 μC, 2.49 V
24.75 a) $(\epsilon_0 L/D)[L + (K-1)x]$
24.77 b) 2.38×10^{-9} F

Chapter 25

25.1 3.89×10^{4} C
25.3 a) 3.13×10^{19} b) $J = 1.51 \times 10^{6}$A/m^2 c) $v_d = 1.11 \times 10^{-4}$m/s d) J would decrease; v_d would decrease
25.5 a) 110 min b) 442 min c) $v_d \propto 1/d$
25.7 a) 329 C b) 41.1 A c) 1333 min
25.9 5.86×10^{28} e$^-$/m^3
25.11 a) 1.216$\Omega\cdot$m @ 20 °C
25.13 a) tungsten $E = 5.16 \times 10^{-3}$ V/m b) aluminum $E = 2.70 \times 10^{-3}$ V/m
25.15 a) $E_{max} = 1.21$ V/m b) $R = 1.45 \times 10^{-2}\ \Omega$ c) $V_{max} = 1.82 \times 10^{-1}$ V = 0.182 V
25.17 0.125 Ω
25.19 15 g
25.21 $1.53 \times 10^{-8}\ \Omega$
25.23 a) $1.53 \times 10^{-8}\ \Omega$ b) $R = 2.4\ \Omega$
25.25 a) 11.1 A b) 3.13 V c) 0.28 Ω
25.27 a) 99.54 Ω b) 0.0158 Ω
25.29 a) $4.67 \times 10^{-8}\ \Omega$ b) $6.74 \times 10^{-4}\ \Omega$
25.31 a) 0.219 Ω b) $P = 3422$ J/s, $E = 1.23 \times 10^{7}$ J
25.33 a) $\mathcal{E} = 9.0$ V b) $r = 4.5\ \Omega$
25.35 a) $I = 0$ b) $\mathcal{E} = 5.0\ V$ c) 5.0 V
25.37 a) $\mathcal{E} = 3.08$ V b) $r = 0.067\ \Omega$ c) 1.8 Ω
25.39 a) 1.41 A b) −13.7 V c) −1.0 V
25.41 b) yes; linear
25.43 a) 576 Ω b) 960 Ω c) 100 W bulb, 0.417 A and 60 W bulb, 0.25 A d) 120 W bulb, $I = 0.500$ A
25.45 a) 25 W b) 0.208 A
25.47 a) $P = JE$ b) $p = J^2\rho$ c) $p = E^2/\rho$
25.49 a) 2.59×10^{6} J b) 0.062 L c) 1.6 h
25.51 12.3%
25.53 a) 24 W b) 4.0 W c) 20 W
25.55 a) 26.7 Ω b) 4.5 A c) 454 W
25.57 a) $3.65 \times 10^{-8}\ \Omega\cdot$m b) 172 A c) 2.58×10^{-3} m/s
25.59 0.060 Ω
25.61 a) 2.5 mA b) 2.14×10^{-5} V/m c) 8.55×10^{-5} V/m d) 1.80×10^{-4} V
25.63 a) $R = \dfrac{\rho h}{\pi r_1 r_2}$ b) $R = \dfrac{\rho L}{A}$
25.65 $I = \dfrac{Q}{\kappa\epsilon_0\rho}$
25.67 a) 0.057 Ω b) $3.34 \times 10^{-8}\Omega\cdot$m c) 0.86 mm d) $2.40 \times 10^{-3}\ \Omega$ e) $1.1 \times 10^{-3}\ (°C)^{-1}$
25.69 a) 0.2 Ω b) 8.7 V
25.71 a) 1000 Ω b) 100 V c) 10 W
25.73 1.42 A
25.75 a) $I_A\left(1 + \dfrac{R_A}{r + R}\right)$ b) 0.0425 Ω
25.77 b) 8-gauge c) 106 W d) 66 W, 175 kWh, $19.25
25.79 a) 0.40 A b) 1.6 W c) 4.8 W d) 3.2 W
25.81 a) $\dfrac{a}{E}$ b) 2.59×10^{6} J c) 4.32×10^{5} J d) 0.96 Ω e) 1.73×10^{6} J
25.83 a) $2.00 = I_s\,[\exp(eV/kT) - 1] + V$ b) V = 0.179 V, I = 1.80 A

Chapter 26

26.1 $\dfrac{3R}{4}$
26.3 a) $R_q < R_1$ b) $R_{eq} < R_1$
26.5 a) $I = 3.50$ A b) $I = 4.50$ A c) $I = 3.15$ A d) $I = 3.25$ A
26.7 0.769 A
26.9 a) 8.8 Ω b) 3.18 A c) 3.18 A d) $V_{2,4} = 7.64$ V; $V_{1,6} = 5.09$ V; $V_{4,8} = 15.3$ V
26.11 $R_{eq} = 5.00\ \Omega$; $I_{total} = 12.0$ A; $I_{12} = 3.00$ A; $I_4 = 9.00$ A; $I_3 = 8.00$ A; $I_6 = 4.00$ A
26.13 a) $I_1 = 1.50$ A, $I_2 = I_3 = I_4 = 0.50$ A b) $P_1 = 10.1$ W, $P_2 = P_3 = P_4 = 1.12$ W; c) $I_1 = 1.33$ A, $I_2 = I_3 = 0.667$ A d) $P_1 = 8.00$ W, $P_2 = P_3 = 2.00$ W e) $R_2 + R_3$ is brighter; R_1 is dimmer
26.15 a) 18.0 V; 3.00 A
26.17 a) 0.100 A for each b) 400-Ω bulb: 4.00 W; 800-Ω bulb: 8.00 W c) 400-Ω bulb: 0.300 A; 800-Ω bulb: 0.150 A d) 400-Ω bulb: 36.0 W; 800-Ω bulb: 18.0 W; total: 54.0 W e) in series, 800-Ω bulb is brighter; in parallel, 400-Ω bulb is brighter and total light output is greater
26.19 1010 s
26.21 a) 2.00 A b) 5.00 Ω c) 42.0 V d) 3.50 A
26.23 a) 8.00 A b) $\mathcal{E}_1 = 36.0$ V, $\mathcal{E}_2 = 54.0$ V c) 9.00 Ω
26.25 a) 1.60 A, 1.40 A, 0.20 A b) 10.4 V
26.27 a) $\mathcal{E} = 36.40$ V b) 0.500 A
26.29 a) −2.14 V, a is at a higher potential b) $I_{100} = 0.250$ A; $I_{75} = 0.200$ A; $I_A = 0.500$ A downward; V = 0
26.31 a) 0.641 Ω b) 975 Ω
26.33 a) 17.8 V b) 22.7 V c) 27.5%
26.35 c) 3.34 V
26.37 a) 543 Ω b) 1.88 mA c) 203 Ω
26.39 a) $C = 8.49 \times 10^{-7}$ F b) $\tau = 2.89$ s
26.41 a) $t = 4.21 \times 10^{-3}$ s b) $I = 0.125$ A
26.43 190 μC
26.45 $I = 13.6$ A
26.47 a) 0.938 A b) 0.606 A
26.49 a) 1.33×10^{-4} C b) $v_R = 9.12$ V, $v_C = 8.88$ V c) $v_R = v_C = 8.88$ V d) 6.75×10^{-5} C
26.51 900 W
26.53 a) 6.0 A, 720 W b) 3.5 A, 420 W
26.55 a) 13.6 $\mu\Omega = 1.36 \times 10^{-5}\ \Omega$ b) $2.14 \times 10^{-8}\ \Omega$
26.57 a) 9.9 W b) 16.3 W, brighter
26.59 a) 18.7 Ω b) 7.5 Ω
26.61 $I_1 = 0.848$ A, $I_2 = 2.14$ A, $I_3 = 0.171$ A
26.63 2.00-Ω resistor: 5.21 A; 4-Ω resistor: 1.11 A; 5-Ω resistor: 6.32 A
26.65 a) 0.222 V b) 0.464 A
26.67 12.7 V
26.69 a) 186 V, upper terminal + b) 3.00 A from − to + terminal c) 20.0 Ω
26.71 a) $P_1 + P_2$ b) $\dfrac{P_1 P_2}{(P_1 + P_2)}$
26.73 a) −12.0 V b) 1.71 V c) 4.20 V
26.75 $R_3 = 10.8\ \Omega$, $R_2 = 1.08\ \Omega$, $R_1 = 0.12\ \Omega$
26.77 a) 114.4 V b) 263 V c) 266 V
26.79 b) 1897 Ω
26.81 a) 224-Ω resistor: 24.8 V; 589-Ω: 65.2 V b) 3.87 kΩ c) 62.6 V d) no

Chapter 27

27.1 a) $(-6.68 \times 10^{-4}\ \text{N})\hat{k}$ b) $(+6.68 \times 10^{-4}\ \text{N})\hat{i} + (7.27 \times 10^{-4}\ \text{N})\hat{j}$
27.3 a) positive b) 5.05×10^{-2}N
27.5 9.47×10^{6} m/s
27.7 a) $\vec{B}_x = -0.175$ T, $\vec{B}_z = -0.256$ T b) yes, $\vec{B}_y$ d) zero, 90°
27.9 a) $\vec{B} = 1.46$ T at 40.0° from the $+x$-axis, toward the z-axis in the xz plane b) $\vec{F} = 7.48 \times 10^{-16}$ N, at 50° from the $+x$-axis toward the $+z$-axis
27.11 a) 3.05×10^{-3} Wb b) 1.83×10^{-3} Wb c) 0
27.13 -7.79×10^{-4} Wb
27.15 a) 1.60×10^{-4} T, into the page b) 1.11×10^{-7} s
27.17 7.93×10^{-10} N, south
27.19 a) 1.2×10^{7} m/s b) 0.10 T
27.21 a) 8.35×10^{5} m/s b) 2.62×10^{-8} s c) 7.26 kV
27.23 a) 107 T b) no
27.25 a) 8.38×10^{-4} T
27.27 a) no b) 1.40 cm
27.29 $B = 4.45 \times 10^{-2}$ T
27.31 1.29×10^{-25} kg, 78
27.33 a) 1.34×10^{4} A b) horizontal
27.35 $F = 0.724$ N, at 63.4° below the $+x$-axis
27.37 9.7 A
27.39 a) 817 V b) 113 m/s^2
27.41 a) $-(ILB)\hat{j}$ b) yes
27.43 a) 1.5×10^{-16} s b) 1.1 mA c) 9.3×10^{-24}A$\cdot$m^2
27.45 a) rotates about axis A_z b) $\alpha = 294$ rad/s^2
27.47 −2.42 J
27.49 a) 1.13 A b) 3.69 A c) 98.2 V d) 362 W
27.51 a) 4.7 mm/s b) 4.5×10^{-3} V/m in the $+z$-direction c) 53 μV
27.53 a) F_2/qv_1 in the $-y$-direction b) $F_2/\sqrt{2}$
27.55 $\vec{B} = 3.68$ T at a right angle to v_i
27.57 a) 8.9×10^{-17} J = 5.5×10^{5} eV b) 7.7×10^{-8} s c) 1.2 T d) same as in (a)

c) 5.22×10^6 rad/s d) 0.0144 V/m
32.13 a) 381 nm b) 526 nm c) 1.38 d) 1.91
32.15 a) 330 W/m^2 b) 500 V/m; 1.7 μT
32.17 1.33×10^{-8} T, $+y$-direction
32.19 a) 1.1×10 W/m^2 b) 3.0×10^{-10} T
c) 840 W; assuming isotropic transmission
32.21 2.5×10^{25} J
32.23 $E_{max} = 12.0$V/m, $B_{max} = 4.00 \times 10^{-8}$ T
32.25 8.5×10^5 W
32.27 a) 8.68×10^{-15} kg/m$^2 \cdot$s
b) 2.60×10^{-6} kg/m$\cdot$s^2
32.29 $S = \epsilon_0cE^2$
32.31 a) 7.10 mm b) 3.55 mm c) 1.56×10^8 m/s
32.33 a) 4.38 mm b) 1.38 mm c) 4.38 mm
32.35 a) $L = 30.5$ cm b) $f = 2.46 \times 10^9$ Hz
c) $L = 35.5$ cm: $f = 2.11 \times 10^9$ Hz
32.39 a) $I = 0.00602$ W/m^2
b) 2.13 N/C, 7.10×10^{-9} T
c) 1.20×10^{-12} N
32.41 a) $E_{max} = 701$V/m, $B_{max} = 2.34 \times 10^{-6}$ T
b) $\mu_E = \mu_B = 1.09 \times 10^{-6}$ J/m^3
c) 1.07×10^{-11} J
32.43 a) $r = R$: $I = 6.4 \times 10^7$ W/m^2, $p_{rad} = 0.21$ Pa;
$r = R/2$: $I = 2.6 \times 10^8$ W/m^2, $p_{rad} = 0.85$ Pa
32.45 7.78×10^{-13} rad/s
32.47 a) $I\rho/\pi a^2$ in direction of current
b) current out of page: $\mu_0I/2\pi a$, clockwise
c) $I^2\rho/2\pi^2a^3$, radially inward
d) $I^2\rho l/\pi a^2 = I^2R$
32.49 0.0368 V
32.51 a) 23.6 h b) throw it
32.53 a) 2.66×10^7 m b) 0.0673 s
c) 6.50×10^{-23} Pa d) 0.190 m
32.55 a) $4\pi R^3\rho Gm^3/3r^2$ b) $LR^2/4r^2c$
c) 1.90^{-7} m, independent of r
32.57 b) $1.4 \times 10^{-11}\text{ s}^{-1}$ c) $2.6 \times 10^{-8}\text{ s}^{-1}$

Chapter 33

33.1 39.4°
33.3 a) 1.55 b) 549 nm
33.5 a) 5.17×10^{-7} m b) 3.40×10^{-7} m
33.7 a) 47.5° b) 66.0°
33.9 2.51×10^8 m/s
33.13 a) frequency $= f$; wavelength $= n\lambda$;
speed $= nf\lambda = nv$ b) frequency $= f$;
wavelength $= \left(\frac{n}{n'}\right)\lambda$; speed $= \left(\frac{n}{n'}\right)f\lambda = \left(\frac{n}{n'}\right)v$
33.15 71.8°
33.17 a) 51.3° b) 33.8°
33.19 a) 58.1° b) 22.8°
33.21 1.77
33.23 24.4°
33.25 a) A: $I_0/2$ B: $I_0/8$ C: $3I_0/32$ b) 0
33.27 a) 1.40 b) 35.5°
33.29 $\alpha = \arccos\left(\frac{\cos\theta}{\sqrt{2}}\right) = \cos^{-1}\left(\frac{\cos\theta}{\sqrt{2}}\right)$
33.31 6.38 W/m^2
33.33 a) first: $I = I_0/2$, second: $I = 0.25I_0$,
third: $I = 0.125I_0$ all linearly polarized along
the axis of their respective filters.
33.35 a) $I_R = 0.374I$ b) $I_V = 2.35I$
33.39 a) $\sin\theta_3 = (n_1\sin\theta_1)/n_3$ c) yes
33.41 72.0°
33.45 1.53
33.47 1.8
33.49 a) 48.6° b) 48.6°
33.51 39.1°
33.53 a) $n = 1.11$ b) i) 9.75 ns
ii) 4.07 ns; total $= 8.95$ ns
33.55 b) 0.22°
33.61 b) 38.9° c) 5.0°
33.63 a) 35° b) 10.1 W/m^2, 19.9 W/m^2

Chapter 34

34.1 39.2 cm to right of mirror; 4.85 cm
34.3 image at (x_0, y_0)
34.5 b) 33.0 cm to left of vertex, 1.20 cm tall,
inverted, real
34.7 0.213 mm
34.9 18.0 m from convex side of glass shell, 0.50 cm
tall, erect, virtual
34.11 a) $m = \dfrac{f}{(f - s)}$ c) $s > f$ d) $s < f$ e) $-\infty$
f) $s = f$ g) $s' = 0$ i) $s < f$ j) $s > f$
k) $s > 2f$ l) it becomes infinite
34.13 a) concave b) $f = 2.50$ cm, $R = 5.00$ cm
34.15 2.67 cm
34.17 a) at the center of the ball, $m = +1.33$ b) no
34.19 $s = 0.395$ m
34.21 8.35 cm to left of vertex, 0.326 mm, erect
34.23 a) 1.06 m to right of lens, 17.7 mm tall, real,
inverted b) all same as (a)
34.25 71.2 cm to right of lens, $m = -2.97$
34.27 $f = 3.69$ cm, object is 2.82 cm to left of lens
34.29 $n = 1.67$
34.33 Object is 26.3 cm from lens with height
1.24 cm; image is erect; same side
34.35 10.2 m
34.37 a) 1.4×10^{-4} b) 5.25×10^{-4} c) 1.50×10^{-3}
34.39 a) 85 mm b) 135 mm
34.41 a) 11 b) 2.160×10^{-3} s
34.43 a) convex b) 50 mm to 56 mm
34.45 a) 80.0 cm b) 76.9 cm
34.47 a) +2.33 diopters b) -1.67 diopters
34.49 a) 6.06 cm b) 4.12 mm
34.51 4.17 cm from lens; image is located on same
side as ant
34.53 a) 8.37 mm b) 21.4 c) 297
34.55 19.4 m
34.57 a) -6.33 b) 1.90 cm c) 0.126 rad $= 7.22°$
34.59 a) 66.1 cm b) -59.1
34.61 4.80 m/s
34.63 $n/2$
34.65 a) 13.3 cm b) 26.2 cm
34.67 a) 46.2 cm from mirror, on opposite side of
mirror; virtual b) 2.88 cm, erect c) no
34.69 a) -12.0 cm $< s < 0$ b) erect
34.71 $f = \pm 4.4$ cm, ± 13.3 cm
34.73 $v = 31$ m/s
34.75 b) i) 120.00 cm from mirror, 119.96 cm from
mirror ii) $m = -0.600$, $m' = -0.360$
c) faces perpendicular to axis: squares with side
0.600 mm: faces parallel to axis: rectangles
with sides of length 0.360 mm (parallel to axis)
and 0.600 mm (perpendicular to axis)
34.77 b) image $= 2.4$ cm high; $m = -0.13$
34.79 a) -3.3 cm b) virtual c) 1.9 cm to right of
vertex at right end of rod d) real, inverted
e) 105 mm
34.81 a) $f = 58.7$ cm, converging
b) $h = 4.47$ mm, virtual
34.83 a) 2.53 mm
34.85 a) $R = 8.8$ mm b) no. behind the retina
c) $s' = 14$ mm from the cornea. In front of the
retina. Yes. The lens needs to complete the
focusing.
34.87 2.00
34.89 a) 3.75 cm to left of first lens b) 332 cm
c) real d) $h = 60.0$ mm. inverted.
34.91 10.6 cm
34.93 a) 0.24 m b) 0.24 m
34.95 Inside the glass, 72.1 cm from the spherical
surface
34.97 0.80 cm
34.99 -26.7 cm
34.101 1.24 cm above page
34.103 a) 46.7 m b) 35.0 m
34.105 134 cm to left of object

Chapter 35

35.1 a) 2.50 m b) 1.00 m, 4.00 m
35.3 0.75 m, 2.00 m, 3.25 m, 4.50 m, 5.75 m,
7.00 m, 8.25 m
35.5 a) 2.0 m b) constructively
c) 1.0 m; destructively

38.57 a) 5.1×10^{-3} J b) 11 W c) $N = 1.5 \times 10^{16}$
38.59 a) 1.69×10^{-28} kg b) -2.53 keV
c) 0.653 nm
38.61 a) $6.99 \times 10^{-24}\ \text{kg}\cdot\text{m/s}$ b) 705 eV
38.63 a) 12.09 eV b) 3 possibilities:
$3 \to 2$ (656 nm), $3 \to 1$ (103 nm),
$2 \to 1$ (122 nm)
38.65 a) 0.90 eV
38.67 a) 5×10^{49} photons/s b) 3×10^4
38.69 2.98×10^4 K
38.71 a) $\Delta\lambda = \dfrac{h}{2mc}$ b) 6.61×10^{-16} m for any n
38.73 a) 5×10^{-33} m b) $(4 \times 10^{-9})°$ c) 0.1 mm
38.75 a) 5.10×10^{-17} J = 319 eV, 1.06×10^7 m/s
b) 3.89 nm
38.77 $5.67 \times 10^{-8}\ \text{W}/(\text{m}^2\cdot\text{K}^4)$
38.79 $f \approx \dfrac{me^4}{4\epsilon_0^2 n^3 h^3}$
38.81 b) 7.08×10^{-15} m c) gamma rays

Chapter 39

39.1 a) 1.55×10^{-10} m b) 8.44×10^{-14} m
39.3 a) $2.37 \times 10^{-24}\ \text{kg}\cdot\text{m/s}$
b) 3.67×10^{-18} J = 19.2 eV
39.5 a) 3.32×10^{-10} m b) 1.33×10^{-9} m
39.7 a) $m = 75$ kg, $v = 1.0$ m/s: $\lambda = 8.8 \times 10^{-36}$ m
39.9 a) photon: 620 nm; electron: 0.274 nm
b) photon: 4.96 eV; electron: 2.41×10^{-5} eV
c) 250 nm; electron
39.11 3.90×10^{-34} m; no
39.13 a) 7.3×10^6 m/s b) 150 eV c) 12 keV
d) electrons
39.15 0.431 eV
39.17 a) $m = 1$: 2.07°; $m = 2$: 4.14°
b) 1.81 cm, 3.61 cm, 1.81 cm
39.19 a) 8.79×10^{-32} m/s; no
39.21 the claim is not valid
39.23 2.03×10^{-32} J = 1.27×10^{-13} eV
39.25 0.087 MeV = $2.8 \times 10^{-5} E$
39.27 a) 8.25×10^3 b) electrons
39.29 a) $x = (2n+1)(\lambda/4)$, n an integer
b) $x = n\lambda/2$, n an integer
39.31 a) $\int_{-\infty}^{\infty} |\Psi|^2 dV = 1$
integrating the probability density function between infinite limits must equal unity
b) no. no. not a valid wave function.
c) $A = \sqrt{2b}\ \text{m}^{-1/2}$
39.33 1
39.35 a) $1.414\ \text{m}^{-1/2}$ c) i) $P = 0.865$ ii) $P = \frac{1}{2}$
iii) $P = 0.0585$
39.37 ψ cannot be a solution
39.39 a) 12 eV b) 1.5×10^{-4} V, 7.3×10^3 m/s,
c) 8.2×10^{-8} V; 4.0 m/s
39.41 a) 9.42×10^5 m/s; nonrelativistic
b) $V_{\text{acc}} = 2.53$ V

Copyright © Pearson Australia (a division of Pearson Australia Group Pty Ltd) 2011 – 9781442517110 - Young/University Physics 1st edition

39.43 a) $E = c\sqrt{2mK} = 4.05 \times 10^{-7}\sqrt{K}$
b) $E_{photon} > E_{electron}$
39.45 1.66×10^{-17} m; no
39.47 a) 1.10×10^{-10} m b) 9.09×10^{-13} m
39.49 a) $(1/\sqrt{15})(h/mc)$
b) i) 1.53 MeV, 6.26×10^{-13} m
ii) 2.81×10^{3} MeV, 3.41×10^{-16} m
39.51 a) 2.1×10^{-20} kg · m/s b) 39 MeV
c) 0.29 MeV; no
39.53 1.4×10^{-35} kg $= (5.8 \times 10^{-8}\, m_{pion})$
39.55 a) 1.1×10^{-35} m/s b) 2.3×10^{27} y, no
39.57 a) 7.27×10^{5} m/s, nonrelativistic
b) $V = 1.50$ V
39.59 a) $2d\sin\theta = m\lambda$, $m = 1, 2, 3 \ldots$ b) 53.1°
c) less
39.61 a) $A|x|/x$, $x \neq 0$ b) $(3/2)(h^2A^2/m)^{1/3}$
39.63 $\omega = E/\hbar$
39.65 a) 0.21 kg · m/s b) 1.7 m
39.67 $P = 4\pi|A|^2 r^2 e^{-2\alpha r^2} dr$, r = $1/\sqrt{2\alpha}$; no
39.69 a) $\psi(x) = (\sin k_0 x)/k_0 x$ b) L c) $2L$
d) h, h
39.71 2.2×10^{-16} m

Chapter 40

40.1 a) 1.2×10^{-67} J b) 1.1×10^{-33} m/s
c) 1.4×10^{33} s d) 3.7×10^{-67} J
40.3 $L = 1.66 \times 10^{-10}$ m
40.5 0.61 nm
40.7 a) 0, $L/2$, L b) $L/4$, $3L/4$ c) yes
40.11 a) 6.0×10^{-10} m, 1.1×10^{-24} kg · m/s
b) 3.0×10^{-10} m, 2.2×10^{-24} kg · m/s
c) 2.0×10^{-10} m, 3.3×10^{-24} kg · m/s
40.15 3.43×10^{-10} m
40.19 2.2×10^{-14} m
40.21 a) 4.3×10^{-8} b) 4.2×10^{-4}
40.23 $1/\sqrt{2}$
40.25 a) 1.3×10^{-3} b) 10^{-143}
40.27 a) 1.11×10^{-33} J $= 6.90 \times 10^{-15}$ eV;
2.21×10^{-33} J $= 1.38 \times 10^{-14}$ eV
40.29 a) 0.21 eV b) 5900 N/m
40.31 $\Delta x \Delta p = (2n + 1)\hbar$
40.33 a) 5.9×10^{-3} eV b) 106 μm
c) 0.0118 eV $= 1.18 \times 10^{-2}$ eV
40.35 $B = \dfrac{K_1 - K_2}{K_1 + K_2}A$; $C = \dfrac{2K_1}{K_1 + K_2}A$
40.37 a) 19.2 μm b) 11.5 μm
40.39 a) $\left(\dfrac{1}{2} + 1/\pi\right)$ b) $\dfrac{1}{2}$ c) yes
40.41 a) $2dx/L$ b) 0 c) $2dx/L$
40.45 a) $B = C$, $A\sin\dfrac{\sqrt{2mE}}{\hbar}L + B\cos\dfrac{\sqrt{2mE}}{\hbar}L = De^{-\kappa L}$
b) $\dfrac{\sqrt{2mE}}{\hbar}A = \kappa C$, $\dfrac{\sqrt{2mE}}{\hbar}\left(A\cos\dfrac{\sqrt{2mE}}{\hbar}L - B\sin\dfrac{\sqrt{2mE}}{\hbar}L\right) = -\kappa De^{-\kappa L}$
40.49 6.63×10^{-34} J $= 4.14 \times 10^{-15}$ eV,
1.33×10^{-33} J $= 8.27 \times 10^{-15}$ eV, no
40.51 b) $A_0 = \left(\dfrac{m\omega}{\hbar\pi}\right)^{1/4}$
c) classical turning points $A = \pm\sqrt{\dfrac{\hbar}{\omega m}}$
40.53 a) $(n_x + n_y + n_z + (3/2))\hbar\omega$
b) $(3/2)\hbar\omega$, $(5/2)\hbar\omega$
40.55 a) $E_n = n^2h^2/8mL^2$, $n = 2, 4, 6 \ldots$
b) $E_n = n^2h^2/8mL^2$, $n = 1, 3, 5 \ldots$ c) same
d) odd in part (a), even in part (b)
40.57 b) increases c) infinite
40.59 a) $-E/A$, $+E/A$ c) decrease

Chapter 41

41.1 a) Possible values of L and L_z: $L = \hbar$ and $L_z = 0$; $L = \sqrt{2}\hbar$ and $L_z = -\hbar$, 0, or $+\hbar$
$L = \sqrt{6}\hbar$ and $L_z = -2\hbar, -\hbar$, 0, $+\hbar$ or $+2\hbar$
b) For $L = \hbar$: $\theta_L = 90.0°$;
For $L = \sqrt{2}\hbar$: $\theta_L = 135°$, 90.0°, or 45°;
For $L = \sqrt{6}\hbar$: $\theta_L = 144.7°$, 114°, 90.0°, 65.9°, or 35.3°
41.3 $l = 4$
41.5 $1.414\hbar$, $19.49\hbar$, $199.5\hbar$
41.7 −14.4 eV
41.9 b) $1/\sqrt{2\pi}$
41.11 a) 5.29×10^{-11} m
b) 1.06×10^{-10} m
c) 2.85×10^{-13} m
41.15 a) 9 b) 3.47×10^{-5} eV c) 2.78×10^{-4} eV
41.17 a) 0.468 T b) 3
41.19 1.68×10^{-4} eV; $m_s = 1/2$
41.21 g
41.23 a) 2.5×10^{30} rad/s
b) 2.5×10^{13} m/s, not valid
41.25

e^-	n	l	m_l	m_s
1	1	0	0	$\frac{1}{2}$
2	1	0	0	$-\frac{1}{2}$
3	2	0	0	$\frac{1}{2}$
4	2	0	0	$-\frac{1}{2}$
5	2	1	−1	$\frac{1}{2}$
6	2	1	0	$\frac{1}{2}$
7	2	1	+1	$\frac{1}{2}$
8	2	1	−1	$-\frac{1}{2}$
9	2	1	0	$-\frac{1}{2}$
10	2	1	+1	$-\frac{1}{2}$

41.27 4.18 eV
41.29 a) $1s^22s^22p^1$ b) −30.6 eV
c) $1s^22s^22p^63s^23p^1$ d) −13.6 eV
41.31 a) −13.6 eV b) −3.4 eV
41.33 a) 8.95×10^{17} Hz, 3.70 keV, 0.335 nm
b) 1.68×10^{18} Hz, 6.93 keV, 0.179 nm
c) 5.48×10^{18} Hz, 22.7 keV, 0.0547 nm
41.35 a) $0, \sqrt{2}\hbar, \sqrt{6}\hbar\ \sqrt{12}\hbar, \sqrt{20}\hbar$
b) 7470 nm, infrared, not visible
41.37 a) $1.51e$ b) i) $1.8e$ ii) $-2.75e$
41.39 a) $2a$ b) 0.238
41.41 b) 0.176
41.43 $\cos^{-1}(-\sqrt{1 - (1/m)})$
41.45 $4a$
41.47 $2 \to 1$, $1 \to 0$, $0 \to -1$, $e\hbar B/2m$;
$1 \to 1$, $0 \to 0$, $-1 \to -1$, 0;
$0 \to 1$, $-1 \to 0$, $-2 \to -1$, $e\hbar B/2m$
41.49 3.00 T
41.51 a) $1 - 2 \times 10^{-7}$ b) 0.9978 c) 0.978
41.53 a) 4, 20 b) $1s^42s^42p^3$
41.55 a) 122 nm b) 1.52×10^{-3} nm; increases
41.57 a) 0.188 nm, 0.250 nm;
b) 0.0471 nm, 0.0624 nm
41.59 b) O shell

Chapter 42

42.1 a) 6.1 K b) 3.47×10^{4} K
42.3 5.65×10^{-13} m
42.5 a) carbon: 0.0644 nm; oxygen: 0.0484 nm
b) 1.45×10^{-46} kg · m^2; yes
42.7 a) 1.03×10^{12} rad/s
b) carbon; 66.3 m/s oxygen: 49.8 m/s
c) 6.11×10^{-12} s
42.9 a) 1.20×10^{-21} J $= 7.52 \times 10^{-3}$ eV
b) 0.165 mm
42.11 b) $\hbar l/2\pi I$
42.13 a) 963 m/s
b) 8.22×10^{-20} J $= 0.513$ eV
c) 2.42 μm, infrared
42.15 2.16×10^{3} kg/m^3
42.17 a) 1.12 eV
42.19 1.19×10^{6}
42.21 1.5×10^{22} states/eV
42.23 b) ground: $E = 3\pi^2\hbar^2/2mL^2$, 2;
first: $E = 6\pi^2\hbar^2/2mL^2$, 6;
second: $E = 9\pi^2\hbar^2/2mL^2$, 6
42.25 a) 0.0233 R b) 7.65×10^{-3} c) no; the ions
42.27 $f(E) = 0.31 = 31\%$
42.29 0.20 eV below the band
42.31 a) 5.56 mA b) −5.18 mA; −3.77 mA
42.33 a) 977 N/m b) 1.26×10^{14} Hz
42.35 a) 3.8×10^{-29} C · m b) 1.3×10^{-19} C
c) 0.78 d) 0.059
42.37 a) 0.96 nm b) 1.8 nm
42.39 a) 0.129 nm b) 8, 7, 6, 5, 4 c) 484 μm
d) 118 μm, 135 μm, 157 μm, 189 μm, 236 μm
42.41 b) i) 2.94 ii) 4.73 iii) 7.58 iv) 0.837
v) 5.5×10^{-9}
42.43 a) 1.147 cm, 2.239 cm
b) 1.172 cm, 2.344 cm; 0.025 cm, 0.050 cm
42.45 4.38×10^{-20} J $= 0.273$ eV
42.47 a) 4.24×10^{-47} kg · m^2 b) i) 4.30 μm
ii) 4.28 μm iii) 4.40 μm
42.49 2.03 eV
42.51 a) 4.66×10^{28} atom/m^3 b) 4.7 eV
42.53 b) 3.80×10^{10} Pa $= 3.75 \times 10^{5}$ atm
42.55 a) 1.66×10^{33} m^{-3} b) yes c) 7×10^{35} m^{-3}
d) no
42.57 a) $-p^2/2\pi\epsilon_0 r^3$ b) $+p^2/2\pi\epsilon_0 r^3$

Chapter 43

43.1 a) $Z = 14$, $N = 14$ b) $Z = 37$, $N = 48$
c) $Z = 81$, $N = 124$
43.3 0.533 T
43.5 a) parallel, 70.3 MHz, 4.27 m, radio
b) antiparallel, 46.2 MHz, 6.48 mm, microwave
43.7 5.575×10^{-13} m
43.9 1.13×10^{7} m/s
43.11 a) 76.21 MeV b) 76.67 MeV
c) 0.6%
43.13 a) $^{235}_{92}$U b) $^{24}_{12}$Mg c) $^{15}_{7}$N
43.15 0.0500 MeV
43.17 156 keV
43.19 a) 0.836 MeV b) 0.700 MeV
43.21 1.58×10^{12} s
43.23 a) 159 decays/min b) 0.43 decay/min
43.25 a) $^{3}_{2}$He b) 40.9 y
43.27 2.80 days
43.29 5730 y
43.31 a) 2.02×10^{15} b) 1.01×10^{15}, 3.78×10^{11} Bq
c) 2.52×10^{14}, 9.45×10^{10} Bq
43.33 a) 0.421 Bq b) 1.14×10^{-11} Ci
43.35 500 rad, 2000 rem, 5.0 J/kg
43.37 a) 1.75 × 10^3 Gy = 1.75 × 10^3 Sv
= 1.75 × 10^5 rem, 263 J
b) 1.75 × 10^3 Gy = 2.63 × 10^3 Sv
= 2.63 × 10^5 rem, 263 J
43.39 a) 12.5 rad, 12.5 rem b) the antineutrinos are not absorbed
43.41 a) = 3, $A = 6$ b) −10.14 MeV
c) 11.60 MeV
43.43 a) $Z = 3$, $A = 7$ b) 7.151 MeV
c) 1.4 MeV
43.45 a) 173.3 MeV b) 4.42×10^{23} MeV/g
43.47 1.586 MeV
43.53 23.9858 u, 0.021%, 0.9%
43.55 a) $^{25}_{13}\text{Al} \to {}^{25}_{12}\text{Mg}$
b) β^+ decay or electron capture
c) 3.255 eV or 4.277 MeV
43.57 a) $^{14}_{6}\text{C} \to {}^{14}_{7}\text{N} + \beta^- + \bar{\nu}_e$
b) 0.1565 MeV/decay
c) 1.35×10^{4} g, 3.44×10^{3} decays/s
d) 539 MeV/s = 8.63×10^{-11} J/s
e) 3.63×10^{-5} Gy = 3.63×10^{-3} rad,
RBE = 1.0: 36 μSv = 3.6 mrem
43.59 0.960 MeV
43.61 1.287×10^{-3} u
43.65 a) 5.0×10^{4} b) $10^{-15000} \approx 0$
43.67 29.2%
43.69 a) 9.6×10^{-7} J b) 1.9×10^{-4} rad
c) 1.3×10^{-4} rem d) 1.5×10^{6} s = 17 d
43.71 1.3×10^{4} y
43.73 a) 0.48 MeV
b) 3.270 MeV = 5.239×10^{-11} J
c) 3.155×10^{11} J/mol
43.77 185 MeV
43.79 b) 4.1×10^{4} Bq, 3.6×10^{5} Bq, 7.5×10^{5} Bq,
1.1×10^{6} Bq, 1.3×10^{6} Bq, 1.5×10^{6} Bq
c) 3.2×10^{9} d) 1.5×10^{6} Bq

refraction at, 1135–1136
sound waves in, 518–519
specific heat of, 566, 568
thermal expansion of, 563–564
triple point of, 559, 614, 670
water-pipe analogy, for Kirchhoff's junction rule, 861
Watkins, Scott, 1071
watt, **193**, 576, 840, 1071, **1510**
Watt, James, 193
wave(s)
electromagnetic (*See* electromagnetic waves)
mechanical (*See* mechanical waves)
particle (*See* particle waves)
sound (*See* sound waves)
wave equation, **482**, 485, 491, **1064**
electromagnetic, 1060, 1063–1065
for free particle, 1322–1323, 1334, 1341
wave front, **1086**, 1087, 1108
wave function, **477**, *501*
bound-state, 1339–1340
'exponential tails', 1340
graphing, 478–479
harmonic oscillator, 1346–1349
hybrid, 1391
many-electron atoms, 1375
for particle in a box, 1334–1337, *1352*, 1403–1404
potential wells, 1340–1341
principle of superposition, 491–492
quantum-mechanical, **1308**, 1319–1325, *1326*
for sinusoidal wave, 477–478, 481, 512, 1066–1067, 1324–1325
for standing wave, 494, 498
stationary-state, 1321
wave intensity, **489**, 490, 521–525
wave interference, 472, **490**, 491, 494
sound, 532–534, *545*
wavelength, **475**, 476, 478
de Broglie, **1308**, 1308–1312, 1314, 1322, *1326*
electromagnetic waves, 1059–1060, 1066, 1077
laser, 1196, 1216
light (*See* light wavelength)
normal mode, 497
sound waves, 514, 518, 527–529, 536–539, 542, 1204
x-rays, 1214, 1380–1381
wave motion, energy in, 487–490, *501*
wave number, **478**, 1066–1067, 1178, 1324–1325, 1334
wave packet, 1324–1325, **1325**
wave-particle duality, 1297–1298, 1307–1332
wave pulse, 474, 490–492, 494, 526
wave speed, **474**, 475, 479
calculating, 486–487, 516
electromagnetic, 541
longitudinal, 519
sound, 516–520, 530, 536, 542
transverse, 483–487, 516
weak interaction, **160**, 1476–1477, 1480–1481, 1486
weather radar, 1060
weber, **894**, 998, **1510**
Weber, Wilhelm, 894
weight, **105**, 114, 117, *126*, 376, *398*
apparent, **141**, 142–145, 376, **391**
earth's rotation and, 391–393
distribution of, in car, 347–348
fluid pressure and, 447
free fall and, 118
gravitational potential energy and, 206–207
gravity and, 117, 119, 142, 159, 371, 376–378, *398*
versus mass, 117–119
measurement of, 119
molecular (*See* molar mass)
rotational dynamics and, 309
symbol for, 176
tension and, 145
torque and, 344
true, **391**, 392
variation by location, 119–120
work and, 179
weightlessness
apparent, 142, 382, 393
relativity and, 1256
weight lifting, equilibrium and, 349–350
Weinberg, Steven, 1486
white noise, 516
wide-angle lens, 1146
width
grating spectrum, 1209
multiple-slit diffraction, 1205–1206
single-slit diffraction, 1203–1205
Wien displacement law, **1294**, 1294–1296
Wilson, Robert, 1501
WIMPs (weakly interacting massive particles), 1493
wind instruments
sound wave perception and, 516–517
sound wave propagation in, 517, 527–532
wings, airflow around, 460
wire(s)
current density and drift velocity in, 826
magnetic field of, 893, 902–903, 933–934
magnetic interaction between, 935–936, 996–997
resistance in, 831
wire chambers, 1475
wire rectangle, volume flow rate through, 731–732
wiring, household, 874–876, *877*
Wiseman, Howard, 1350
woofer, 1034
work, **176**, 176–180, *196*
in composite systems, 185–186
done by constant force, 176–177
done by friction, 22
done by torque, 318–320, *330*
done during volume changes, 627–629, 642–644
done in thermodynamic process, 630, 634, 642–644, *645*
electrical (*See* electric potential)
forces providing, 209–211, 218
heat transfer and, 566
negative (*See* negative work)
positive (*See* positive work)
potential energy and, 217
relativistic, 1252–1255
as scalar quantity, 177
sign of *(W)*, 627
in slidewire generator, 971
symbol for, 176
total (by several forces), 179–180, 185, 187, 207, 319
with varying forces, 186–192, *196*
in wave motion, 487
zero, 177–179, 181–182, 221, 223
work–energy theorem, 180–186, **181**, *196*
conservation of mechanical energy, 207–209
elastic potential energy, 216
electric potential energy, 759
for fluid flow, 456–458
momentum and impulse, 238–244
for motion along a curve, 190–192, *196*
relativistic, 1252–1253
for straight-line motion with varying forces, 189–190
work function, **1269**, 1271
working substance, **655**, 661, 665

X

x-acceleration
average, **41**, *58*
instantaneous, **43**, *58*
signs of, 44
x-component
in periodic motion, 408–411, 420–421
of velocity (*See x*-velocity)
x-momentum, 239
x-ray(s), 1060
absorption spectrum, 1383
applications of, 1293
from black holes, 396
medical use of, 1446
production of, 1289–1293, *1299*
scattering of, 1268, 1289–1293, *1299*
wavelength of, 1214, 1380–1381
x-ray crystallography, 1212–1214, 1397–1398
x-ray diffraction, 1211–1214, **1212**, *1221*, 1310, 1312
