The cylindrical filament wound composite overwrapped shells with a metal liner have been widely used in spaceflight and nuclear fuel centrifuge rotors due to their high strength and low weight. However, optimizing the structure of these high-speed rotating cylinders is more complicated due to the counterbalanced factors of load-bearing capacity, structural stiffness, and servility stability, coupled with dimensional parameters and the filament winding process. To reveal the mechanism of the initial reinforcement effects of filament winding of GFRP on metal liner, including load sharing ability, stiffness and buckling capacity, this study proposes a filament wound GFRP, which offers a high strength-to-weight ratio compared to existing metallic material. The 3D finite element model is built using ABAQUS software to predict the dynamic and stability characteristics of circular cylindrical shells with fixed boundary conditions. The computation models are validated by comparing with reported results in previous literatures. The hybrid GFRP cylindrical shells is further studied by varying filament winding process parameters such as winding angle and stacking sequence. The reinforcement effect on the metal liner resulting from the filament wound was achieved by using the equivalent temperature drop method and the element birth and death technology. The critical circumferential stress in composite shell which protects the metal liner from plastic material failures and keep the minimum tension load inside the GFRP composite material during high-speed rotation condition is determined. The discrete assumption is employed to depict the critical buckling strength considering the external hydrostatic pressure force and the winding process effect, to shed light on the underlying mechanism principles behind the buckling strength of such hybrid structures. Moreover, to reveal the impact of design-related parameters on the structure’s natural frequencies and linear buckling strength, sensitivity analyses are conducted on structural thickness, rotation speed and pretensions in composite materials. It was found that although the critical buckling strength of the hybrid structure under hydrostatic pressure force is lower than the pretension-induced compression force, the structure is still free from buckling failure. In conclusion, determining the relative contributions from mass and stiffness facilitates the optimization of structural geometric parameters. The numerical analysis method can provide valuable suggestions for engineering applications and promote lightweight design and safety conditions.

STRUCTURE-PERSEVERING METHOD FOR MECHANOELECTRICAL FLEXIBLE HUB-BEAM MODEL OF IONIC-TYPE SOLVENT-FREE NANOFLUIDS

Weipeng Hu[1]*

[1]*Xi'an University of Technology*

ABSTRACT

The liquid-like properties of ionic-type solvent-free nanofluids at room temperature can realize various advanced functions[1, 2], which has important applications. At present, the problems related to determining the critical flow conditions of solvent-free nanofluids are still unresolved. In this paper, the microscopic flow mechanism of solvent-free nanofluids is revealed from the perspective of kinetics. The vibration of the canopy and coronal layers of ionic solvent-free nanofluids can be excited by the external environment, which drives the rotation of the nanocore and shows liquid-like properties. Focusing on the microscopic mechanism, a mechanoelectrical flexible hub-beam model in a circular electric field is established for ionic-type solvent-free nanofluids. A structure-preserving method[3] combining generalized multi-symplectic and symplectic precise integration is constructed to simulate the dynamic behavior of ionic solvent-free nanofluids. The merits of the numerical method include the high precise and the structure-preserving characteristic, which implies that, the tiny rotation velocity can be captured and the liquid-like behaviors of ionic-type solvent-free nanofluids can be reproduced by the complex structure-preserving method exactly. The critical initial perturbation intensity of ionic solvent-free nanofluid flow is obtained from the numerical results, and the upper limit of flow velocity is confirmed, which provides an important guidance for the preparation and dynamic control of ionic solvent-free nanofluid.

AN SPH FORMULATION FOR GENERAL PLATE AND SHELL STRUCTURES WITH FINITE DEFORMATION AND LARGE ROTATION

Dong Wu[1] *and Xiangyu Hu**[1]

[1]*Technical University of Munich*

ABSTRACT

In this work, we propose a reduced-dimensional smoothed particle hydrodynamics (SPH) formulation for quasi-static and dynamic analyses of plate and shell structures undergoing finite deformation and large rotation. By exploiting Uflyand–Mindlin plate theory, the present surface-particle formulation is able to resolve the thin structures by using only one layer of particles at the mid-surface. To resolve the geometric non-linearity and capture finite deformation and large rotation, two reduced-dimensional linear-reproducing correction matrices are introduced, and weighted non-singularity conversions between the rotation angle and pseudo normal are formulated. A new non-isotropic Kelvin-Voigt damping is proposed especially for the both thin and moderately thick plate and shell structures to increase the numerical stability. In addition, a shear-scaled momentum-conserving hourglass control algorithm with an adaptive limiter is introduced to suppress the mismatches between the particle position and pseudo normal and those estimated with the deformation gradient. A comprehensive set of test problems, for which the analytical or numerical results from literature or those of the volume-particle SPH model are available for quantitative and qualitative comparison, are examined to demonstrate the accuracy and stability of the present method.

ON REALIZING SPECIFIC FAILURE CRITERIA IN PHASE FIELD MODELS

Xiaofei Hu[*1], Weian Yao[1] and Zhi Sun[1]*

[1]*Dalian University of Technology*

ABSTRACT

Phase field model (PFM) can be viewed as an extension of classic energy competition the-orem proposed by Griffith, and can realize crack initiation and propagation without any ad-hoc criterion, which was considered as a merit of the phase field model. However, it may become an obstacle when a specific failure criterion is required in a specific problem calculation. In order to solve this issue, we propose a simple way to embed different failure criteria into the PFM in this work. On one hand, an activation parameter is introduced into the PFM's driving force to control the fracture timing. On the other hand, a structural tensor is introduced into the PFM's surface density function to reflect the fracture direction predicted by the specified criterion. The fracture evolution direction is enforced in line with the criterion through a penalty parameter. Several numerical examples are provided to testify our proposed method, and the comparison of our model with both the results from extended finite element method (XFEM) and experiments testify the effectiveness of the proposed model.

A 3D NONLOCAL HYBRID ELASTO-PLASTIC FRACTURE MODEL OF ROCK-LIKE MATERIALS

Xiaokun Hu[*1] and Haitao Yu*[1]

[1]*Tongji University*

ABSTRACT

In order to simultaneously describe the elasto-plastic and damage behaviors of rock-like materials under various pressure conditions, a 3D nonlocal hybrid elasto-plastic model based on three-dimensional Hoek-Brown criteria is proposed in this paper. The proposed model couples the non-ordinary state-based peridynamics (NOSBPD) method and the nonlocal differential operator method to eliminate the surface effect due to the incomplete integral region near the boundary, and to simplify the imposition of boundary conditions. A plastic constitutive model with the well-known three-dimensional Hoek-Brown criterion is integrated within this framework to accurately represent the nonlinear behavior of rock-like materials. Note, that the effect of intermediate principal stress on elastic-plastic fracture behavior is considered in this model. The segmented flow rule is used for different pressure conditions. Strain-softening and fracture criteria, based on the equivalent plastic strain, capture the elasto-plastic response and damage-fracture processes in rock. The dynamic relaxation method is combined with the return mapping method to address quasi-static nonlinear problems. The proposed model is verified by comparing its results with those from the Finite Element Method (FEM), as well as with experimental data from the literature. Numerical examples contain the triaxial compression tests and compression tests of rock specimens with pre-existing flaws. Numerical examples demonstrate that the proposed model captures well the entire elasto-plastic fracture process for rock-like materials, including elasto-plastic deformations, crack propagation and progressive failure.

COMPARISON OF VORTEX STRUCTURES AND TURBULENT HEAT TRANSPORT FOR A SINGLE JET AND MULTIPLE JETS IN CROSSFLOW FOR PREDICTION OF HOT AIR RECIRCULATION

Xidong Hu[*1] and Ryo Onishi*[1]

[1]*Tokyo Institute of Technology*

ABSTRACT

The flow pattern of the hot air discharged from Air-Cooled Heat Exchanger (ACHE) fans under the crosswind condition is similar to a single jet in cross flow (SJICF) or multi-jets in crossflow (MJICF). The understanding of the physics in SJICF and MJICF will help predict Hot Air Recirculation (HAR) phenomena for achieving more production increase of LNG plant. Large Eddy Simulation (LES) has been carried out for a single jet and five spanwise jets with the jet-to-jet spacing of 1.6 jet nozzle diameter. The jet to crossflow velocity ratio VR is 3.3 and the Reynolds number Re_c is 2100, based on the crossflow velocity and jet nozzle diameter. The numerical schemes used in this study can provide good prediction accuracy in mean velocity/temperature, RMS velocity fluctuation, and Reynolds stress.

A significant difference in the vortical structures, shedding frequency, and jet trajectory is found between the sing jet and multi-jets. Firstly, the counter-rotating vortex pair (CVP) is only formed in a very short distance and cannot evolve in the streamwise direction. The hanging vortex is found to be split into two disconnected parts. No coherent large-scale vortical structure such as wake vortex and horseshoe vortex legs can be observed behind the multi-jets except for a lot of small-scale wakes. The Proper Orthogonal Decomposition (POD) analysis reveals that the dominant shedding frequency of the shear layer vortex in the multi-jets increases to 32 Hz compared with 18 Hz in the single jet. Secondly, the comparison shows that the multi-jets penetrate 20% less into the cross flow. Thirdly, the interaction mechanism between adjacent jets is revealed in this study. The analysis of sampling data in the flow path between the jets shows that the flow in the jet-to-jet spacing behaves as a pulsating jet flow with a frequency of 32 Hz. The width of the flow path in the spanwise direction shrinks and expands alternately causing the fluctuation in the streamwise velocity, which subsequently generates a lot of small wakes to the jet downstream.

The feature of the turbulent heat transport in multi-jets is revealed. It is found that the time-averaged turbulent heat flux in the vertical direction is larger in the jet-to-jet border because of the interaction while the time-averaged turbulent heat flux in the streamwise direction is larger at the jet rear because of the velocity acceleration in the multi-jets body.

ON NONLOCAL CONTINUUM MECHANICS OF FINITE STRAIN BOND-BASED PERIDYNAMICS

Xuan Hu[*1], Hailong Chen[2] and Shaofan Li[1]*

[1]University of California, Berkeley
[2]University of Kentucky

ABSTRACT

Peridynamics (PD) is a non-local continuum mechanics theory over two scales, where the macro-scale material responses are built based on the interaction forces among meso-scale material points. Unlike molecular dynamics, where the pairwise bond forces consist only of normal components along the bonds, our recent research demonstrated that the pair-bond force of peridynamics can include both normal and tangential components to capture macroscale material responses without introducing micro-polar continuum theory. In this study, we systematically developed a consistent finite strain nonlocal continuum theory based on a consistent and compatible bond-based peridynamics formulation that incorporates interactions in both normal and tangential directions among material points. A key feature of the proposed formulation is the alignment of meso-scale bond deformation with the finite-strain deformation theory, resulting in a meso-scale pairwise bond potential that is compatible with the finite strain energy density of macro-scale cohesive continuum. In contrast to conventional bond-based peridynamics and recently proposed extended-bond-based peridynamics which calculate relative displacements of bonds in a manner akin to structural truss elements, the proposed formulation uses the finite deformation strain measure, specifically the Green-Lagrange strain, as its primary deformation measure. This allows the finite strain bond-based peridynamics to capture the full spectrum of material deformation, including tension, shear and torsion, making it suitable for both infinitesimal and finite deformations in nonlocal continuum mechanics. Notably, our proposed formulation completely resolve the issue of zero-energy modes that inherently and persistently existence in the current peridynamics formulations. Moreover, utilizing the proposed formulation enables us to derive the general non-local stress measures through a standard mathematical procedure. The proposed novel peridynamics formulation cohesively integrates all essential elements of non-local continuum mechanics, kinematics, constitutive relation, governing equations, into one unified framework. Numerical examples, covering a range of problems from elasticity to nonlinear fracture, are provided to demonstrate the effectiveness of the proposed formulation.

A STABILIZED FRAMEWORK FOR NONLINEAR TOPOLOGY OPTIMIZATION BASED ON TIME-SERIES MOVING MORPHABLE COMPONENTS METHOD

Xueyan Hu[*1], Zonghao Li[2] and Weiqiu Chen[2]*

[1]Qihang Union & Innovation Center (QUIC), Huanjiang Laboratory
[2]Zhejiang University

ABSTRACT

The topology optimization of structures under large deformation has long been a challenging problem lacking stability during iteration. Getting the responses of every possible topology is the biggest challenge for this problem. For the density-based topology optimization, a linear interpolation scheme for the voids is introduced to enhance the stability of iteration. However, instability caused by the gray elements still persists. The explicit feature of the moving morphable components (MMC) method endows a good control of gray elements in the design space and hence has potential advantages in the problem under large deformation. This paper introduces the time-series moving morphable components method to solve the nonlinearity topology optimization problems. To further enhance the stability during iteration, various strategies are proposed. A direct modification of nonlinear strain is proposed to adress the instability caused by voids. The buckling control strategy is introduced to eliminate the instability caused by slender components. Further, the global-local mixed design variable as well as the trust-region based moving asymptotes optimizer are adopted to eliminate the instability of iteration reported in the traditional MMC framework.

INVESTIGATION OF STRESS IN LINK SLABS OF JOINTLESS STEEL-CONCRETE COMPOSITE BRIDGES

Zhijian Hu[1], Shoubin Wang[2] and Fei Wu[3]*

[1]*Wuhan University of Technology*
[2]*Shangdong Lihan Construction Engineering Groups Ltd. Co.*
[3]*Jiangxi Jiaogong Assembly-Manufacturing Ltd. Co.*

ABSTRACT

Jointless steel-concrete composite bridges have been widely applyed due to their merits of fully utilizing the mechanical properties of both steel and concrete and of getting rid of expansion joints by link slabs. Well link slab detailing, therefore, is crucial for their successful application. This study focuses on the analysis of transverse stresses in the link slab of a jointless steel-concrete composite bridge. By employing linear elastic theory of plate, the deflection and stress distribution functions of the link slab are determined. The validity of the close solution was first verified with both numerical simulation and load testing. The results indicate that the upper face of the link slab, located at the end of the steel girder, experiences the highest tensile stress in both transversal and longitudinal directions of the bridge. Furthermore, the impact of the link slab's area size on the peak stress in the transversal direction of the bridge is investigated. It is indicated that smaller spacing and longer end length of longitudinal beams lead to an increase in the maximum transversely tensile stress in the link slabs, resulting in the initiation of cracks before reaching their design loads. Therefore, for jointless steel-concrete composite bridges, transversal stresses must be considered in the link slabs except for longitudinal stress investigation.

DEVELOPMENT AND TESTING OF SUBCIRCUIT SURROGATE MODELS USING DATA-DRIVEN EXTERIOR CALCULUS AND XYCE-PYMI

Mamikon Gulian[1], Ravi Patel[1], Edgar Galvan[1] and Andy Huang[1]*

[1]Sandia National Laboratories

ABSTRACT

We evaluate data-driven surrogate models of subcircuits within the model-based design paradigm. Our goal is to design subsystem models that offer fidelity when integrated in a larger system, ensuring that systems designed using the surrogate models perform as expected when built. Physics-based constraints that augment data-driven methods are advantageous for intelligent, validated, and credible model-based design. The Data-Driven Exterior Calculus can be applied to learn subcircuit surrogate models based on deep neural networks that obey physical constraints such as Kirchoff's current law. These Python-based subcircuit models can be trained using imported from Xyce simulations, then reintegrated into the Xyce workflow as devices within Xyce-PyMi. We demonstrate training and evaluation results within this workflow on several direct current examples that are of broad interest as benchmarks and based on national lab circuit designs. We discuss best practices for training the surrogate models, which may be sensitive to architectural choices and hyperparameter values.

HEAT TRANSFER ANALYSIS OF VORTEX-RING COLLISIONS WITH A VERTICAL CONSTANT-TEMPERATURE WALL BASED ON DNS

Bohua Huang[*1], Zichao Jiang[1], Zhuolin Wang[1], Xuan Luo[1], Qinghe Yao[1] and Yi Zhang[2]*

[1]*Sun Yat-sen University*
[2]*Guilin University of Electronic Technology*

ABSTRACT

The impact of vortex rings generated by impinging jets plays a significant role in heat transfer processes. However, the simulation of such phenomena poses Challenges in mesh resolution and computational accuracy due to the involvement of complex multi-scale flow effects. This study introduces a high-resolution direct numerical simulation (DNS) approach, employing the Fast Fourier Transform (FFT) and the Semi-Implicit Method for Pressure Linked Equations (SIMPLE), to investigate the interaction between vortex rings and a vertical wall. The research is based on the DNS results to explore the coupling effects between the boundary layer and vortex rings, along with secondary vortices. It includes an examination of secondary vortex formation and evolution in different spatial regions, as well as the flow structure under varying Reynolds numbers. The study provides a comprehensive analysis of the flow dynamics, exploring the intricate patterns and interactions that occur during the collision of vortex rings with the wall surface. Moreover, the investigation delves into the effects of different flow states on boundary heat transfer. Numerical results illustrate that the high-resolution DNS, combining FFT and SIMPLE, has effective in capturing the detailed physics of vortex-wall interactions.

A COUPLED SPH-FDM METHOD FOR SIMULATIONS OF UNSTEADY FLOWS

Can Huang[1], Haonan Jiang[2], Fang He[2] and Ahmad Shakibaeinia[3]*

[1]*North China University of Technology*
[2]*Zhejiang University*
[3]*Polytechnique Montreal*

ABSTRACT

Smooth particle hydrodynamics (SPH) has significant advantages in the flows with the moving boundary or the free surface, however it is often limited due to its expensive computational cost. Finite particle method (FDM) is convenient to implement multi-resolutions, so it is usually high efficient. A coupled SPH - FDM is proposed to simulate the unsteady flows with the moving boundary or the free surface. The coupled SPH - FDM can solve fluid equations in Euler coordinate system [1] or Lagrangian coordinate system [2]. For Euler coordinate system, the overlapping particles and grid nodes are created near the interface between particles and grids in order to exchange the information of two methods, and the shifting particle technology is applied into simulations to adjust the positions of the particles for matching the movement of the boundary. For Lagrangian coordinate system, as well as the overlapping particles and grid nodes and the shifting particle technology, the creation (or deletion) of particles is introduced into the simulations to maintain the numerical stability. Euler coordinate system is usually convenient to simulate the flows around the moving body in a closed computational domain while Lagrangian coordinate system is convenient to simulate the flows with the free surface or the multi-phase flows. Some classical unsteady flows or applications are simulated and the results are compared with literature or experimental results to verify the accuracy of the coupled SPH-FDM.

[5]*National Central University*

ABSTRACT

Nanoglass, composed of heterogeneous glassy domains created by introducing interfaces into metallic glasses at the nanoscale, could be a promising strategy against severe shear localization, as demonstrated by a series of atomistic simulations. In this study, a mesoscale morphological model based on the kinetic Monte Carlo (kMC) algorithm is used to investigate the effect of grain size on nanoglasses (NGs). Considering that the development of shear bands during deformation can be categorized into four stages according to the aged-rejuvenation-glue-liquid model, we propose a variable characteristic strain (VCS) based on a sigmoid function to capture this process. Our simulations reveal that a transition from inhomogeneous to homogeneous deformation occurs as the NG grain size decreases to approximately 10 nm. This transition is attributed to the impediment of shear band formation by the small grain size, leading to strain hardening. The critical grain size predicted by our mesoscale model is in good agreement with molecular dynamics simulations. Furthermore, a progressive reduction of elastic constants is introduced to characterize the failure response. Numerical examples demonstrate that our kMC model is valuable for designing NGs to counteract shear localization, particularly when the appropriate VCS can be obtained from atomistic simulations.

FEATURE-DRIVEN SAMPLING STRATEGY IN ADAPTIVE MODEL ORDER REDUCTION FOR SHOCK-DOMINATED PROBLEMS

Cheng Huang[*1] and Ali Mohaghegh*[1]

[1]*University of Kansas*

ABSTRACT

Physical problems featuring strong shock advection (e.g., hypersonic flows and detonations) often present significant challenges and are well-recognized to be not amendable for conventional model-order reduction (MOR) methods. This can be mainly attributed to the well-known issues associated with the slow decay of Kolmogorov N-width. In literature, several remedies have been proposed to address this challenge via local subspaces, nonlinear manifolds, or adaptive MOR. In the current work, we focus on establishing an adaptive MOR methodology to construct reduced-order models (ROMs) for shock-dominated problems. In general, the adaptive MOR techniques seek to update the subspace in the online stage to satisfy an optimal representation of the evaluated dynamics in the target problems. One of the most crucial factors in adaptive MOR is the sampling points/locations selection for dynamics evaluations to minimize the posterior errors in representing the target physics. Therefore, specifically in this work, we develop a feature-driven sampling strategy to identify and select points near the shock wave fronts in adaptive MOR to improve the predictive capabilities of the resulting ROMs. Two canonical shock problems are considered to assess the proposed sampling strategy: 1) a sod shock tube; and 2) a 1D detonation tube.

FP-IRL: FOKKER-PLANCK-BASED INVERSE REINFORCEMENT LEARNING - A PHYSICS-CONSTRAINED APPROACH TO MARKOV DECISION PROCESSES

Chengyang Huang[*1], Siddhartha Srivastava[2], Xun Huan[1] and Krishna Garikipati[2]*

[1]*University of Michigan*
[2]*University of Southern California*

ABSTRACT

Seemingly identical cells in a biological system exhibit distinct responses to the same environmental cues, so how are heterogeneous behaviors being provoked? There is a lack of a systematical method to understand the behavior of a single living agent (e.g. cells) in a complex biological system. The current modeling approach utilizes partial differential equations that build upon the Markov process without considering the possibility of the decision-making process in a living agent and the quantitative causality between decisions and states. In contrast, we employ Markov decision processes to characterize living agents in biological systems as intelligent agents that can make decisions following a policy that maximizes the expected cumulative reward. The reward function encapsulates the incentive mechanism and quantifies the motivation of the agent’s behavior. This will establish a new paradigm for studying complex behaviors in multiple biomedical systems. The reward structure driving the decision-making of an agent is generally unknown. To help uncover the motivation behind the behavior of the living agent, we leverage Inverse Reinforcement Learning (IRL) to estimate this unknown reward function from observation data of the studied agent. Like other inverse problems, IRL is typically ill-posed and becomes especially challenging when the transition model is unknown or inaccessible for sampling because the evolution of states and actions depends both on the transition model and the agent's policy, which is derived from the transition model as well together with the reward function. Conventional IRL approaches either assume the transition model is accessible or utilize data-driven methods to estimate the transition model beforehand without considering physics. We propose a novel physics-aware IRL algorithm that can simultaneously infer the reward function and transition probability function from observed temporal data. We first establish a connection between the reward function in IRL and the potential function in the Fokker-Planck equation (FPE), a partial differential equation that governs the time evolution of the probability density of the agent's states. Next, we employ variational system identification to infer the potential function in FPE, which in turn allows the reward, policy, and transition probability functions to be evaluated instantaneously leveraging the established connection. In addition to obtaining the reward function, new cell states and decisions can also be predicted and simulated as the state transition is mathematically modeled. We demonstrate our approach using a Gridworld benchmark problem and a cancer cell migration problem.

A FULLY COUPLED THERMO-MECHANICAL LOCALIZING GRADIENT DAMAGE MODEL WITH A MODIFIED MAZARS STRAIN

HanWei Huang[*1], Hao Yu[1] and HengAn Wu[1]*

[1]*University of Science and Technology of China*

ABSTRACT

Thermal crack is a common thermomechanical coupling phenomenon in both natural and engineering situations, such as the drying of soils, the shrinkage of concrete, and the quenching test of ceramics. The bidirectional thermo-mechanical coupling exerts a substantial influence on crack patterns, especially in situations sensitive to temperature variations. Besides, varying constraints give rise to tension or compression zones within the material, leading to distinct modes of thermal cracks. Comprehensively describing the thermomechanical coupling effects and accurately capturing different failure modes remain challenges in thermal crack modeling. To address this issue, a thermodynamically consistent and fully coupled gradient damage model is proposed based on a differential form of non-local damage theory. This model is designed for thermal cracks in both quasi-static and dynamic scenarios, and it accurately characterizes the impact of thermal expansion on the stress field and the contribution of volumetric strain and damage evolution to the temperature field. Furthermore, to precisely describe different modes of thermally induced cracks, a modified Mazars strain is formulated as the driving force for the gradient damage model, which introduces the first invariant of the strain tensor and the tension-compression strength ratio to the traditional Mazars strain. The numerical results confirm the reliability of the modified Mazars strain in capturing different modes of failure and demonstrate the capability of the proposed damage model to characterize complex damage patterns under thermal loading in both quasi-static and dynamic scenarios. Additionally, in the simulation of the quenching test of ceramic plates, traditional models, which ignore the influence of volumetric strain and damage evolution on the temperature field, tend to overestimate temperature changes, resulting in fewer cracks and larger crack spacing compared to experimental results. While the proposed fully coupled damage model aligns well with experimental results. In the simulation of thermal shock on cylindrical specimens, the damage pattern is found associated with compression strength, which transfers from spiral shear bands to a halo-like annular damage zone and radially developed damage.

PARAMETER IDENTIFICATION OF PIEZOELECTRIC ENERGY HARVESTER BASED ON ISOGEOMETRIC ANALYSIS VIA BAYESIAN UPDATING

Jian Huang[*1], Mehrisadat Makki Alamdari[1] and Elena Atroshchenko[1]*

[1]*University of New South Wales*

ABSTRACT

The piezoelectric energy harvesters (PEHs) have been widely studied in recent years, with various models employed to simulate their dynamic behavior. However, the accuracy of these models is often affected by uncertainties arising from both manufacturing and operational factors [1]. This work aims to identify the most probable input parameters of the model based on nominal value to align numerical results with experimental results, considering the above-mentioned uncertainties. In this work, a Kirchhoff-Love plate model utilizing isogeometric analysis (IGA) [2] is employed to generate numerical Frequency Response Functions (FRFs) of PEHs, which are then compared with experimental FRFs. The Bayesian updating is the key technique applied to find out the most likelihood parameters by the posterior probability function which is obtained from the Transitional Markov Chain Monte Carlo (TMCMC) algorithm. Additionally, given the increased number of input parameters associated with the plate model, a model class selection study is also conducted to find out the most appropriate group of parameters for Bayesian updating. The study tests a total of 5 devices with different widths, 4 of which are cut from a standard commercial PEH. The results from the model class selection show that parameters of piezoelectric material and geometry properties will have higher uncertainty. This uncertainty is primarily due to the thin structure of PEHs, leading to variations of PEH properties during manufacturing and the cutting process to obtain different sizes of PEHs. Furthermore, Bayesian model updating effectively identifies key parameters, matching numerical FRFs with experimental results. Updated parameters also perform well in an extended Multi-PEHs model, showing good agreement with experimental data from coupled devices. In the future, a direct model updating on the Multi-PEHs model will proceed for further comparative analysis.

INCORPORATING ANISOTROPIC MATERIAL MODELS INTO AUTOMATED IMAGE-BASED MODELING AND MESH GENERATION FOR VASCULAR FLUID-STRUCTURE INTERACTION

Jiayi Huang[*1], Yujie Sun[1], Xinhai Yue[1] and Ju Liu[1]*

[1]*Southern University of Science and Technology*

ABSTRACT

This study presents a refined framework for vascular modeling and mesh generation to enhance the accuracy of vascular Fluid-Structure Interaction (FSI) simulations. The method begins with the acquisition and preprocessing of medical images to construct a three-dimensional representation of vascular structures. This underpins the ensuing arterial wall constitutive model[2].

A crucial aspect of our methodology is the computation of the vascular centerline, imperative for delineating complex vascular network geometries and ensuring accurate 2D segmentation of blood vessels. We utilize a deep learning algorithm to extract 3D vascular lumen segmentation from medical images, followed by an efficient method[1] for centerline and radius computation. This approach is convenient and cost-effective compared to traditional methods without loosing accuracy in capturing the vascular network.

Our methodology advances vascular wall model generation and mesh generation through the application of scaling and lofting techniques based on the lumen geometry. It circumvents the limitations of traditional extrusion-based methods.

A fundamental aspect of our approach is the establishment of a local basis within the vascular tissue, due to the anisotropic properties of biological tissues[2]. We define a local basis at each mesh node, which is informed by the vessel's morphology and the derived centerline data. This technique is particularly appealing for patient-specific vascular structures. Through simulations of idealized curved geometries and two-layered abdominal aorta models, our method proves to be more robust and accurate than the existing elasticity-based method, especially in regions with varying diameters and bifurcations, highlighting the importance of anisotropic arterial wall models in vascular FSI.

Our approach, integrating advanced image processing, precise segmentation, and sophisticated mesh generation, performs well in defining fibers in patient-specific models. This technology suite advances vascular modeling and thus enhance the pipeline of image-based simulation.

STUDY ON GAS ADSORPTION BEHAVIOR IN SHALE NANOPORES BASED ON MOLECULAR KINETIC THEORY AND MACHINE LEARNING METHOD

Mengcheng Huang[*1], Hao Yu[1] and Hengan Wu[1]*

[1]*University of Science and Technology of China*

ABSTRACT

Understanding the shale gas adsorption behavior in shale nanopores is essential for the reservoir estimation of shale gas, and understanding the competitive adsorption behavior of CO2 and CH4 in shale nanopores is crucial for enhancing the recovery of shale gas and sequestration of CO2. Considering the complexity of geological environment and nanoporous structure of shale, traditional methods based on experiments and molecular dynamics simulations are always expensive and inefficient. In our work, we analyzed and predicted the adsorption behavior of shale gas and the competitive adsorption behavior of CO2 and CH4 by combining microscopic analysis methods and machine learning methods, respectively. One the one hand, a machine learning framework to predict the methane adsorption behavior in shale nanopores is constructed from the microscopic and kinetic theory perspectives, where some novel parameters related to potential energy distribution are proposed to represent the methane adsorption characteristics of shale slit nanopores. Machine learning model based on the uniformly constructed dataset is introduced to realize fast and accurate prediction of methane adsorption behavior, which is well validated by typical inorganic and organic models. On the other hand, the theoretical connection between inherent characteristics of molecules and adsorption behavior is built to reveal the general laws in the behavior of CO2/CH4 competitive adsorption through posture analysis of the molecules. A machine learning algorithm, aided by molecular kinetic theory, is proposed to facilitate the fast and accurate predictions of competitive adsorption behavior, and detailed analyses of the influencing factors are conducted accordingly. The insights gained from our work provide a foundation for expeditiously estimating the competitive adsorption behavior of CO2/CH4, with potential implications for CO2 sequestration and enhanced gas recovery process, and would be beneficial for the exploitation and development of shale gas reservoirs.

EXPERIMENTAL CHARACTERIZATION AND NUMERICAL MODELING OF DEFECTIVE BATTERY CELLS INDUCED BY MECHANCIAL ABUSE

Qingdan Huang[*1], Chao Zhang[1] and Yikai Jia[1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

In challenging operational environments, lithium-ion batteries (LIBs), as cutting-edge power sources for diverse applications, inevitably endure external loads like impact and extrusion, posing risks of battery damage and failure. Consequently, investigating the safety performance of LIBs under mechanical loading becomes a central focus in LIBs research. Simultaneously, the concept of cascaded utilization is introduced to maximize the remaining value of retired batteries and alleviate recycling pressure from discarded batteries. Hence, before recycling and reusing batteries, especially older models or damaged ones, a thorough assessment of their electrochemical performance, safety risks, and the implementation of targeted design controls and management algorithms are crucial. This is integral to achieving efficient energy storage device utilization and ensuring overall safety throughout the battery lifecycle. To achieve a more accurate electrochemical analysis and prediction of damaged batteries, this study conducts relevant experimental characterization and numerical modeling. In the experimental section, the impact of low-velocity impacts on the performance and safety of LIBs, influenced by electrochemical cycling and dynamic loading, is explored. Various conditions, such as impact energy, State of Charge (SOC), and C-rates, systematically reveal mechanical, electrochemical, and thermal responses, as well as damage behaviors. The study demonstrates that higher impact energy leads to increased structural stiffness, maximum temperature, and maximum voltage drop. Additionally, heightened impact energy and SOC significantly influence electrochemical parameters, including charging capacity and internal resistance. In the simulation section, for a more precise mechanism explanation and parameter analysis through numerical simulations, it is essential to consider the distribution of current and Li concentration, including the inherent structural non-uniformity of the cell, as well as geometric and material non-uniformities. The uneven charge distribution resulting from these non-uniformities has been identified in previous studies as a significant factor contributing to battery cycling performance degradation and a reduction in safety. In this work, the focus is on electrode-level non-uniformities introduced by battery structure and electrode accidental deformation damage. We investigate the impact mechanisms of intra-electrode non-uniformities on the electrochemical performance and safety of batterie aiming to elucidate the quantitative relationship between non-uniformities and the extent of performance degradation. The methodology and experimental findings provide insights for enhancing safety design, conducting risk assessments, and enabling the cascading utilization of energy storage systems based on LIBs.

STRUCTURAL DESIGN AND EXPERIMENTAL ANALYSIS OF PORTABLE ROPE-CLIMBING ROBOT

Renjie Huang[1], Dongyan Shi[1], Shijie Yao[1], lan Zhang[1] and Zhengyu Zhang[1]*

[1]*Harbin Engineering University*

ABSTRACT

For the extreme environments such as special combat, high altitude operation, earthquake rescue and other extreme environments, the manual operation is difficult, high operating cost, high risk factor, and the traditional rope climbing robot fixed the power system and transmission system in advance at the end point of the operation, the operation area is fixed and inefficient. Therefore, based on the optimized design of rope-sheave lifting mechanism, a portable rope-climbing robot is designed. The flexible rope is used as the transmission medium, which is wrapped around the inside of the rope-climbing robot, one end of which is fixed at the end of the transmission, and the other end of which is freely suspended, and the friction between the rope and the rope-sheave is used as the motive force to support the operator's movement along the direction of the rope. Experiments show that the portable rope-climbing robot can realize the functions of crossing, cable-stayed, vertical up and down multi-direction operation and rapid lifting in the high-altitude environment. At the same time, it shows good stability of high-altitude operation, with small size, light weight, high transmission efficiency, high timeliness, convenient and other advantages. It has important application value in earthquake rescue, special operation and robot transmission, and provides theoretical guidance and design basis for the research and development of rope-climbing robot.

COUPLED ADHESION AND FRICTION OF GRAPHENE NANORIBBONS

Rui Huang[*1], Ganbin Chen[1] and Kenneth Liechti[1]*

[1]*The University of Texas at Austin*

ABSTRACT

Peeling of graphene nanoribbons (GNRs) atop a graphene substrate can be used to characterize both adhesion and friction due to van der Waals interactions. In this work, we develop a continuum model for peeling and sliding of GNRs, using a periodic potential energy function to simulate the van der Waals interactions between the GNRs and the substrate in both the normal and tangential directions. Numerical simulations and associated analyses reveal remarkably rich dynamics in peeling and sliding of GNRs. It is found that the simple 90-degree peeling of a GNR depends primarily on the normal (adhesive) interactions, with negligible sliding or shear interactions. In contrast, peeling with the end fixed in the in-plane directions leads to stick-slip sliding, with a higher peeling force and a critical peeling angle depending on both adhesion and friction. Notably, the stick-slip sliding is facilitated by formation and gliding of strain solitons in GNRs, and different types of strain solitons may form in the zigzag, armchair and chiral GNRs. The peak pulling force as a measure of the sliding friction depends on the ribbon width quasi-linearly but becomes nearly independent of the ribbon length for relatively long GNRs (L >20 nm). Two cases with coupled peeling and sliding of GNRs are considered, and a simple analysis is proposed to simultaneously determine the adhesion and friction properties of GNRs from measurable quantities in potential experiments.

ABSTRACT

Physics-informed machine learning has become increasingly popular for discovering evolution equations from data. Such great success has led in the last few years to the development of thermodynamic-based approaches to enforce constraints, such as the second law of thermodynamics, and learn the thermodynamic structures of system, including the driving operators and potentials. Yet, unless further information is provided, the same macroscopic evolution can be obtained from different thermodynamic structures, indicating that this inverse learning problem is non-unique. This significantly challenges the discovery of the true physics. In this talk, we introduce a new machine learning strategy, called Statistical-Physics-Informed Neural Networks (Stat-PINNs), that can resolve this non-uniqueness issue for the first time, by encoding statistical mechanics relations. This strategy is developed for isothermal dissipative phenomena with the goal of predicting long-time macroscopic evolutions from short-time particle dynamics. Demonstrated on several examples, Stat-PINNs can successfully coarse-grain particle systems with known analytic macroscopic descriptions as well as discover, yet unknown, potentials and operators. Furthermore, our results indicate that the statistical mechanics relations within Stat-PINNs can increase the predictive capability and robustness of the machine learning algorithm.

ADVANCED MATERIAL POINT FORMULATION FOR GEOMECHANICAL PROBLEMS UNDER EXTREME LOADING CONDITIONS

Tsung-Hui Huang[1], Cameron Rodriguez[1] and Sung-Han Yu[1]*

[1]*National Tsing Hua University*

ABSTRACT

The Material Point Method (MPM) has emerged as a valuable tool for modeling geomechanical phenomena like explosive mining or ground upheaval. Yet, it encounters significant challenges related to accuracy and pressure instability due to limitations in its domain integration scheme. Numerical issues, including undrained-induced pressure oscillation/locking and shock-induced instability under extreme loading conditions, further impede its effectiveness. This study introduces the VC-RKMPM approach [1], building upon previously developed variational consistent (VC) and reproducing kernel (RK) enhancements. The aim is to tackle these numerical challenges in geomechanical applications. Specifically, we implement a stabilized mixed formulation [2] to investigate blast behavior in porous geomaterials. Our approach involves exploring suitable stabilization techniques for shock wave dynamics and integrating a pressure stabilization method to rectify the shortcomings of the equal order approximation scheme. To demonstrate the efficacy of our proposed framework, we present several benchmark numerical examples. These examples showcase how our approach effectively addresses the aforementioned issues, thereby enhancing the reliability and accuracy of geomechanical simulations.

A PHASE FIELD MODEL FOR FATIGUE FRACTURE CONSIDERING CRACK RETARDATION EFFECT DUE TO SINGLE OVERLOAD

Wei Huang[*1], Yu-xuan Ying[1] and Yu-e Ma[1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

Phase Field Method is a powerful tool which takes the advantages of fracture mechanics and continuum damage mechanics [1-3]. Over the last decade, the phase field method has been developed to simulate the brittle fracture, ductile fracture, cohesive fracture, and fracture in multi-physics problems. It has the potential capability to model complicated crack patterns including crack initiation, crack propagation, crack merging, crack branching and crack kinking. In this work, a phase field fatigue model is proposed to simulate fatigue crack propagation behavior considering crack retardation effect based on the Griffith threshold degradation method and the Wheeler model.

Based on the Griffith threshold degradation method, the crack tip fatigue degradation zone is defined and the analytical solution of fatigue crack growth rate can be derived. This method is combined with the phase field model and fatigue acceleration algorithm. The simulation results show that the fatigue crack growth rate obtained by the phase field model of AT1 dissipation function is more consistent with the analytical solution. The fatigue life increases with the decrease of the radius of fatigue degradation zone. Compared with the other numerical methods, the proposed phase field fatigue model requires fewer parameters, and the simulation results are closer to the experimental results.

Based on the Wheeler model for crack growth retardation, we proposed a three-parameter driven degradation function for phase field fatigue model that responds to fatigue crack propagation retardation induced by single overload. This modified phase field fatigue model high load history variables is demonstrated to effectively capture the whole stage of fatigue crack retardation (including: delayed retardation, nonlinear recovery, retardation vanish). Simulation results are also in good agreement with the experimental results.

The predictions of the proposed model agree well with the experimental results reported in the literature. This achievement contributes significantly to the structural safety design and life prediction, and can provide a theoretical basis for structural integrity assessment.

WEAKLY ENFORCED DIRICHLET BOUNDARY CONDITION IN HEMODYNAMIC SIMULATIONS

Xuanming Huang[*1] and Ju Liu*[1]

[1]*Southern University of Science and Technology*

ABSTRACT

It is well-known that the weak enforcement of the Dirichlet boundary condition can be effective in the wall modeling of turbulent flows [1]. Current research assesses the wall-modeled computation results with DNS or experimental data based on relatively simple geometries (such as channel flow). It is less common to see studies that considered weak enforcement of boundary conditions in cardiovascular flows. Blood flows may involve complex flow patterns, including laminar, transitional, and fully turbulent flows. This demands a specific consideration of the wall modeling. Moreover, the geometry of patient-specific models involves tortuous paths, bifurcating branches, and non-uniform vessel radius. Consequently, the boundary layer mesh generation for blood flows can sometimes be quite challenging. Thus, it remains a crucial task to evaluate the existing treatment of the wall boundary and offer guidance in cardiovascular applications.

In this study, we investigate the effect of the weakly enforced no-slip boundary condition of the incompressible Navier-Stokes equations in hemodynamic simulations. Our scheme is based on the residual-based variational multiscale method and the generalized-α time marching method. Three approaches are studied: (i) strong enforcement for the velocity in all directions with boundary layer meshes, (ii) weak enforcement for the velocity in all directions, (iii) weak enforcement for the wall-tangential velocity component in combination with strong enforcement for the wall-normal velocity component. Besides, we will discuss a critical method for generating outward normals at the nodes on polygonal surface meshes [2]. The nodal normals are employed in the third approach, and they can be applicable for postprocessing wall shear stresses.

The adopted numerical benchmarks include (i) the idealized medical device designed by the US Food and Drug Administration (FDA), (ii) the centrifugal blood pump designed by the FDA, (iii) CFD and FSI cases of the aorta, with emphasis on physiologically realistic domains. We will compare our results to experimental data and existing numerical results, and we will then draw conclusions based on the assessment.

MATHEMATICS-INFORMED NEURAL NETWORK FOR WAVE SCATTERING PROBLEMS

Xun Huang[*1] and Sicong Liang*[1]

[1]*Peking University*

ABSTRACT

In this work, we propose a mathematics-informed neural network (MINN) approach for resolving the long-term challenge in wave scattering modelling. The key contribution is the innovative concept of the incorporation of the Cauchy-Riemann equation into machine learning architectures, which eventually learn to produce matrix kernel factorization for Wiener-Hopf analytical models. To validate and demonstrate the approach, a guiding example of wave scattering from parallel hard-soft plates is studied by comparing the machine learning results with the available analytical solutions. Overall, the proposed MINN approach could extensively enhance the theoretical modelling capability for a number of wave scattering and fluid mechanics problems.

EFFECTS OF THE LIGAMENTS ON VERTEBRAE AND MATERIAL PROPERTIES OF DISCS DURING THE S2AI SURGERY FOR SCOLIOSIS: A FINITE ELEMENT STUDY

Ying-Hsuan Huang[*1], Chaung-Sian Yang[1], Chi-Kuang Feng[2], Jing-Jing Fang[1] and Chung-De Chen[1]*

[1]National Cheng Kung University
[2]Taipei Veterans General Hospital

ABSTRACT

Scoliosis and anterior pelvic tilt are frequently observed spinal deformities that can significantly impact a patient's quality of life and overall health. Early diagnosis and treatment are essential for correcting these deformities. Traditionally, clinical observations, radiology, and surgeries have been relied upon for research in the field of scoliosis and pelvic tilt, but these methods have limitations. Finite element method (FEM) has received attentions as a computational method to study spinal models, enhancing our understanding of biomechanical behaviors.

The objective of this study to simulate the procedure of a scoliosis correction surgery with S2AI by using FEM. The numerical model to simulate the entire correction surgery process, providing useful insights that can guide improvements in surgical procedures. The geometric models are established based on Computed Tomography (CT) data obtained from a 16-year-old female patient. The finite element model was conducted with the commercial FEM software ABAQUS. The model is composed of lumbar L1 to L5, sacrum, pelvis, ligaments, discs, screws (including S2AI) and rods. The discs and ligaments are modeled by hyperelastic material and spring elements, while the others are by linear elastic materials. The acetabulum is fixed for boundary condition. The analysis for the surgical procedure includes four stages: the establishment of follower load, movement of screws and vertebrae, contact between screws and rods, and the release of screws. The effects of the ligaments on vertebrae and material properties of discs during the S2AI surgery for scoliosis are investigated by FEM.

According to the FEM results, a spring back is observed in the finite element calculations after rod release. It reveals that the rod near S2AI have lowest spring back displacement as it is near fixation region. The spring back displacements increases for upper vertebrae. The existence of spring back displacements suggests that the correction angle may be less than expected. The pullout forces of screws can also be calculated by the FEM model. The risk for screw-loosening can be evaluated.
The numerical results obtained in the model can provide a reference to a doctor for plan of pre-operation.

MULTI-SCALE DAMAGE AND FRACTURE SIMULATIONS OF CONCRETE

Yu-jie Huang[*1] and Hui Zhang[1]*

[1]*North University of China*

ABSTRACT

Concrete is composed of multiple phases such as coarse aggregates, mortar, pores, initial cracks, and interfaces at micro/meso-scale, which exhibit randomness, heterogeneity and phasic interactions contributing to highly nonlinear and stochastic failure processes at material/structural level. Accurately and efficiently simulating the multi-scale damage and fracture of concrete has become one of the major challenges in the fields of composites science and computational mechanics. This paper introduces our recent studies on micro-CT experiments and static/dynamic fracture simulations of concrete, including the generation of high-fidelity random fields and novel models with realistic aggregate morphology and distribution. We also present automatic meshing algorithms for complex meso-structures integrated with the Scaled Boundary Finite Element Method (SBFEM) and Smoothed Finite Element Method (SFEM), and develop efficient computational frameworks with the discrete cohesive model [1], quasi-brittle phase field model [2], and nonlocal damage model [3], respectively. Through a series of typical benchmarks, the work validates the simulated fracture processes and load-carrying capacities, evaluates the accuracy and computational efficiency of various algorithms, and offers flexible control in reconstructing meso-structures. We focus on the crack-netting mechanisms, stochastic mechanical responses, and impacts of meso-scale parameters on macroscopic performance, elucidating the complicated multiple micro-crack initiation, propagation, branching, merging, and macroscopic crack formation. The proposed computational frameworks are also applicable to other composite materials such as fiber-reinforced composites, metal-matrix composites and ceramic-matrix composites, benefiting the development of new materials and structures.

A NUMERICAL STUDY FOR SHEAR-INDUCED AMORPHIZATION IN ALLOY

Yuntong Huang[*1], Shuyang Dai[2], Yang Xiang[1] and Chuqi Chen[1]*

[1]*The Hong Kong University of Science and Technology*
[2]*Wuhan University*

ABSTRACT

Amorphization due to severe plastic deformation has been discovered in various crystalline materials. Despite its importance, developing a rigorous and general theory of strain-induced amorphization remains a significant challenge due to the intricate nature of modeling microstructural changes and deformation mechanisms. In this study, we propose a novel model integrated with elastic-plastic theory to shed light on shear-induced amorphization in nanocrystalline alloys. Our model incorporates the martensite transformation of the austenite phase under large plastic deformation, followed by the intensification of crystal fracture on the martensite phase to form an amorphous phase. Our simulations suggest that amorphous nucleation is more likely to occur in high-stress regions, such as shear bands, and that the critical plastic strain for amorphization increases as grain size grows. These observations align with experimental data, indicating that our phase-field model captures the physical picture of shear-induced amorphization and can predict the threshold for amorphization. Overall, our work offers valuable insights into shear-induced amorphization and paves the way for enhancing the understanding of amorphous materials and fostering the development of more precise and comprehensive models for investigation.

CONSISTENT AND CONSERVATIVE PHASE-FIELD METHOD FOR CHALLENGING INCOMPRESSIBLE AND COMPRESSIBLE MULTIPHASE PROBLEMS

*Ziyang Huang**[1]

[1]*University of Michigan*

ABSTRACT

The Phase-Field method has been widely used to model complex systems including moving and deforming interfaces, as either a thermodynamic model or numerical tool. However, the coupling of the Phase-Field description of interfaces to the dynamics of continua is non-trivial and missed in the literature. This presentation provides an overview and recent progress on the consistent and conservative Phase-Field method, which addresses the coupling of the Phase-Field mechanism to a wide range of challenging multiphase problems including an arbitrary number of materials, arbitrarily large density ratios, heat and mass transfer, solidification and melting, and shock and rarefaction waves. The corresponding numerical framework that preserves the physical structure of both incompressible and compressible multiphase flows is also introduced. Various multiphase problems are reported to demonstrate the efficacy of the Phase-Field method.

MODEL-REDUCED IGA BASED ON LOCALLY-REFINED SPLINES FOR BUCKLING ANALYSIS OF IMPERFECT FGM SHELLS

Yang Huashi[1], Liu Pengke[1] and Li Jiaxing[1]*

[1]*Northwest Institute of Mechanical & Electrical Engineering*

ABSTRACT

Buckling responses of imperfect FGM shells (perforated or cracked), whose material properties grade continuously in specified directions, are numerically investigated through the combination of extended isogeometric analysis and isogeometric finite cell method based on locally-refined splines. On the basis of inheriting the superiorities of the geometric smoothness and exactness of isogeometric analysis, the locally-refined splines can accurately describe the geometry of the middle-surface of FGM shells and flexibly control the meshes' density around the defects, directly linking the CAD model to the structural one. Besides, the higher continuity of locally-refined splines basis functions can automatically satisfy the requirement of C1-continuity for the Kirchhoff–Love theory. The main superiority of the presented method is that the representation of all types of internal defects is mesh-independent of the underlying grids. The displacement discontinuous across the crack face and the stress singular phenomena in the vicinity of the crack tip are efficiently captured by using the local enrichment patterns in isogeometric approximation. The geometric interfaces of cutouts are approached and approximated by means of an adaptive integration scheme based on quadtree subdivision technique in the distinguished cut elements. This implementation avoids the tricky process of multiple patches to represent the geometry of shells, thus eliminating the enforcement of higher continuity across these patches' boundaries. The cylinder arc-length iteration technique in combination with modified Newton–Raphson iteration algorithm, which embeds three strategies arc-length control, eigenvalue analysis and mode imperfections, is applied to implement geometrically nonlinear dynamic analysis. Furthermore, to maintain a balance between computational efficiency and computational accuracy, the reduced-order modeling technique via proper matrix decomposition is employed into the isogeometric framework coupled with dynamic response analysis. After validating the effectiveness and reliability of the developed approach through available benchmark problems, a series of factors, including material volume fraction, boundary condition, defects size, imperfection sensitivity etc., affecting the buckling responses of imperfect FGM shells are performed and investigated.

ASYMPTOTIC DESIGNABILITY AND THE STRUCTURE OF SELF-ASSEMBLY

Maximilian Huebl[*1] and Carl Goodrich*[1]

[1]*Institute of Science and Technology Austria*

ABSTRACT

The spontaneous self assembly of complex structures from simple building blocks is of prime importance in biology and is a promising candidate for the creation of novel functional materials. The potential for synthetic material design leads directly to a formulation of self assembly as an inverse problem: “How should we tune our building blocks, such that they self-assemble into the structures or materials we desire?” However, such inverse problems are usually tackled through direct optimization, which can lead to one-off solutions that do not generalize or reveal broader principles.
Here, we will show that the space of self-assembly yields has an internal structure that is hierarchically organized. To achieve this, we exploit an underlying correspondence between inverse self-assembly and the theory of convex polyhedra. We then introduce the concept of Asymptotic Designability, which refers to a structure (or group of structures) that can, in principle, be assembled at high yield. Using algorithms from polyhedral computation, we can completely and efficiently enumerate all sets of asymptotically designable structures, which form the basis for a comprehensive view of the design space. Furthermore, in an asymptotic regime of parameter space, the mapping from parameters to yields becomes linear, meaning that the complete inverse problem reduces to an easily solvable linear program. This framework is highly generalizable, provides geometrical intuition for complex self assembly processes, and can easily incorporate experimental constraints.

SURROGATE MODELS FOR STROKE OPTIMIZATION IN PARAMETERIZED FLOWS

Matteo Giacomini[1] *and Antonio Huerta**[1]

[1]*Universitat Politècnica de Catalunya*

ABSTRACT

Simulating complex flow systems with parameterized geometries in order to determine critical quantities of interest (QoI) is often prohibitively expensive due to the high dimensionality of the problem. This challenge is further inescapable in optimization loops where multi-querying is essential to the scheme. Additionally, simplified models usually lack the accuracy needed by physicists and engineers to provide reliable QoI estimates. This computational bottleneck poses a significant challenge for the effective conception, design, and operation of industrial systems, especially when geometric parameters are involved.

After providing a brief overview of a priori and a posteriori ROM strategies for geometrically parametrized incompressible flows [1], optimal strokes for the push-me-pull-you (PMPY) model of an euglenoid micro-swimmer are determined using the non-intrusive Encapsulated Proper Generalized Decomposition (PGD) to calculate separated expressions of forces and velocity, explicitly depending on the design parameters [2].

[5]University of Pavia

ABSTRACT

Active surveillance (AS) is a standard clinical management option for the abundant newly-diagnosed prostate cancer (PCa) cases exhibiting low and favorable intermediate clinical risk. Since these tumors do not require immediate treatment, AS offers longitudinal monitoring via multiparametric magnetic resonance imaging (mpMRI), serum prostate-specific antigen (PSA) tests, and biopsies. If these exams detect progression to higher-risk disease, then the patient is prescribed treatment. Hence, AS combats the current overtreatment of PCa. However, AS is based on an observational population-based approach, which does not account for each patient's tumor dynamics and may delay the detection of tumor progression. This work proposes to address these issues by means of personalized predictions of PCa growth and progression informed by each patient's clinical and mpMRI data collected during AS [1]. We use a biomechanistic model to describe spatiotemporal PCa growth in terms of tumor cell density as a combination of tumor cell mobility and net proliferation. This model is posed on the patient's prostate geometry defined on T2-weighted MRI data. Apparent diffusion coefficient (ADC) maps obtained from diffusion-weighted MRI data are used to estimate tumor cell density. Model calibration consists of minimizing the mismatch between model predictions and mpMRI measurements of tumor cell density, and we validate predictions against further mpMRI measurements at later times. We leverage isogeometric analysis to solve our model numerically and, hence, obtain patient-specific tumor forecasts. Additionally, we construct a logistic classifier of PCa risk utilizing model-based biomarkers calculated from the model forecasts (e.g., tumor volume, total proliferation activity) at the times of histopathological assessment (i.e., biopsy, surgery). In a cohort of 16 PCa cases with three longitudinal mpMRI datasets, we obtained a concordance correlation coefficient (CCC) for tumor volume of 0.89 both at the second and third scan times (i.e., calibration and prediction horizons). The corresponding spatial fits and forecasts of tumor cell density maps resulted in a CCC of 0.59 and 0.60, respectively. Our logistic classifier of clinical risk yielded an area under the receiver operating characteristic curve of 0.90, operates at optimal sensitivity, specificity, and accuracy of 86.7%, 93.8%, and 90.3%, and anticipates PCa progression by more than 1 year with respect to standard AS. Thus, we believe that our technology shows promise to guide clinical decisions for each PCa patient during AS.

ABSTRACT

Accurate identification of structural loads is critical in digital twin applications such as structural health monitoring. Structures are rarely equipped with sensors that can adequately characterize the loads but may have sensors that measure the resulting response. In this work, we consider an indoor footbridge monitored by six strain gauges. We demonstrate that we can infer from strain data a detailed description of a pedestrian's motion, including speed, stepping rate and walking path. We observe that the walking path has a significant impact on structural response. Furthermore, we observe that a higher fidelity walking path model (e.g. allowing for curved walking paths) improves our ability to infer other parameters of the pedestrian motion. The increased fidelity in the walking model incurs an increased computational cost to our parameter inference procedure, motivating the following contributions.

Our first contribution is the development of a projection-based reduced order model (pROM) for the bridge which ensures rapid evaluation of the strain and its gradient with respect to the walking model parameters. In standard pROM training, we collect snapshots of the system response for representative load conditions and then construct the reduced model using the snapshots. However, the standard sampling procedure is intractable in our case because an attempt to sample the space of all possible bridge traversals results in too large of a training set. Instead, we exploit that the walking load is decomposable into individual footfall loads and develop a pROM training procedure that takes advantage of such a decomposition.

Our second contribution is a tailored optimization strategy that identifies the walking model parameters, enabling the use of a walking model with sufficient fidelity to accurately describe complex pedestrian motion. We find the pedestrian motion that minimizes the difference between the measured strain and the predicted strain, leveraging the speed-up provided by the pROM and employing a gradient descent method with a modified basin-hopping scheme to quickly minimize this difference. We apply these methods to strain data collected from a real bridge and find that our preliminary results agree well with camera footage of the actual pedestrian motions.

Microstructures of chemically complex materials and their impacts on material properties from multiscale simulations

MECHANICAL INSIGHTS THROUGH MULTI-SCALE SIMULATION OF CHEMICALLY COMPLEX INTERFACES IN ALL-SOLID-STATE BATTERIES

Ming-Yuan Hung[1], Yu-Ting Tai[1], Hong-Zong Huang[1], Yueh-An Wu[1] and Hong-Kang Tian[1]*

[1]*National Cheng Kung University*

ABSTRACT

All-solid-state batteries are at the forefront of energy storage innovation, offering heightened safety and reliability. This research delves into the intricate world of chemically complex materials, specifically focusing on the electrode-electrolyte interface. Challenges at this interface, leading to high impedance and chemical interphases, pose critical questions regarding their impact on battery performance. Drawing inspiration from the chemically complex materials paradigm, we present a study employing Density Functional Theory (DFT) and Finite Element Analysis (FEA) to unravel the microstructural nuances of the $LiCoO_2$ (LCO) /$Li_{1+x}Al_xTi_{2-x}(PO_4)_3$ (LATP) interface. Co-diffusion into LATP and Co_3O_4 formation during sintering have been identified as key processes. Our investigation screens the most energetically favorable LATP atomic structures, replacing Ti with Co (LACTP). Through a continuum model integrating DFT-calculated properties, we simulate the mechanical response, uncovering crucial insights into material properties. Utilizing a particle-based 2D composite-electrode geometry, grounded in scanning transmission electron microscopy and electron energy-loss spectroscopy (STEM-EELS) images[1], we bridge DFT and FEA simulations. This approach not only allows us to understand stress generation near the interfaces during LCO lithiation but also provides a comprehensive view of the microstructure. DFT calculations highlight a 12.25 GPa decrease in Young's modulus when LATP transforms into LACTP and a transformation into Co_3O_4 results in a 77.89 GPa increase in Young's modulus with a 0.053 increase in Poisson's ratio compared to LATP. Integrating these insights, FEA simulations revealed that Co diffusion significantly increases peak stress within the LATP, escalating from 2966 MPa to 5650 MPa, potentially leading to crack formations, emphasizing the importance of microstructure in battery performance. This study contributes to the symposium's focus by utilizing computational techniques to explore chemically complex materials' microstructures, offering valuable insights into the intricate relationships among process, structure, and properties, thereby enhancing our understanding of both material composition and their applications in energy storage.

UNCERTAINTY QUANTIFICATION OF STOCHASTIC FUNCTIONALLY GRADED PLATE STRUCTURES BASED ON NOVEL PROBABILITY INTEGRAL PERSPECTIVE

Hui Huo[*1], Jian Zhao[1] and Dixiong Yang[1]*

[1]*Dalian University of Technology*

ABSTRACT

The functionally graded plate structures with excellent thermal resistance and high efficiency of load-bearing capacity have a broad application prospect in various engineering fields. Determining the responses' probability density functions (PDFs) and dynamic reliabilities of stochastic functionally graded plates subjected to random excitation is of great significance in the field of uncertainty quantification and structural design, while the popular intrusive stochastic finite element methods (SFEMs) are difficult for solving this complex problem. The direct probability integral method (DPIM) was recently developed by the authors' team to calculate the response PDFs and reliabilities for stochastic structures. For the functionally graded plates considering random fields of structural parameters and external random excitations, this paper proposes an efficient and accurate non-intrusive SFEM based on the novel perspective of probability integral. Firstly, the probability density integral equation (PDIE) is derived based on the principle of probability conservation, and the DPIM with adaptive strategy is introduced from the viewpoint of probability integral. Secondly, decoupling the deterministic finite element analysis and PDIE, the non-intrusive approach based on DPIM is constructed to compute the PDFs of random vibration responses and dynamic reliabilities of functionally graded plates, where the representation of random field is implemented through Karhunen-Loève expansion, and the random excitation is generated by the random function-based spectral representation. Then, the comparisons of the results with those from Monte Carlo simulation and the literature indicate the high accuracy and efficiency of the proposed non-intrusive method. Finally, the key parameters affecting the nonlinear random vibration responses of stochastic functionally graded plates are elaborated. This study possesses has important scientific significance and application potential for uncertainty quantification, reliability and safety assessment of functionally graded plate structures.

ELECTROCHEMICAL RESPONSES IN FOCUS: A VOLTAMMETRIC EXPLORATION OF TWO-PHASE LITHIATION IN HIGH-CAPACITY ANODES

Umair Hussain[*1], Narasimhan Swaminathan[1] and Gandham Phanikumar[1]*

[1]*Indian Institute of Technology Madras*

ABSTRACT

The increasing demand for higher energy capacity in lithium-ion batteries has underscored the significance of modeling lithiation with alternative electrode materials, such as silicon (Si) and tin (Sn). This research addresses the need for comprehensive insights into the (dis)charging process, particularly focusing on the intricate phase transformations in the anode. Phase-field modeling has proven effective in capturing these transformations [2], revealing volumetric deformations of up to 300% during (dis)charging cycles [1]. Unfortunately, these deformations compromise material integrity, leading to reduced battery cycle life and reliability.

To address these challenges, our work presents a novel framework for modeling lithiation in materials exhibiting two-phase diffusion using phase field modeling. Unlike previous models limited to single-phase diffusion, our framework provides a more realistic representation of the diffusion process. This realism is achieved by incorporating the time-dependent voltage applied to the anode, a crucial factor in understanding the electrochemical response during lithiation [3].

Furthermore, we leverage the currents generated during the lithiation and delithiation processes to conduct a comprehensive voltammetric study. This study goes beyond existing research by considering the impact of phase separation on the currents developed during Li-ion battery operation. Our findings aim to contribute valuable insights into optimizing battery performance and addressing challenges associated with phase transformations, ultimately advancing the development of high-capacity anodes for lithium-ion batteries.

PATH PLANNING IN A DYNAMIC ENVIRONMENT USING SPHERICAL PARTICLE SWARM

Mohamed Abido[1] *and Alaa Hussein**[1]

[1]*King Fahd University of Petroleum and Minerals*

ABSTRACT

Efficiently planning an Unmanned Aerial Vehicle (UAV) path is crucial, especially in dynamic settings where potential threats are prevalent. A Dynamic Path Planner (DPP) for UAV using the Spherical Vector based Particle Swarm Optimization (SPSO) technique is proposed in this study. The UAV is supposed to go from a starting point to an end point through an optimal path according to some flight criteria. Path length, Safety, Attitude and Path Smoothness are all taken into account upon deciding how an optimal path should be. The path is constructed as a set of way-points that stands as re-planning checkpoints. At each pathway-point, threats are allowed some constrained random motion, where their exact positions are updated and fed to the SPSO-solver. Four test scenarios are carried out using real digital elevation models. Each test gives different priorities to path length and safety, in order to show how well the SPSO-DPP is capable of generating a safe yet efficient path segments. Finally, a comparison is made to reveal the persistent overall superior performance of the SPSO, in a dynamic environment, over both the Particle Swarm Optimization (PSO) and the Genetic Algorithm (GA). SPSO outperformed both PSO and GA, showcasing cost reductions ranging from 330% to 675% compared to both algorithms.
In essence, this work focuses on:
1) Introducing Spherical Particle Swarm Optimization Dynamic Path Planner (SPSO-DPP).
2) Investigating the efficiency of SPSO-solver within a dynamic setting characterized by the presence of randomly moving obstacles.
3) Comparing the SPSO-DPP performance with PSO and GA performances in a dynamic environment.
Four scenarios have been presented, each of which modifies the parameters to reduce distance or prioritize safety. The results demonstrate that SPSO consistently produces superior cost values than both GA and PSO, demonstrating the algorithm’s efficacy in generating optimal paths. The effect of prioritizing distance reduction above hazard avoidance is best shown in Case 3, where the decision leads to a more direct path that circumvents obstacle constraints. This realization emphasizes the necessity of carefully weighing objectives against constraints in situations including dynamic UAV path planning. Furthermore, we intend to validate our algorithm’s output with real-world simulations, to confirm that the algorithm operates as efficiently and robustly as possible under demanding and dynamic UAV conditions.

OBSERVATIONAL GUIDANCE FOR MECHANICAL MODELS OF PACK ICE

Jennifer Hutchings[1], Pedro Elosegui[2] and Angela Bliss[3]*

[1]*Oregon State University*
[2]*MIT*
[3]*NASA*

ABSTRACT

Past studies find there is multi-fractal behavior for horizontal sea-ice deformation from 10 to 1000 km. Various observational studies point to seasonality and large inter-annual variability in this scaling behavior, suggesting different mechanical energy dissipation rates based on the state of the ice pack. Moreover, recent field observations demonstrate that such behavior does not hold for spatial scales below 10 km}. Indeed, we find that sea-ice deformation is not scale invariant between the scale of individual sea-ice floes and aggregates of floes. Therefore, we cannot expect the same physical laws to describe sea-ice mechanics over these regimes, or the forcing and boundary conditions must be treated differently at different scales. Using an assumed scaling behavior as a metric to validate models that resolve sea ice floes and their interactions is thus not recommended. However, observations might provide insight into the different physical regimes of pack-ice mechanics allowing, in turn, better models to be designed that capture seasonality and the mechanical response to ice-pack state changes, such as increasing damage, realistically. We will present a summary of current knowledge on multi-scale behavior of sea ice, describing the features that define each scale over which a single model can be applied and the bounds defining these scales.

PRECONDITIONED SOLVERS FOR COMPOSITE DG DISCRETIZATIONS OF CARDIAC CELL-BY-CELL MODELS

Ngoc Mai Monica Huynh[*1]*

[1]*University of Pavia*

ABSTRACT

The drive to better understand complex phenomena like cardiac functions has led to mathematical models that are able to describe the multiscale structure and dynamics of the heart. The numerical simulation of these complex cardiac models is very challenging since it requires high-resolution space and time discretizations, as well as numerical tools that can handle natural discontinuities (for instance, disconnected cells).

The development of effective and scalable solvers for the solution of these models has grown increasingly in the last decade, and modern computational architectures have increased the possibility to run large-scale simulations within reasonable computational times. In any case, the multiscale systems arising from discretizations of such models has required the development of specific techniques which can balance accuracy in the solution while being computationally competitive (in terms of efficiency and scalability). Indeed, being able to describe and computationally reproduce the many interactions between the macroscopic and microscopic events leads to numerical choices that yield large scale nonlinear algebraic systems of equations, exceeding millions of degrees of freedom.

In this talk, we focus on the numerical simulation of the cardiac electrical activity from a microscopic point of view, by means of cell-by-cell mathematical models. We propose ad-hoc preconditioned solvers inspired by well-known Domain Decomposition methods, e.g. the generalized Drijia-Smith-Widlund (GDSW) or non-overlapping Spectral Additive Schwarz (NOSAS), where special constraints are imposed in order to reflect the physiological discontinuities of the mathematical model. We provide a strong theoretical analysis, validated then through extensive numerical tests, showing scalability and quasi-optimality of these solvers. These results provide a basis for improving parallel solvers for cardiac electrophysiology models that combine parallel efficiency and solution accuracy.

PREDICTING LIVER FIBROSIS STAGES: A HYBRID APPROACH INTEGRATING MACHINE LEARNING AND DATA-DRIVEN COMPUTATIONAL TECHNIQUES WITH DCI-MRI

Feng-Nan Hwang[1], Yi-Zhen Su[1] and Dennis Hwang[2]*

[1]*National Central University*
[2]*Academia Sinica*

ABSTRACT

Liver diseases consistently rank among the top ten causes of death in numerous countries. The progression of these diseases is generally categorized into three stages: liver fibrosis, liver cirrhosis, and liver cancer. Addressing the need for early diagnosis and intervention, a research study focusing on clinical practice is underway, developing noninvasive techniques to determine liver disease status. Early detection of liver fibrosis, coupled with appropriate treatments, can significantly reduce the risk of hepatocellular carcinoma. We propose a hybrid approach that integrates machine learning methods with a data-driven computational technique employing dynamic contrast-enhanced MRI (DCI-MRI) for predicting a patient's fibrous stages, healthy, mild, and severe. The kernel component of the computational technique is a Darcy solver weakly coupled with an unsteady convection-diffusion solver that is used for simulating the blood flows through the liver, assumedly as a kind of porous medium, and the relative signal enhancement scanned by MRI varied in time. During the preprocessing phase, we extract new features simulating liver properties, including porosity, diffusion rate, and flow speeds of the portal vein and hepatic artery. Combining these features with patients' blood tests and the characteristics of DCE-MRI curves, we used KNN and Naive Bayes models in conjunction with feature selection to achieve the accuracy of predicted results of healthy versus others and severe versus others around 80%. This study underscores the potential value of simulating liver signal concentration models in liver fibrosis assessment, providing biomedical researchers with a deeper understanding and new avenues for research.

[3]*Jeonbuk National University*

ABSTRACT

Multi-body contact analysis will become computationally cumbersome for a complex object usually due to large number of degrees of freedom and nonlinearities involved. Therefore, the reduced order model (ROM) will be used for an efficient alternate computation. Projection-based ROM (PROM) will be a popular method that reduces the order by projecting the governing formulation. Meanwhile, a contact analysis with enhanced computational capability is often applied with an explicit method to extract the result at a short time step. In such circumstance, however, there is a limitation of the reducing time step size with a sole PROM due to repetitive matrix-vector multiplication for the projection. Therefore, it is additionally required to apply a hyper-reduction method that improves the computational time-saving capability of PROM by employing only sampled indices.

In this presentation, both PROM and hyper-reduction approach will be incorporated into the three-dimensional multi-body contact analysis. The proper orthogonal decomposition (POD) idea is used for reducing the order of the matrices. Also, the energy-conserving sampling and weighting method [1] is applied to select a dominant element in the contact-impact response to reduce the cost of element-wise computation of nonlinear force vector. The velocities of the multiple bodies are selected as the parameter. The discrete empirical interpolation method [2] will also be attempted to reduce the computational cost of the contact force.

HYBRID STRESS AND HEAT-FLUX FORMULATION OF THERMODYNAMICS FOR LONG-TERM SIMULATIONS IN THERMO-VISCOPLASTICITY

Adnan Ibrahimbegovic[*1] and Samir Suljevic*[1]

[1]*University of Technology Compiegne*

ABSTRACT

Adnan Ibrahimbegovic1,2, Samir Suljevic1
1University of Technology Compiegne, France
2Institut Universitaire de France

We present a variational formulation for coupled problems in thermodynamics the most suitable for long-term simulations of plastic behavior. We start with mixed formulation that is first regularized, which allows us to eliminate the rotation field and recover the corresponding hybrid stress format for equations of motion and transient heat conduction. The regularized variational formulation is further combined with discrete approximation based upon the Raviart-Thomas vector space for both mechanical and thermal fields, which enforces continuity across element boundaries for stress vector and normal component of heat flux. The conservation properties are validated with energy-conserving scheme for thermoelastic behavior. The time integration of thermo-viscoplastic behavior is carried out by energy-decaying scheme to provide superior accuracy for computed stress in a long term simulation. The proposed approach offers higher computational robustness and results accuracy than the classical finite elements and time-integration schemes. Such a performance is illustrated on several numerical simulations in non-stationary problems for thermo-viscoplastic behavior.

A MULTISCALE METHOD TO SOLVE PARTICLE-LADEN TURBULENT FLUID FLOWS

Sergio Idelsohn[1], Juan Gimenez[1] and Eugenio Oñate[1]*

[1]*Centro Internacional de Métodos Numéricoso en la Ingenieria*

ABSTRACT

Particle-laden flows refer to a kind of two-phase fluid flow in which one of the phases is continuously connected and the other phase is made up of small immiscible particles. A wide variety of scientific and engineering applications belong to particles-laden flows, for instance dispersion of contamination in the atmosphere, fluidization in combustion processes, deposition of aerosols in aerosol drugs, spread of virus in the air, rain formation in clouds, sand and dust storms, protoplanetary disks, volcanic eruptions, geological sedimentation processes, pharmaceutical sprays, liquid-fuelled combustion and solid rocket motors, among many others.

Typically, the fluid is treated in a Eulerian frame, while the particles are treated in a Lagrangian way. However, problem with the Lagrangian treatment of the particles is that once the number becomes large, it may require a prohibitive amount of computational power to track a sufficiently large sample of particles required. In addition, if the particles are sufficiently light, they behave essentially like a second fluid. This is the main objective of this presentation.

On the other hand, due to the interactions between turbulence structure and dispersed particles, turbulence characteristics of momentum and heat transport can be modified by the presence of particles. This last phenomenon is known as turbulence modulation and can lead to a significant increase or decrease in the parameters that regulate turbulence.

The authors presented in Ref. [1] a multi-scale method called Pseudo-Direct Numerical Simulation (P-DNS) [2] to study the phenomenon of turbulence modulation in a particle-laden flows. However, in that article, the particles in both, the fine scale and the coarse scale, were treated in a discrete way moving in a Lagrangian reference frame within the fluid. In this presentation, the same P-DNS method will be used to simulate the presence of particles as a continuum function that moves within the fluid. In this way, the need to represent each of the particles that move in the fluid is avoided.

OPTIMAL LOCAL TRUNCATION ERROR METHOD FOR SOLUTION OF PDES ON IRREGULAR DOMAINS AND INTERFACES WITH OPTIMAL ACCURACY AND UNFITTED CARTESIAN MESHES. COMPARISON WITH FINITE ELEMENTS.

Alexander Idesman[*1]

[1]*Texas Tech University*

ABSTRACT

Here, we review as well as present some new developments of the optimal local truncation error method (OLTEM) for the solution of partial differential equations [1]. Similar to the finite difference method, the structure and the width of discrete equations are assumed in advance. The unknown coefficients of the discrete system are calculated by the minimization of the local truncation error. The main advantages of OLTEM are an optimal high accuracy of discrete equations and the simplicity of the formation of a discrete (semi-discrete) system for irregular domains and interfaces (composite materials). In contrast to finite elements, trivial unfitted Cartesian meshes (no need in complicated mesh generators) are used with OLTEM. OLTEM does not include unknowns on irregular boundaries and interfaces. The known interface and boundary conditions at small number of selected points are added to the discrete equations as the right-hand side. A new OLTEM post-processing procedure for the calculation of the spatial derivatives of the primary functions (e.g., stresses or heat fluxes) that is based on the use of original PDEs significantly increases the accuracy of the spatial derivatives. For example, we have obtained the 10-th order of accuracy for stresses calculated by OLTEM with ‘quadratic elements’ applied to elastostatics problems with heterogeneous materials and irregular interfaces. Currently, OLTEM has been applied to the solution of the wave, heat, elastodynamics, Helmholtz, Poisson, Stoke’s and elastostatics equations. The theoretical and numerical results show that at the computational costs of linear finite elements, OLTEM yields the 4th order of accuracy for the considered scalar PDEs on irregular domains (it is much more accurate compared with linear and high-order finite elements at the same number of degrees of freedom). E.g., 3-D numerical examples on irregular domains show that at accuracy of 5%, OLTEM applied to the wave equation reduces the number of degrees of freedom by a factor of greater than 1000 compared to that for linear finite elements. At the computational costs of quadratic finite elements, OLTEM yields the 10th order of accuracy for the time-independent elasticity equations and the 11th order of accuracy for the Poisson equation with complex irregular interfaces [1], i.e., the increase in accuracy by 7 and 8 orders compared to FEM.

ABSTRACT

The blood shows complicated rheological behaviors due to complex fluid-structure interactions of plasma and blood cells. Understanding the rheological features in a finite inertial range in curved pipes is important in designing microfluidic cell-sorting devices. A single capsule behavior in curved pipes has been investigated at finite Reynolds numbers [1]; however, much is unknown how inertial flows with multiple capsules generate both axial and in-plane flow fields. In this study, large-scale simulations are performed for inertial flows of suspension of deformable capsules mimicking red blood cells in toroidal tubes. The immersed boundary method was applied for the fluid-capsule interaction, where the fluid is assumed as an incompressible Newtonian fluid and the capsule membrane is modeled by a hyperelastic material with bending resistance. An in-house code for a fluid-capsule interaction solver [2] was developed, in which a hybrid parallelization with OpenMP and MPI is implemented for both fluid meshes and material points of capsule membrane. We applied various values for the hematocrit (Ht), a volume ratio of capsules to toroidal tube, from 0 to 25%. In our simulations, an axial velocity profile at low Ht is similar to that of a well-known curved pipe flow [3], whereas at high Ht the profile shows a similar trend with a suspension of capsules in straight tubes, where two different velocity regimes arise due to aggregation of capsules in tube center. A snapshot for the in-plane velocity on a tube cross-section shows a non-organized flow field at high Ht, whereas its spatiotemporal average in the axial direction shows a well-organized secondary flow with two counter-rotating vortices, known as Dean vortex. Relative magnitudes of the in-plane velocity to the axial velocity are reduced when increasing Ht. To reveal a mechanism of this reduction, we introduced a macroscopic non-Newtonian model, in which spatial variation of dynamic viscosity is considered that depends on a distribution of local hematocrit obtained by a large-scale simulation. Our investigation predicts two possible mechanisms, which are energy dissipation due to capsule-capsule interactions and macroscopic viscoelasticity of capsule-rich suspension, would reduce the level of secondary flow even though the same level of axial velocity is maintained.

ABSTRACT

In this study, we construct a conditional diffusion model that suggests the optimal microstructure and temperature for polyphenylene sulfide (PPS), which commensurate with a desired elastic modulus. PPS is a thermoplastic resin often used in carbon fiber reinforced plastics. During the solidification of thermoplastic resin, the microstructure of dendritic crystal is generated. Typically, the macroscopic mechanical properties are determined from the microstructure. Here, in engineering, these microstructures are affected by the process temperature, which governs the macroscopic mechanical properties. This process temperature is still decided by several expensive experiments. Using the framework of inverse analysis with conditional diffusion model, we aim at predicting the process temperature from the desired macroscopic elastic modulus as inputs. In this way, we can significantly reduce the number of experiments and lead to the effective cycle of PPS manufacturing operations.
The data sets of microstructures of thermoplastic resin are generated by the phase-field method. Nuclei are placed in the initial state as heterogeneous nucleation, and nucleation is considered to probabilistically based on the nucleation rate as homogeneous nucleation. Furthermore, crystal growth from these nuclei is calculated. Then, the extended finite element method (XFEM) is performed on the thermoplastic resin created by the phase-field method to obtain the elastic modulus. We use the elastic modulus as the condition when training the conditional diffusion model. In XFEM, the macroscopic stress is obtained by averaging the stress distribution in each direction by applying three patterns of unit strain, and is used as the value of the elastic modulus. Training data for the conditional diffusion model are the microstructure of the final step in the phase-field method when the crystal has finished growing and the process temperature. The training is performed by adding and removing noise to the set of temperature and microstructure. By adding conditions to the time information during the process of noise removal and addition, the weight of each condition is changed, and it becomes possible to train each condition separately.
Using the conditional diffusion model, we are able to reproduce the detailed microstructure of dendrites. In addition, the model enables us to generate microstructures different from the microstructures of training data. It is shown that a microstructure which satisfies the given conditions is generated and a proper temperature is proposed as a process parameter for the microstructure.

FROM VOXELS TO BALLS: TOWARDS CONNECTED PREDICTIONS OF MACHINE LEARNING MODELS IN TOPOLOGY OPTIMIZATION

Mohammad Behzadi[1] *and Horea Ilies**[1]

[1]*University of Connecticut*

ABSTRACT

Although topology optimization has recently seen a multitude of machine learning advances, most algorithms rely on processing and outputting solutions as binary 2D or 3D images. While this state of affairs offers some insight into interpretability and compatibility with existing analysis tools, it suffers from critical drawbacks. Firstly, the massive number of variables, especially in 3D, demand complex and computationally expensive deep learning models. Secondly, the method is highly sensitive to errors, where even minor pixel/voxel inaccuracies can jeopardize structural integrity. Finally, the predicted design solutions often struggle to maintain connectivity, which is essential for load-bearing, and ultimately impact both design performance and manufacturability. These limitations hinder achieving truly optimal structural designs with machine learning models, highlighting the need for alternative approaches.

We explore the use of Maximal Disjoint Ball Decomposition (MDBD) as a new, efficient way to represent and learn shapes in topology optimization as a structured and hierarchical collection of tangent d-dimensional balls and of its associated connectivity graph. Unlike the pixel/voxel approach, MDBD accurately captures optimal designs and enhances their structural connectivity through integration with graph neural networks. Crucially, MDBD requires far fewer parameters, enabling simpler deep learning models, less computational power, and smaller training datasets. At the same time, the connectivity graph of MDBD can be exploited to quantify and enforce the connectivity of the resulting predictions. Therefore, MDBD has the potential to significantly improve the effectiveness and efficiency of machine learning in topology optimization, while maintaining design accuracy and practicality.

MINIMUM ACTUATION RECONFIGURATION OF STRAW-LIKE ELEMENTS

Dotan Ilssar[1] and Dennis Kochmann*[1]

[1]*ETH Zurich*

ABSTRACT

Reconfigurable structures having a multitude of carefully designed stable configurations, have a great potential for diverse applications such as deployable and shape morphing structures, as well as architected materials with configuration dependent mechanical properties. Multistability, allowing to stabilize a structure in different configurations can be achieved by embedding it with elements which have instability regions, such as precompressed elastic beams. A promising multistable elastic element discussed here is inspired by the ‘bendy straw’. Under the assumption of planar motion, such straw-like element is modelled as an array of unit-cells having up to four stable equilibria, allowing it to be stabilized in a large number of multiaxial configurations. These elements can be further used to form networks of different geometries and operative stable configurations. For applicability, the transition between different stable configurations of a reconfigurable structure should be done with a minimal number of actuators, which raises a challenge of path finding in a highly nonconvex energy landscape.

Here we focus on minimal actuation reconfiguration of a single straw-like element. For this we begin by setting up the theoretical foundations and introduce a numerical scheme used to describe its mechanical behavior under prescribed relative translational and rotational displacements between its ends. Next, we present an algorithm based on the Nudged elastic band (NEB) method, which is utilized to find the boundary conditions needed to be applied to the straw, for a wanted reconfiguration. These theoretically obtained boundary conditions are then applied to the forward numerical simulation, as well as to an actual straw utilizing an XY-Theta stage, to validate that the wanted reconfiguration is achieved. It should be noted that the presented method can be employed in various multistable systems in order to find the actuation needed to be applied by a set of actuators to cause a wanted reconfiguration, given that the actuation scheme can cause the desired reconfiguration.

A NOVEL PERIDYNAMICS ELASTIC-PLASTIC FATIGUE DAMAGE MODEL FOR PREDICTING CRACK BEHAVIOR INCORPORATING ELASTO-PLASTIC DEFORMATION FIELD

Dongjun Bang[1] and Ayhan Ince[1]*

[1]Concordia University

ABSTRACT

Currently, no fatigue damage model has been established that incorporates the nonlocal damage concept by considering the elasto-plastic deformation field. Understanding short crack behavior is complex, and current approaches that focus only on fatigue damage at a single material point instead of within a finite material volume, cannot accurately model abnormal behavior in short cracks [1]. The different mechanisms driving short and long crack propagation require distinct modeling approaches to address the unique nature of damage mechanics in these crack regimes. Hence, a new peridynamics (PD) model has been developed to predict short crack behavior by considering the evolution of elasto-plastic mechanical fields around growing cracks to consider the non-local nature of the damage mechanism. Recently, the authors developed a PD fatigue damage model specifically accounting for R-ratios to simulate crack growth behavior in long cracks within the elastic state [2-3]. Acknowledging the significant influence of local elastic-plastic mechanistic fields on short crack behavior, the authors have expanded the original PD fatigue model to develop a novel PD elastic-plastic fatigue damage model capable of simulating crack propagation in both short and long crack regimes, while incorporating nonlocal damage and elastic-plastic mechanistic fields associated with a propagating crack. Additionally, a new PD elastic-plastic material model is integrated with a PD fatigue damage model. This integration enables simulation not only of crack propagation but also of the actual elasto-plastic stress, strain, and displacement fields around propagating cracks. The elasto-plastic PD fatigue model can simulate damage behaviors across various length scales for crack growth in both short and long crack regimes. To validate the model, predictions of crack growth modes are compared with mechanistic deformation fields for crack growth in various metallic alloys like 2024-T3 and 7075-T6 aluminum alloys. Results demonstrated a close match between model predictions and experimental crack and mechanical deformation data under various R-ratios loading conditions.

MECHANICS OF QUASI-PERIODIC TWO-DIMENSIONAL TRUSS METAMATERIALS

Matheus Inguaggiato Nora Rosa[*1], Konstantinos Karapiperis[1], Kaoutar Radi[1] and Dennis Kochmann[1]*

[1]ETH Zurich

ABSTRACT

To date, the design of architected materials (or metamaterials) has mostly been limited to periodic configurations, with extensions to gradually varying local periodicity, or irregular architectures that are usually built by adding disorder to primitive periodic architectures. In contrast, quasicrystalline designs (inspired by atomic quasicrystals) are rarely considered. While they do not exhibit translational periodicity, quasiperiodic lattices retain long-range order and exhibit symmetries which are forbidden in periodic materials, such as 5,7, 8 and 10-fold rotational symmetries in the plane. The consideration of quasiperiodic structures leads to a largely unexplored design space for architected materials and consequently to an untapped property space that promises materials with unprecedent features, potentially surpassing the performance of their periodic counterparts in applications relying on lightweight, stiff, and impact-resistant materials.

This talk will describe recent progress on the exploration of the mechanics of two-dimensional quasi-periodic architected materials. A class of two-dimensional truss metamaterials that are inspired by quasicrystal tilings such as the canonical Penrose and Ammann-Beenker tiles is considered. First, the linear stiffness properties of the designs are characterized and compared to classic two-dimensional trusses such as the square, triangular and hexagonal lattices. Among our findings, we show that the quasicrystal designs are isotropic in the linear regime and may exhibit a mixture of bending and stretch-dominated deformation mechanisms. While purely stretch-dominated periodic truss lattices achieve higher linear stiffness, they usually suffer from global buckling instabilities, which significantly hinder their energy absorption capabilities under large nonlinear deformation. Indeed, our simulations confirm that quasicrystal designs avoid global buckling instabilities and only experience localized buckling, leading to designs that may surpass periodic trusses in terms of nonlinear energy absorption. Preliminary experimental results for additively manufactured samples under uniaxial compression are shown to support our findings, and possibilities for future work are also discussed.

A COLLOCATION MODEL REDUCTION SCHEME FOR PDES (CMOR)

Angelo Iollo[1], Michele Giuliano Carlino[2] and Tommaso Taddei[1]*

[1]*Inria*
[2]*ONERA*

ABSTRACT

Model reduction essentially involves seeking the solution to a partial differential equation (PDE) in a vector space of small dimension compared to the high-fidelity problem. This search is typically performed using the residual of the underlying numerical model associated with the solution of the PDE, either by minimizing it in a suitable norm or by determining the solution in such a way that the residual is orthogonal to an appropriate test space. This operation typically requires a step called hyper-reduction to compute the residuals on a modest number of discretization points. In this presentation, we will demonstrate an approach that departs from this now-classic method and relies solely on the numerical scheme used, or chosen, for the integration of the initial model, while conducting this operation with an extremely reduced number of mesh points. These points are obtained through a numerical quadrature technique. Examples related to finite difference schemes, ADER, and DG schemes will be presented.

NUMERICAL INVESTIGATION ON THE STRENGTH OF BI-MATERIAL JOINT FABRICATED BY WIRE ARC ADDITIVE MANUFACTURING

Muhammad Irfan[*1], Yun-Fei Fu[1], Shalini Singh[1], Osezua Ibhadode[1] and Ahmed Qureshi[1]*

[1]*University of Alberta*

ABSTRACT

Wire Arc Additive Manufacturing (WAAM) is a prominent Additive Manufacturing (AM) method because of its ability to use different metallic and composite materials. A majority of research efforts on WAAM have focused on singular material fabrication. As multiple combinations of materials can achieve the desired performance more easily than a single material, the investigation of the interaction between different materials can provide guidance for more practical applications. To complement experiments and alleviate research cost and time, numerical models are beneficial. This work aims to model and predict the bond strength of a bi-material joint fabricated by WAAM using the commercial Finite Element Analysis (FEA) software package LS-DYNA. The joint configuration comprises a layer of 17-4 PH alloy and another layer fabricated from Inconel alloy 625. Two typical methods, automatic surface-to-surface contact tie break and cohesive element, are used to study the mechanical behavior between two different materials (i.e., 17-4 PH alloy and Inconel alloy 625) in LS-DYNA. Automatic surface-to-surface contact is extensively used to simulate the interaction between different materials, making it suitable for multi-material joints. Cohesive elements enable the simulation of adhesive joints where materials are bonded together. It provides an accurate representation of the behavior at the bonded interfaces. This allows the fracture prediction in the adhesive bonding of two materials. Specifically, the properties of the interface layer are obtained through experiments on the mechanical characterization of printed multi-material WAAM samples. To validate the effectiveness of the two established simulation methods, the stress-strain curves and fracture obtained by simulation are comprehensively compared with the experimental results via a joint fabricated with 17-4 PH alloy and Inconel alloy 625 in WAAM subjected to the uniaxial tension. The comparison between simulation and experiment demonstrates the fidelity of the numerical models in capturing the intricate complexities of the bonding types. The advantages and disadvantages of using automatic surface-to-surface contact and cohesive elements bonding are comprehensively discussed. Future work will investigate the effects of microstructures on the mechanical behavior of the bi-material joint.

CNN-BASED SURROGATE MODEL AND TEMPERATURE PREDICTION METHOD USING SUPERPOSITION PRINCIPLE

Miyoko Irikiin[*1] and Yukihiro Iwata*[1]

[1]*Panasonic Connect Co., Ltd.*

ABSTRACT

A CNN-based surrogate model is being developed to speed up CFD calculations.The larger the scale of training data, the higher the cost of training data creation.Therefore, it is difficult to exhaustively learn all shapes, materials, and part arrangements, etc., and improving generalizability is an issue.We referred to the methods of transfer learning and fine tuning, which are often used in the field of image recognition, but it was difficult to create a surrogate model with high generalizability.Therefore, we propose a temperature prediction method using the principle of superposition as one of the solutions to this problem.Among the three forms of heat transfer, i.e., heat conduction, radiation, and convection, the superposition principle holds for heat conduction.By taking advantage of this property, we have devised a method to predict the temperature distribution of multiple heating elements in a circuit board individually, and then fuse these elements to predict the temperature of the entire model.Since the principle of superposition does not hold for radiation and convection, the prediction accuracy is poor if the individually predicted temperatures are only superimposed. Based on the relationship between the temperature after superposition and the temperature difference predicted individually, we corrected the temperature after superposition to improve the accuracy.

[3]*Kyushu University*

ABSTRACT

Sintering is a fundamental technology for manufacturing various materials. To improve the mechanical, electrical, magnetic, and other properties of sintered materials, it is necessary to understand, predict, and control the microstructural evolutions and structure formulation during sintering. Cutting-edge experimental techniques have realized the four-dimensional (three-dimensional space and time) observation of microstructural evolution during solid-state sintering [1]. Although such experiments provide various useful information, the sintering behavior has not been fully observed due to some limitations in target materials, experimental equipment, and experimental conditions.

Phase-field (PF) method is a powerful numerical methodology for solving free-boundary problems occurring at nano- and mesoscales, and thus it has been used in several recent studies to understand the microstructural evolution during solid-state sintering [2]. Because the PF model is a continuum one, accurate material parameters such as physical values and model parameters are required to perform PF simulation quantitatively. However, many material parameters of sintered materials are largely unknown and some of them are difficult to identify experimentally.
Recently, data assimilation (DA) has attracted attention as an effective method for the inverse estimation of unknown material parameters from small experimental datasets. DA integrates time-series experimental data and numerical simulation results based on Bayesian inference. In the previous study [3], a DA method using tree-structured Parzen estimator (DMC-TPE) is applied to a PF simulation of solid-state sintering, and it is demonstrated through a numerical experiment that DMC-TPE can estimate multiple temperature-dependent material parameters with high accuracy. However, no study has reported the estimation result from DA using actual experimental observation data of solid-state sintering.

In this work, we achieved to perform high-fidelity PF simulation of solid-state sintering with copper nanoparticles by estimating the material parameters via DMC-TPE using morphological data observed using an in situ scanning transmission electron microscopy and PF simulation results. The high-fidelity PF simulation quantitatively predicted the sintering behavior.

ABSTRACT

There is a high demand for efficient mixing of multiple liquids in small quantities in the manufacturing process of industrial products. For example, when stirring two liquids in a small amount in a vessel, in addition to mixing the two liquids, it is necessary to simulate the three-phase multi-phase flow, including bubbles that are entered due to the waves of the liquid surface generated during mixing. Under conditions where the amount of liquid is small, it is also necessary to consider the effect of the surface tension generated on the liquid surface. Simulations using conventional computational mesh are effective in predicting the flow of the liquids in the vessel as well as predicting the waves of the liquid surface. However, high-resolution computational mesh is required to predict the mixing process considering the interaction between the two liquids and bubbles. In simulating such the mixing processes, the particle method is an effective approach. The simulation using the particle method (moving-particle semi-implicit method [1]) has an advantage that can reduce the deterioration of prediction accuracy affected by the resolution of the computational mesh shown above. For these reasons, we investigated the application of the mesh and the particle methods to the simulation of the mixing process of multi-phase flow consisting of two liquids and bubbles. By using the mesh method, it was possible to predict the flow of the liquid in the vessel and the waves generated on the liquid surface with a small calculation time. Furthermore, by using the particle method to predict the mixing process phenomenon caused by the interaction between two liquids and bubbles, highly accurate prediction was possible. The simulated results were verified using experimental results. The liquid surface shape generated on the liquid surface of the liquids was in good agreement with the results of the experiment. In addition, it was clarified that the mixing phenomenon caused by the interaction of two liquids and bubbles can qualitatively reproduce the phenomenon shown in the experiment.

INVESTIGATION OF A NOVEL LASER-INDUCED SPALLATION METHOD: ANALYSIS OF SHOCK AND SPALL BEHAVIOR THROUGH ATOMISTIC, FINITE ELEMENT, AND THEORETICAL MODELING

Mewael Isiet[*1] and Mauricio Ponga*[1]

[1]*The University of British Columbia*

ABSTRACT

In this talk, we discuss a novel laser method for studying material spall behaviour. Here, the front and back surfaces are irradiated with a laser, resulting in the formation of two pressure pulses that contain a leading compressive wave and an unloading tensile wave. When the superimposition of these two unloading tensile waves produces a state of hydrostatic pressure that exceeds the spall strength of the material, failure occurs. To investigate this method, perfect Nickel crystals were photo-excited using femtosecond laser pulses in atomistic simulations, and the laser-metal interactions were simulated using a two-temperature master equation. Our results show that the two-pulse laser configuration can induce spallation in the material, and the resulting spall strength can be traced through the material's free surface velocity. The mechanism of spallation, i.e. void nucleation, growth, and coalescence, was observed, and it is seen that the formation of stacking faults and Shockley partials is critical. In addition, failure of an imperfect Nickel crystal revealed that the presence of a pre-existing void increases dislocation emission when compared to a perfect crystal. Next, it was shown that the type of laser-induced damage can be controlled by tuning the laser fluence, pulse duration, and initial temperature. Finally, a macro-scale FEM model was developed to reproduce spall behaviour, and it was that by delaying one of the pulses, the location of spall plane can be controlled.

A COMPUTATIONAL FLUID DYNAMICS APPROACH FOR METAL HYDRIDE HYDROGEN STORAGE

Mohammad S. Islam[*1], Puchanee Larpruenrudee[1], Nick Bennett[1], Emilie Sauret[2] and YuanTong Gu[2]*

[1]*University of Technology Sydney*
[2]*Queensland University of Technology*

ABSTRACT

Metal hydride hydrogen storage (MHSS) systems offer promising solutions for efficient and safe hydrogen storage. However, the low thermal conductivity of metal hydride materials poses challenges to hydrogen absorption kinetics. Therefore, this study aims to address this issue by applying a passive technique of various heat exchanger designs and enhancing the thermal performance of the MHSS system. This study investigates the performance of MHSS systems employing different heat exchanger configurations, including internal and external heat exchangers, to improve hydrogen absorption kinetics. The combination of internal semi-cylindrical coil heat exchangers (SCHE) with external heat exchangers such as phase change materials (PCM) and cooling jackets (CJ) is examined. The study evaluates hydrogen absorption kinetics, average bed temperatures, and reaction fractions across different MHSS designs through simulations and analyses. The methodologies involve computational modelling based on energy equations governing the hydrogen absorption process and thermo-physical properties of metal hydride alloys and PCM. Results demonstrate that integrating internal and external heat exchangers significantly enhances hydrogen kinetic reactions, leading to faster absorption rates. Incorporating PCM and cooling jackets facilitates rapid temperature reduction during absorption, consequently improving hydrogen reaction fractions. Compared to the standalone SCHE configuration, the combination of SCHE with PCM and CJ reduces absorption duration by 37.72% and 50.69%, respectively. This study highlights the potential of combined heat exchanger systems to enhance MHSS performance and offers insights into optimising hydrogen storage technologies for industrial applications. The findings underscore the importance of efficient heat transfer mechanisms in accelerating hydrogen absorption kinetics. Moreover, the study highlights the significance of integrating internal and external heat exchangers to optimise MHSS designs for improved energy storage and utilisation. In future applications, the insights gained from this study could inform the development of advanced MHSS systems with enhanced hydrogen absorption capabilities. Further research may explore the optimisation of heat exchanger configurations and investigate the scalability and practical feasibility of implementing optimised MHSS designs in industrial settings.

MODEL REDUCTION OF THE PLASMA KINETIC EQUATIONS

Opal Issan[*1] and Boris Kramer*[1]

[1]*University of California, San Diego*

ABSTRACT

We propose a data-driven projection-based reduced-order model (ROM) to reduce the computational cost of the spectral plasma solver (SPS) of the Vlasov-Poisson equations. The SPS solver is based on a Fourier spectral expansion in space, asymmetrically-weighted Hermite expansion in velocity, and an implicit temporal integrator. The main advantages of the SPS solver are its conservation and fluid-kinetic coupling properties, where the first three expansion coefficients correspond to the macroscopic description of the plasma, while higher-order expansion coefficients correspond to higher-order fluid moments capturing the kinetic effects of the plasma. A core contribution of this work is to introduce a reduced-order model for the kinetic effects into SPS while keeping the macroscopic description intact. We show that this preserves its fluid-kinetic property, and conserves mass, momentum, and energy. Moreover, the suggested strategy overcomes the nonlinear bottleneck by efficiently handling convolutions. The numerical results show that our method can adequately emulate the SPS simulations at a fraction of the cost, which we test on the following benchmark problems: 1D-1V weak Landau damping, 1D-1V bump-on-tail instability, and 2D-2V current-driven ion acoustic instability.

CFD-MRI: CHARACTERIZATION OF REACTIVE FLOWS BY SOLVING INVERSE PROBLEMS

Shota Ito[*1], Alexander Zimmermann[2] and Mathias J. Krause[1]*

[1]*Lattice Boltzmann Research Group, Karlsruhe Institute of Technology*
[2]*University of Bremen*

ABSTRACT

Catalytic processes are of tremendous importance: many everyday life products and technologies require catalysts. Improving heterogeneous catalytic processes in a chemical reactor often necessitates detailed knowledge of concentration, velocity, and temperature distributions. Magnetic resonance imaging (MRI) can measure those distributions noninvasive and spatially resolved, presenting a clear advantage compared to conventional techniques as they are often invasive and only capable of measuring locally. In our project, we develop a combined framework of computational fluid dynamics (CFD) and MRI wherein we solve two inverse problems to characterize heterogeneous reactive flows. In the first step, we utilize an adjoint-based topology optimization approach to obtain the porous structure from the measured velocity distributions. The flow field is computed by solving the discrete porous media BGK-Boltzmann equation, which approximates the homogenized Navier-Stokes equations in the hydrodynamic limit. In the second step, we identify reaction rate parameters from given concentration distributions using algorithmic differentiation and a lattice-Boltzmann method (LBM) to approximate the system of reaction-advection-diffusion equations. In both steps, we solve the conservation equations as side constraints of our optimization problem, ensuring the physical behavior of the flow and concentration fields. As MRI measurements suffer from a relatively low signal-to-noise ratio (SNR), we aim to reduce the ”non-physical” statistical noise from the velocity and concentration distributions via the presenting method.

MODELING OF SOFTENING PHENOMENA IN ELASTOMERS BY DEEP SYMBOLIC REGRESSION

Mikhail Itskov[*1] and Rasul Abdusalamov*[1]

[1]*RWTH Aachen University*

ABSTRACT

Rubber-like materials exhibit pronounced softening after the very first loading cycle. This phenomenon, known as the Mullins effect, plays an important role in the stress-strain response not only of elastomers but also soft biological tissues. Despite numerous modeling approaches proposed in the last years in literature, accurate prediction of the Mullins effect, especially under complex loading conditions, still remains a challenging task.

In this contribution, we propose a novel method to model the Mullins effect using deep symbolic regression [1]. The first goal is to find an algebraic expression of a strain energy which fits the given experimental data from the primary loading as accurately as possible. By incorporating the continuum mechanical framework, the method combines the advantages of known physical relationships with the unbiased optimization approach of symbolic regression. The procedure has already been applied to discover incompressible hyperelastic material models and is benchmarked against the generalized Mooney-Rivlin model [2]. In the second step, the method is extended to inelastic effects. To this end, stress-strain data of unloading and secondary loading are artificially created by the Ogden-Roxburgh model [3] and described again by the deep symbolic regression. In addition, the proposed model is tested on an experimental temperature-dependent data set. Good agreement between the so obtained material models and the experimental data is demonstrated.

INVESTIGATION OF CNN-BASED MULTIGRID-BIDIRECTIONAL NETWORKS

Yukihiro Iwata[*1], Yoshihisa Inagaki[1] and Miyoko Irikiin[1]*

[1]Panasonic Connect Co., Ltd.

ABSTRACT

A technology to super-speed physics simulation by deep learning is under development. This ultra-fast technology can speed up calculation speed by a factor of several hundred to a thousand, which is expected to improve design efficiency and performance quality through optimization. Significant reductions in design time can be realized by allowing design changes and performance and quality evaluations to be performed interactively. In design optimization, it is necessary to run physical simulations under a very large number of conditions, and in the past, the design parameter space to be explored was sometimes limited. However, by greatly speeding up the physical simulation, it becomes easier to search in a wide parameter space, and optimal solutions with fewer omissions can be obtained.

Currently, we are developing a multi-grid CNN-based network for models with a mixture of coarse and fine grids (dense grids) as a technology to address the issues of model scaling (high-definition), insufficient hardware specifications, and increased training man-hours. We are working on the development of a multi-grid CNN-based network for models with mixed coarse and fine grids.

As a basic study, a technique for propagating physical information from one coarse grid to one dense grid has already been reported at a conference on Computational Engineering and Science (June 2023: Application of CNN-based multi-grid networks to CFD). This time, we developed a technique that enables bidirectional propagation of physical information between the coarse and dense grids, as well as prediction with three basic networks without limiting the number of grids, and applied it to a basic temperature distribution prediction model for circuit boards. This report describes the results of applying the technology to a basic temperature distribution prediction model for circuit boards.

This technology is not limited to temperature prediction, but can be widely applied to simulations that predict the spatial distribution of physical quantities.

LATTICE BOLTZMANN SIMULATION OF POLLUTANT DISPERSION USING EULERIAN AEROSOLS MODELS: APPLICATION TO NATURAL VENTILATION INSIDE BUILDINGS

Jerome Jacob[*1]*

[1]*Aix Marseille Université*

ABSTRACT

Lattice Boltzmann method (LBM) has been used successfully in the field of urban flow simulation such as pollutant dispersion in recent years [1] thanks to its interesting numerical properties (low numerical dissipation, easy implementation for parallel simulation). However, it has mainly been used for pollutant dispersion in urban areas (outside flow) recently rather than for simulation of air quality and natural ventilation inside buildings.
This study presents the extension of previous work [1] based on the hybrid recursive regularized lattice Boltzmann model (HRR LBM [2]) to the simulation of natural ventilation inside buildings. Gaseous transport equation method previously used in different studies are compared with an aerosol model in Eulerian framework implemented in the lattice Boltzmann solver. The different LB simulations are validated with experimental [3] and numerical [4] data on a configuration of pollutant release inside a building with open windows immersed in an atmospheric boundary layer. The accuracy of obtained results is evaluated using the quality criteria introduced in Chang and Hanna [5] in order to evaluate the performance of the proposed LB model for air quality studies.
Depending on the data available in the literature, the accuracy and computational cost of the proposed method will be compared to Eulerian and Lagrangian aerosol model in the Navier Stokes framework to evaluate the interest of using LBM for such applications.

ON AUTOMATED DISCOVERY OF THERMODYNAMICALLY CONSISTENT FINITE STRAIN PLASTICITY MODELS

Asghar Arshad Jadoon[*1], Knut Andreas Meyer[2] and Jan Fuhg[1]*

[1]*The University of Texas at Austin*
[2]*Technical University of Braunschweig*

ABSTRACT

Constitutive modeling lies at the core of mechanics, allowing us to map strains onto stresses for a material in a given mechanical setting. Historically, researchers relied on phenomenological modeling where simple mathematical relationships were derived through experimentation and curve fitting. After the recent revival of machine learning, the community started exploring the idea of modeling constitutive behavior through neural networks. It started with a purely data-driven, black-box approach where the neural network could assume any arbitrary mapping function as long as it could accurately relate stresses and strains. However, these architectures violated established mechanical principles. Therefore recent efforts concentrate on designing neural network architectures that could incorporate physics and mechanistic assumptions into machine-learning-based constitutive models. For history-dependent materials, these models have so far predominantly restricted to small-strain formulations[1,2].

In this work, we develop a finite strain plasticity formulation based on thermodynamic potentials[3] to model mixed isotropic and kinematic hardening. The goal of this work is an automated discovery framework of hardening models using neural networks that a priori satisfy all thermodynamic constraints. We test our model on experimental uniaxial cyclic-loading data. We show that the framework is able to not only interpolate well but also to extrapolate remarkably to unseen data. This ability to generalize beyond the training set underscores the robustness and predictive power of our model. By automating the discovery of hardening models, our approach eliminates user bias and ensures that the resulting constitutive model complies with thermodynamic principles, thus offering a more systematic and physics-informed framework.

OPTIMIZATION OF STRUCTURAL INSTRUMENTATION FOR BRIDGE HEALTH MONITORING

*Shahed Jafarpour Hamedani**[1]

[1]*University of New South Wales*

ABSTRACT

The bridge structures are of utmost importance due to their critical role in the transportation network. Data-driven approaches offer promising tools for continuous long-term condition monitoring of such large-scale structures. In this study, time-series segmentation has been utilized for damage detection in a real-case bridge structure. Signals taken from accelerometers installed on the bridge structure are processed to detect damage(s). Instrumentation of the entire bridge structure, however, may be laborious, expensive, and time-consuming. Therefore, the quantity and location of sensors are optimized to yield the most efficient arrangement. The presented approach can contribute to the development of more cost-effective methods for bridge health monitoring.

[4]University of California, Riverside

ABSTRACT

In this work we introduce the heterogeneous peridynamic neural operator (PNO) approach, for data-driven constitutive modeling of heterogeneous materials. The goal is to learn both a nonlocal constitutive law together with the material microstructure from loading field-displacement field measurements. To this end, we propose a two-phase learning approach. First, we learn a homogeneous constitutive law in the form of a neural network-based kernel function and a nonlocal bond force, to capture complex homogeneous material responses from data. Then, in the second phase we fix the learnt bond force and fine-tune the kernel function for each material point, so as to capture the material heterogeneity. Owing to the state-based peridynamic skeleton, our PNO-learned material models are objective and have the balance of linear and angular momentum guaranteed. In this study, the new PNO architecture learns a constitutive model for a biological tissue with anisotropic heterogeneous response undergoing large deformation regime. The anisotropy and heterogeneity of this tissue stems from collogen fibers with unknown natural orientation, resulting in a location-dependent anisotropy. To demonstrate the applicability of our approach, we apply the heterogeneous PNO in learning the material model and fiber orientation field from digital image correction (DIC) data containing the planar displacement field on the tissue in a biaxial test. The learned orientation angles are validated against experimentally detected fibers.

[4]*Indian Institute of Technology Guwahati*

ABSTRACT

The curvature of the biological membrane is a crucial aspect of many cellular processes like tubular formations, invaginations, fusion, and budding [1]. The Helfrich model is a widely used continuum model that describes the bending energy of cellular membranes as a function of their curvatures - mean and Gaussian.

In this work, we present a modified Helfrich model aimed at providing improved control over the asymmetric morphological changes in biological membranes. We conduct a comparison of the stresses and moments generated by our model with those of the classical Helfrich model and another modified Helfrich model introduced in [2].

The membrane surface and its large bending deformations are modeled as a liquid shell using curvilinear coordinates. The finite element approach to solve the resulting equation requires C1-continuous discretization for which NURBS-based isogeometric finite elements are used. Furthermore, we analyze a numerical example related to the budding process, similar to the work in [3].

NONINTRUSIVE COMPUTATION OF INVARIANT MANIFOLDS AND THEIR REDUCED DYNAMICS IN LARGE NONLINEAR FINITE ELEMENT MODELS

*Shobhit Jain**[1]

[1]*TU Delft*

ABSTRACT

Invariant manifolds, in general, and Spectral Submanifolds (SSM), in particular, have emerged as rigorous and predictive model reduction tools for nonlinear dynamical systems. Recent developments have enabled direct computation of invariant manifolds and their reduced dynamics for high-dimensional finite-element (FE) models by solving the associated invariance equations in physical coordinates using only the eigenvectors associated with the master modal subspace. However, FE models in commercial solvers generally do not provide information on the nonlinearities required for the direct approximation of invariant manifolds.

In this talk, we show how to overcome this limitation using a nonintrusive construction of invariant manifolds and their reduced dynamics in both equation-driven and data-driven environments. Specifically, in the data-assisted setting, we use a small number of unforced FE simulations to learn SSM-based ROMs and use these ROMs to predict the forced response of the FE model without performing any costly forced simulation. We demonstrate our methods a range of nonlinear mechanical systems from simple structures, such as beams and shells, to more complex geometries, such as a micro-resonator model containing more than a million degrees of freedom.

SENSITIZING THE RANS APPROACH TO A SCALE-RESOLVING COMPUTATIONAL FRAMEWORK FOR COMPLEX MULTI-PHYSICS TURBULENT FLOWS

Suad Jakirlic[1]

[1]*Technical University of Darmstadt*

ABSTRACT

The present work deals with the scale-resolving simulation of complex multi-physics turbulent flows. The complexity of flow refers to a variety of differently structured flow and heat-transfer phenomena including plasma-actuated flow control relevant to aircraft and car aerodynamics, internal-combustion engines and corresponding cooling channels, two-phase flow in bubble columns, particle dynamics in pipes, physiological flows in the human aorta, flows around blunt bodies, thermal mixing in cross-stream type T-junctions, flow in a concentric annulus subjected to inner/outer cylinder rotation and complex duct and pipe configurations characteristic of various industrial applications. Comparative evaluation of the results with reference databases from relevant experimental and numerical studies shows the correctly predicted instantaneous character of the flow as well as its averaged pattern [1-3]. The anisotropic turbulence residing in unresolved motion is described by a RANS-based (Reynolds-averaged Navier-Stokes) eddy-resolving closure that accounts for the dynamics of the entire subscale stress tensor. The eddy-resolving capability of the model is enabled by the introduction of an additional production term into the length-scale determining equation. Its functional dependence is motivated by the Scale-adaptive Simulation (SAS) strategy by Menter and Egorov (2010, FTaC 85:113-138). The essence of this term is its dependence on the second derivative of the underlying velocity field, providing the rationale for its definition originally introduced by Rotta (1972), which adequately implies the recognition of the inhomogeneity of the flow that occurs specifically in the shear layer regions, with an emphasized inflection of the velocity profile, and promotes the detection of flow structures. This RANS-based Reynolds-stress model, sensitized to the turbulent fluctuations, brings important advantages. This primarily concerns the grid spacing-independent model formulation, which is particularly effective for arbitrarily complex grid cell arrangements.

ATOMISTIC SIMULATION OF COLD SPRAY PROCESS FOR ALCOCRFENI HIGH-ENTROPY ALLOY

Nashit Jalal[1], André McDonald[1] and Wylie Stroberg[1]*

[1]*University of Alberta*

ABSTRACT

Cold spray deposition is a widely used solid-state surface coating technology. In this process, micron-scale solid particles are deposited on a substrate at high velocities causing severe plastic deformation, thus resulting in buildup of a coating. In contrast to thermal spray deposition, the particle temperature in the cold spray process remains below the melting point of the feedstock material. This helps prevent oxidation and phase changes during the process, making it ideal for various engineering applications. Despite several experimental studies on cold spray deposition, understanding the bonding phenomenon involved is difficult due to the complex mechanisms that occur at the nanometer scale. Recent simulations suggest that the bonding mechanism may involve a combination of impact-induced jetting, formation of adiabatic shear bands, and hydrodynamic spall.

The present study explores these phenomena using molecular dynamics simulations. A series of atomistic simulations were conducted for AlCoCrFeNi high-entropy alloy particle impacting an Fe substrate, considering variations in particle size and velocities. Interfacial jetting is observed at high impact velocities. Based on the simulation results, the optimal parameters for achieving a dense and uniform coating of the high-entropy alloy on the substrate are also identified. The coating performance is quantified using the horizontal and vertical flattening ratio of the particle. The results obtained can be instrumental in the design and parameter optimization of the cold spray process for high-entropy alloy deposition.

TOPOLOGY OPTIMIZATION OF GEOMETRICALLY NONLINEAR COMPLIANT MECHANISMS WITH VARIABLE LOADS AND SUPPORTS

Lee Alacoque[1] and Kai James[2]*

[1]University of Illinois Urbana-Champaign
[2]Georgia Institute of Technology

ABSTRACT

In this study, we present a novel method for performing design synthesis of compliant mechanisms in which the locations of the fixed supports and applied loads are subject to optimization along with the internal material distribution. Previous studies have demonstrated that by including the load and support locations as design variables, one can achieve significantly enhanced performance when compared with designs whose loads and support locations are selected arbitrarily or by intuition [1]. The current work extends this method to a variety of more complex design problems. In the examples presented, the compliant mechanisms all exhibit large, geometrically nonlinear displacements. To solve the nonlinear elasticity problem, we implement a modified nonlinear Neo-Hookean hyperlelastic model and we compute the displacements using nonlinear finite element analysis. The equilibrium equation is solved using a displacement-control method, and we compute sensitivities using a discrete adjoint formulation. In order to prevent large mesh distortion in regions where the material density is low, we continuously interpolate between the nonlinear elasticity model, and a linear elasticity model, which is applied only in low-density regions.

In earlier work, we developed an original super-Gaussian projection method for parameterizing the support locations [1]. Here we extend this method to accommodate both variable support locations and input displacement orientation as design variables. We demonstrate our method by performing topology optimization of three example mechanisms: a gripper with maximum displacement at the jaws, an airfoil with snap-through displacement for actuation of the trailing edge, and an airfoil with path-following displacement at the leading edge. In each example, the optimized mechanism outperforms an analogous design in which the support locations and load orientation are fixed during the optimization.

A FREE SOFTWARE APPLICATION FOR ONE-CLICK STRESS COMPUTATION OF ABDOMINAL AORTIC ANEURISM

Mostafa Jamshidian[*1], Adam Wittek[1] and Karol Miller[1]*

[1]*The University of Western Australia*

ABSTRACT

Abdominal aortic aneurysm (AAA) refers to a permanent and irreversible dilation of the lower aorta. Symptomless, AAA can expand to the point of rupture if left untreated. Based on mechanics, an artery ruptures when the local wall stress exceeds the local wall strength. Therefore, the AAA wall stress, determined reliably and quickly through non-invasive approaches, can help with patient-specific treatment. BioPARR (Biomechanics based Prediction of Aneurysm Rupture Risk) is a free software package for AAA stress analysis based on finite element (FE) method [1]. Fed with the patient's blood pressure and the AAA and intraluminal thrombus (ILT) label maps extracted from the medical images, BioPARR conducts automatic robust computations based on the contemporary computational biomechanics approaches that obviate the requirement for patient-specific material properties [2]. As a truly patient-specific approach based solely on the clinical data, BioPARR presents a clinically applicable standardized approach for comparative evaluation of AAA.

While seamless at the time of release, BioPARR can be improved based on recent software advancements. BioPARR relies on multiple libraries and external software, e.g., 3D Slicer image computing platform, ParaView, and Abaqus. It functions optimally with the recommended versions of these external software, but subsequent updates may compromise BioPARR's robustness. Generally, the recommended older version of freeware may lack adequate support for new hardware and operating systems. Hence, BioPARR requires updates and maintenance, aligned with updates to the external software. Another limitation involves using expensive software like Abaqus, though it could potentially be substituted with freely available FE packages.

In this presentation, we introduce a one-click free software application for AAA stress analysis developed based on MATLAB programming language. The redistributable application is a royalty-free standalone single executable file that is automatically installed on a typical system with no specific hardware requirements. During installation, it automatically fetches and installs MATLAB Runtime as a collection of shared libraries, MATLAB code, and other files that enable the execution of compiled and packaged MATLAB applications on systems without an installed version of MATLAB. The frontend provides a user-friendly window for the end user to input the required data. A single click on the application window initiates the backend computations and visualizes the AAA stress results. The backend utilizes recent MATLAB capabilities, including the Partial Differential Equation Toolbox for FE computations.

COMPRESSION MOLDING-STRUCTURAL COUPLED ANALYSIS OF SHORT-FIBER REINFORCED COMPOSITE UNDER VARIOUS COMPRESSION MOLDING CONDITIONS

Da-Young Jang[1], Geung-Hyeon Lee[1] and Jang-Woo Han[1]*

[1]*Kumoh National Institute of Technology*

ABSTRACT

Composite structures are typically manufactured through various molding processes such as injection molding, compression molding, resin transfer molding, and so on. These molded structures made by composite materials are widely used in various engineering applications due to its high-stiffness-to-weight ratio and multi-functional properties. Although the many advantages of the Compression molding, a phenomenon must be taken into consideration during the design and manufacturing process is that various flow characteristics can be appeared by the initial conditions of the molding process. Especially in the case of short fiber reinforced composite materials, arbitrary fiber orientation characteristics can be occurred by various flow as well as matrix-fiber interaction characteristics, and these local fiber orientation characteristics can directly impact the mechanical behavior of the molded product.[1]

Therefore, this study investigated the flow and its corresponding local fiber orientation characteristics of short fiber-reinforced composite materials under various molding conditions and conducted molding-structural coupling analysis considering local fiber orientation characteristics in order to provide reliable results during the design process. In addition, the study tried to enhance the accuracy of the molding-structural coupling analysis by considering the matrix-fiber interaction as well as residual stresses.

Compression molding analysis of short fiber-reinforced composite materials under various molding conditions was conducted by using the Moldex 3D software, where the local fiber orientation characteristics depending on the resin flow, matrix-fiber interaction as well as residual stresses were investigated for the various molding conditions. Furthermore, compression molding-structural coupled analysis for the short fiber-reinforced composite materials was conducted by connecting the Modlex3D, Digimat and commercial FE softwares (Ansys and Abaqus). Mean-field homogenization is employed in order to evaluate the effective local anisotropic mechanical properties depending on the fiber orientation, and these local anisotropic properties are mapped in the structural finite element model.

In the numerical study, the mechanical behavior of the ASTM D638 tensile specimens which are manufactured by various molding conditions are investigated to verify the effect of fiber orientation on the local behavior of the short fiber reinforced composite structure.

[1]*Technische Universität Braunschweig*
[2]*Chalmers University of Technology*

ABSTRACT

The Structural Battery represents an innovative carbon fiber-reinforced polymer composite, designed to serve a dual purpose: As a storage device for electrical energy (viz. as a battery) and as a robust support for mechanical loads. Carbon fibers play a multifaceted role, acting as an active electrode material, current collector, and mechanical reinforcement. These fibers are integrated into a Structural Battery Electrolyte, comprising a solid phase (a porous polymer network) and a liquid electrolyte that facilitates the movement of ions, particularly Li-ions. The ion-mobility is brought about by stress-assisted diffusion (driven by the chemical potential gradient), migration (induced by the electric field), and convection (resulting from fluid motion, i.e., seepage) [1]. In summary, the liquid phase within the porous polymer network promotes ion transport between electrodes, while the solid phase effectively distributes mechanical stresses.

This presentation showcases the capabilities of a recently developed computational two-scale modeling framework, exemplified by [2,3], in evaluating the integrated electro-chemo-mechanical properties of Structural Battery electrode materials. The governing equations of the problem are established upon coupling Gauss law for electric fields and mass conservation for each mobile species with mechanical (quasi-static) equilibrium. By utilizing Variationally Consistent Homogenization, we are able to establish a two-scale model where both the macro- and the sub-scale equation systems emerge from a single-scale formulation. We explore various couplings and their properties across the scales through numerical assessment of the intricate characteristics of Structural Battery composites.

NEURAL PARTIAL DIFFERENTIAL EQUATION MODELS OF COMPLEX DYNAMICAL SYSTEMS

Sanket Jantre[*1], Anthony DeGennaro[1] and Nathan M. Urban[1]*

[1]*Brookhaven National Laboratory*

ABSTRACT

In science and engineering domains, we often turn to mechanistic computer simulation models to predict the behavior of natural systems, such as fluid dynamics, molecular dynamics, or particle interactions in a collider. These simulations are often based on differential equations and provide critical information about the underlying governing equations but often are computationally expensive. To address this limitation, we explore the use of machine learning based approach, neural partial differential equation (NPDE), which seeks to emulate a complex computer model with a simpler partial differential equation (PDE) whose governing equation or “right hand side” is learned from data in the form of a neural network. As a test case we look at Cahn Hilliard equations for phase separation in self-assembling nanomaterials. We emulate the fast transient behavior in the PDE and incorporate the emulator in solver for time stepping in the extrapolation domain. Subsequently, we will explore ways to quantify the neural network uncertainty via a Bayesian deep learning framework. To recover useful physical equations from limited simulation data, we will also explore the reduction of overparameterized neural network weight spaces through linear subspace methods and Bayesian inference on this reduced parameter space.

COMPUTATIONAL APPROACH FOR HYDROGEN COMBUSTION MODELLING OF GRAIN DRYING MACHINE

Sams Jarin[*1], Zhongzheng Wang[1], Md Imran Hossen Khan[2], Nawshad Haque[3] and Emilie Sauret[1]*

[1]Queensland University of Technology
[2]Agridry Dryers Pty Ltd.
[3]CSIRO

ABSTRACT

The drying process is a critical step in agricultural grain processing, contributing significantly to the final product's quality and shelf life. Various drying techniques are employed in the agricultural industry, ranging from traditional methods to more advanced technologies like mechanical and thermal drying. The drying industry heavily relies on thermal drying methods which is highly energy-intensive and contributes to greenhouse gas emissions, worsening the global warming issue. Replacing fossil fuels with green hydrogen fuel in the grain drying process can significantly reduce the greenhouse gas emissions and offer a carbon-neutral solution for powering drying operations. However, the widespread adoption of hydrogen as a fuel faces several challenges, particularly in understanding the complex combustion kinetics of hydrogen fuel. The unique properties of hydrogen, such as its high diffusivity and wide flammability range, pose challenges for effective combustion and mixing dynamics in drying process. Furthermore, there is an urgent demand to develop the advanced mathematical model for simulating the hydrogen combustion processes more accurately for optimizing drying performance. To meet these challenges and develop efficient and clean hydrogen derived drying system, a comprehensive understanding of the mixing and combustion dynamics of hydrogen-oxygen components is essential. This necessitates the use of sophisticated mathematical modelling tools such as CFD model to simulate and analyze the intricate gas dynamics involved in hydrogen combustion. The principal aim of this work is to generate and evaluate an efficient CFD model for the hydrogen combustion process using premixed hydrogen gas for the grain drying process. To simulate the combustion of hydrogen – air, a transient CFD model of energy, turbulence, radiation, and species transport are going to be implemented in the ANSYS Fluent software. This model provides the optimum velocity of hydrogen gas for maximum achievable temperature for a premixed hydrogen combustion CFD model of grain drying operation. To achieve the maximum accuracy from the model, different ratios of hydrogen – air combination are going to be investigated which can then eventually lead to generate a successful new hydrogen derived grain dryers' machine.

A FINITE ELEMENT FRAMEWORK WITH GLOBAL DIVERGENCE-FREE CONSTRAINTS FOR NON-STATIONARY NON-LINEAR NAVIER-STOKES EQUATIONS

Jan Jaśkowiec[*1] and Sławomir Milewski*[1]

[1]*Cracow University of Technology*

ABSTRACT

The Navier-Stokes (N-S) equations characterize the dynamics of fluid flow, capturing phenomena ranging from laminar to turbulent behaviors over time [1,2]. While the N-S equations inherently constitute a non-stationary and nonlinear problem, simplified linear equations are applicable under specific conditions, such as low Reynolds numbers and laminar fluid flow. This project focuses on incompressible fluids, introducing a mathematical model that enforces the divergence-free velocity constraint. Traditionally, the Sobolev space serves as the foundation for determining solutions to the velocity and pressure fields through weak problem formulations. However, this project proposes an alternative approach, decomposing the problem into two distinct subproblems for velocity and pressure. The decomposition is achieved by constructing a divergence-free Sobolev subspace for velocity and its test functions. This innovative approach allows the formulation of a symmetric problem solely for velocity, while the pressure problem is derived by applying the complement of the divergence-free Sobolev subspace for test functions.
In the finite space, an approximation field of arbitrarily high orders is constructed using the standard finite element method. The null-space method [3] is then employed to build a global divergence-free approximation subfield, ensuring compliance with Dirichlet boundary conditions. Subsequently, the approximate velocity field can be calculated using a linear or non-linear approach, depending on the type of N-S problem. The complement of the divergence-free approximation subfield is also constructed using the null-space formulation, facilitating the determination of the approximate pressure field. The effectiveness of this method is demonstrated through representative 2D and 3D examples, encompassing domains with both straight and curved boundaries. The scenarios include linear and non-linear problem formulations, as well as stationary and non-stationary fluid flows. This advantage is particularly pronounced in non-linear formulations, where the iteration procedure focuses solely on the velocity field, with pressure obtained once the velocity is established.

LARGE DEFORMATIONS OF GRADIENT ELASTIC SHELLS

Mohammadjavad Javadi Sigaroudi[*1] and Marcelo Epstein*[2]

[1]*Carleton University*
[2]*University of Calgary*

ABSTRACT

Based on a generalization of Budiansky's nonlinear shell theory, a novel mechanical formulation for the fully nonlinear gradient shell theory in the large deformation regime is developed. The field equations are obtained in their weak forms based on kinematically exact models. An extension of a linear constitutive equation is presented to capture the effect of an internal material length scale in the shell deformation. An appropriate finite element is developed and used to incorporate the additional degrees of freedom arising in the strain gradient theory. To demonstrate the capability of the proposed formulation in dealing with large deformations, specific examples involving an axisymmetric gradient shell structure subjected to severe circumferential load and a gradient plate are analyzed. The numerical results reveal that the deflections of a micro-scale shell predicted by the new model are smaller than those predicted by classical shell theory in the small and large deformation regimes.

IN SILICO TRIALS INFORMED BY EXPERIMENTAL MEASUREMENTS REVEALS THE IMPACT OF PATIENT HETEROGENEITY ON DOSAGE PROTOCOL FOR A NOVEL CANCER THERAPEUTIC

Adrianne Jenner[*1]*

[1]*Queensland University of Technology*

ABSTRACT

Cancer growth and response to therapy varies significantly across the population. Immunotherapies have become an integral part of cancer therapy in recent years. Unfortunately, there is large variability in the responses of cancer patients to these therapies, including complete remission or rapid tumour growth. Bispecific T-cell engagers (BiTEs) are one promising immunotherapy that enhance cellular antitumour immunity by targeting T cells and priming them to recognize cancer cells. Recent evidence has suggested that BiTE efficacy can be heightened through encoding in oncolytic measles virus (MV-BiTE) vectors. Infection of cancer cells with MV-BiTEs causes the local production of BiTEs and has shown efficacy and safety in a murine model, however, the translated efficacy of this treatment in a heterogeneous human population is unknown. In this work, we generate an in silico clinical trial of MV-BiTE therapy in a cohort of heterogeneous virtual individuals informed by experimental measurements. Patients are generated through sampling parameters in an ordinary differential equation system based on variability in experimental measurements. Model predictions show there is a strong correlation between an individuals immune response and their response to this novel therapy. The methods developed here are easily translated to other cancer modelling areas, where understanding the impact of heterogeneity in patients is crucial.

Industrial applications of IGA

GEOMETRICALLY WATERTIGHT UNSTRUCTURED SPLINES APPLIED TO CAD, FEA, IGA, CAM, AND CAI FOR A DESIGN-THROUGH-MANUFACTURING DIGITAL THREAD

Ryan Jennings[*1], Benjamin Urick[2] and Daniel Keller[2]*

[1]*Kansas City National Security Campus*
[2]*nVariate, Inc.*

ABSTRACT

Currently, one of the Kansas City National Security Campus (KCNSC) initiatives is implementing a digital engineering approach that uses authoritative sources of data and models. A barrier to this approach is that computer-aided tools used in the design-through-manufacturing workflows (i.e., Computer-Aided Design (CAD), Computer-Aided Engineering (CAE), Computer-Aided Manufacturing (CAM), and Computer-Aided Inspection (CAI) etc., generically CAx) were initially developed independently, and as a result each domain utilizes a unique Model Based Definition (MBD) data model. Data consumed or generated in one CAx domain data model cannot always be accurately translated, consumed by, or associated with another CAx domain data model, severely limiting the degree to which any particular CAx domain data can be effectively linked to or leveraged by another domain. The fundamental way in which these CAx MBD data models are constructed severely limits the ability to perform isogeometric analysis (IGA) and update CAx geometry to create digital twins.
The root of this problem is that currently, native CAD models are not suitable for many of the requirements of the other CAx domains due to mathematical inconsistencies, such as non-geometric watertightness, that create problems for downstream users. This is due to inaccuracy of computing complex intersections of the non-uniform rational basis splines (NURBS) used in boundary representations (B-Reps), the de facto modeling description utilized by modern CAD systems, and means NURBS surface intersections must be represented as curve approximations. Thus, while CAD B-Rep definitions of geometry are topologically watertight, gaps of geometric discontinuity are introduced at these approximated intersections that do not allow them to be geometrically watertight.

KCNSC is partnering with nVariate, Inc. to address this by utilizing their patented watertight Boolean operation technology to create geometrically watertight models. These models consist of un-trimmed surface patches of explicit geometric continuity and can be accurate to the same model tolerance employed in existing CAD systems. The technology is implemented to produce watertight spline CAD models directly linked to traditionally authored CAD models in PTC Creo Parametric, the model authoring application at KCNSC. The watertight spline CAD model is used for improved workflows for finite element analysis (FEA) and IGA, creation of an improved digital twin model updated by analysis results, inspection data, and manufacturing data, and generation of improved slice files for additive manufacturing (AM).

The Department of Energy’s Kansas City National Security Campus is operated and managed by Honeywell Federal Manufacturing & Technologies, LLC under contract number DE-NA0002839.

INTEGRATING MULTIPLE LOADING CASES IN HIGH-RESOLUTION TOPOLOGY OPTIMIZATION: A MULTI-SCALE APPROACH

Peter Dørffler Ladegaard Jensen[*1], Rebekka Varum Woldseth[1] and Ole Sigmund[1]*

[1]*Technical University of Denmark*

ABSTRACT

The seminal works on high-resolution topology optimization procedures have provided new insights into structural design [1]. Despite these advancements, their high computational costs limit practical industry applications. Concurrently, industrial-grade additive manufacturing (AM) has seen substantial improvements, highlighting the need for AM-specific high-resolution inverse design methods that integrate infill as a structural component.

These challenges were addressed by Jensen et al. [2] by extending the de-homogenization topology optimization method [3] to 3D unstructured grids, where a multi-scale optimization approach was employed by considering an orthotropic periodic rectangular-hole material, which is reminiscent of the stiffness optimal Rank-3 material. The microstructure orientations and laminates are regulated to enhance stability and manufacturability. The coarse multi-scale structure is reconstructed on a high-resolution single-scale by considering a finite periodicity of the microstructure, which corresponds to a minimum length scale, by computing stream surfaces that align with the microstructure, resulting in a high-resolution structure with a minor reduction in structural performance compared to the coarse scale optimized solution. However, this method was limited to a single-load assumption, resulting in suboptimal results if applied to multi-load scenarios. This work extends [2] by incorporating the optimal Rank-N microstructure as the material model, enabling the optimization of structures under multiple load-case scenarios. This advancement allows for the reproduction of complex structures like the wing study in [1], with significantly reduced computational resources and comparable structural performance.

EXPERIMENTAL AND NUMERICAL STUDIES ON SHEAR BAND FORMATION AT HIGH STRAIN RATES

Stefan Jentzsch[*1], Daniel Stock[1], Ralf Häcker[1], Birgit Skrotzki[1], Reza Darvishi Kamachali[1], Dietmar Klingbeil[1] and Vitaliy Kindrachuk[1]*

[1]*Federal Institute for Materials Research and Testing*

ABSTRACT

The essence of dynamic failure is closely linked to dramatic shear deformations frequently resulting in the emergence of adiabatic shear bands (ASB). Under high loading velocities and the subsequent rapid temperature increase, the localization of shear strain is crucial in view of safety issues, especially with respect to fast rotating components and diverse crash scenarios. Therefore, we perform and numerically investigate high speed impact tests at the split Hopkinson pressure bar (SHPB) setup specifying notched hat-shaped specimen geometries that resemble the stresses and failure conditions at the component level.

First, using specimens manufactured from the steel S690QL and the nickel-based superalloy Inconel 718 we connect series of SHPB impact tests at high strain rates of 10^3-10^4 s^(-1) and quasistatic tests at rates of 10^(-3) s^(-1). Optical microscopy and electron backscatter diffraction (EBSD) unveil significant shear localization accompanied by grain refinement in the SHPB tests. Thus, the yield strength is doubled in the affected region which can be described by the Hall-Petch relation.

The displacements across the surface of the specimens are captured with subset-based local digital image correlation (DIC) during the impact time and combined with implicit and explicit finite element (FE) simulations to solve the inverse problem on the identification of the underlying viscoplastic constitutive model for finite deformations. More specifically, we identify the damage parameters of the widely recognized viscoplastic Johnson-Cook (JC) model with an enhanced description of the damage evolution. The temperature evolution is assumed to be adiabatic and compared with high-speed thermography measurements.

To ensure the well-posedness of the boundary value problem (BVP) we consider an extension by a nonlocal formulation. Therefore, we use the implicit gradient model approach formulated for the viscoplastic equivalent strain. Finally, we determine the additional internal length scale introduced by the gradient model from the inverse problem associated with the SHPB tests.

A REACTIVE MOLECULAR DYNAMIC SIMULATION STUDY ON HYPERTHERMAL EROSION OF BNNT BASED NANOCOMPOSITE UNDER LEO AND SUB LEO ENVIRONMENT

Inseok Jeon[*1] and Seunghwa Yang[1]*

[1]*Chung-Ang University*

ABSTRACT

Satellites and space vehicles aviating the LEO (Low Earth Orbit) are inevitably experience pyrolysis and ablation due to the collision with gaseous molecules and debris. Especially, under the LEO environment, atomic oxygen(AO) is the most abundant component of the atmosphere and causes a critical surface damage of thermal protection materials (TPM) for its high reactivity. In the sub LEO near 200~300km of altitude, however, the nitrogen molecule (N2) is as abundant as the AO. Therefore, the impact of these two main components should be considered in the design of TPM.
Boron nitride (BN) nanostructures such as hexagonal BN sheet and BN nanotubes (BNNT) are promising materials as reinforcement in TPM for their exceptional stability at elevated temperature. At the same time, BN nanostructures are highly conductive, stiff, strong comparable to the carbon nanotubes and possesses neutron absorption capability. Therefore, continuous attempts to utilize BNNT as coating materials for spacecrafts are being made.

In this study, a comparative hyperthermal bombardment simulation on the impact of AO and N2 in surface erosion of BN-based nanocomposites was performed using a reactive molecular dynamic simulation. The ReaxFF was adopted to describe the material's recession due to bond breaking in detail. Reflecting the atmospheric profile in sub LEO, AO and N2 were collided to the surface of polyimide (PI) and PI-BN nanocomposites with a kinetic energy of 4.5eV and 8.0eV, respectively for each component. To predict the ablation properties of PI-BN nanocomposite, the surface recession rate, temperature rising ratio by the AO and N2 were determined and compared with each other. Additionally, difference in the reaction products by the two components were predicted and discussed in conjunction with the recession ratio. Finally, erosion yield of PI and PI-BN nanocomposites were determined according to the ratio of colliding AO and N2 and compared with MISSE experimental results.

EFFECT OF TANGENTIAL FRACTURE PROPERTIES ON MIXED-MODE COHESIVE ZONE MODELING

Siwoo Jeon[*1] and Kyoungsoo Park*[1]

[1]*Yonsei University*

ABSTRACT

Determining tangential fracture properties poses significant challenges, particularly in solving mixed-mode problems. Thus, most previous researchers simply focused on the normal cohesive fracture properties while either neglecting the tangential traction with a low stiffness or assuming the same traction-separation relation as the normal one. To investigate the effect of tangential fracture properties on mixed-mode cohesive zone modeling, the Park-Paulino-Roesler (PPR) model (Park et al., 2008) is employed and modified (Jeon and Park, 2024). The original PPR model provides both normal and tangential cohesive traction-separation relations in conjunction with corresponding fracture properties, while displaying a tangential traction discontinuity at zero separation in the extrinsic cohesive zone modeling. The extrinsic PPR model is modified through removing the tangential traction discontinuity with an initial elastic region only for the tangential traction. Then, three mixed-mode examples, i.e., mixed-mode bending test, semi-circular bending test, and four-point shear test, are simulated using the modified PPR model in conjunction with stress recovery and domain integral (Choi and Park, 2019). The computational results demonstrate the significant effects of tangential fracture properties on load-displacement responses. Furthermore, this model is anticipated to have broad applications across various mixed-mode failure scenarios, taking into account the effects of normal and tangential fracture properties.

NOVEL TOPOLOGY OPTIMIZATION FRAMEWORK USING PHYSICS-INFORMED NEURAL NETWORK

Hyogu Jeong[*1], Jinshuai Bai[2], Yubo Chen[1] and YuanTong Gu[2]*

[1]*Queesland University of Technology*
[2]*Queensland University of Technology*

ABSTRACT

To this date, Deep Learning (DL) data-driven methods have been successfully applied to various topology optimization problems where DL models are trained to establish a mapping between the optimized topology with corresponding boundary conditions. Such method has inherent drawbacks, where the DL model requires a large training dataset to train and yet is challenged due to the poor generalization of their models. Therefore, mitigating the reliance on data while demonstrating superior generalization ability is highly desirable. The present study introduces a novel DL-based computational paradigm for topology optimization by leveraging the Physics-Informed Neural Networks (PINNs) that can be trained without labelled data to solve computational physics problems while respecting the laws of physics in the format of Partial Differential Equations (PDEs) [1]. In our proposed framework, we employ the Deep Energy Method (DEM) to numerically calculate the displacement field of the given problem domain by minimizing the overall potential energy as the natural loss of the PINN [2]. Subsequent sensitivity analysis is carried out using the automatic differentiation feature in DL to solve the derivative of the objective function with respect to the network parameters [3]. The numerical examples demonstrate that the proposed framework is capable of solving various topology optimization problems without facing any generalization issues for compliance minimization, stress-constrained and three-dimensional problems. In particular, the resulting designs exhibit comparable objective values to the designs obtained via Solid Isotropic Material with Penalization (SIMP) method.

A NUMERICAL ANALYSIS OF PPTC2 PROPELLER OPEN-WATER CHARACTERISTICS USING DISCONTINUOUS GALERKIN METHOD

Sung-Ho Jeong[1], Dong-Quen Kim[1] and Hyung Taek Ahn[1]*

[1]*University of Ulsan*

ABSTRACT

This paper introduces the unstructured grid-based incompressible flow solver, ULSAN3D-Unstr and presents the numerical analysis results of the propeller open-water characteristics of the PPTCⅡ-P1727 tip-rake propeller developed by SVA Potsdam. ULSAN3D-Unstr employs Discontinuous Galerkin Method and for discretize Incompressible Navier Stokes equation. In order to the treat incompressiblity fluid flow, Artificial Compressibility Method is used and calculates flow fluxes using Upwind schemes, enabling much stable flow analysis. The fluid flow around the propeller is simulated using the Multiple Reference Frame (MRF) approach, and pseudo-time stepping to a steady-state is conducted using an Implicit Method, allowing for dramatical convergence without constraints on time advancement. Through a numerical analysis of PPTCⅡ Propeller Open-Water Characteristics propeller, the paper aims to figure out rake performance which reduce vortex shedding behind the propeller blades of the PPTCⅡ and validate the accuracy of unstructured grid-based incompressible flow solver, ULSAN3D-Unstr.

A MODULAR NONLINEAR STOCHASTIC FINITE ELEMENT FORMULATION FOR UNCERTAINTY ESTIMATION AND PARAMETER SENSITIVITY ANALYSIS

Yanis Ammouche[1] and Antoine Jerusalem[1]*

[1]Oxford University

ABSTRACT

The Monte Carlo method has been widely used for the uncertainty estimation in mechanical engineering design. While extremely flexible, this method remains impractical in terms of computational time and scalability. To circumvent these limitations, other approaches such as the Galerkin stochastic finite element method (GSFEM) have been proposed. GSFEM, pioneered by Spanos and Ghanem [1], provides accurate statistics of the output, has the advantage of being sampling-independent and can be modular in terms of operations, albeit code intrusive. While linear elasticity has been extensively covered in the literature, the application of GSFEM to nonlinear mechanical behaviour remains relatively unexplored. Here, we proposed a formulation of GSFEM that i) makes use of a hybrid formulation to capture discontinuous behaviours [2], ii) allows for nonlinear behaviour, and iii), by special consideration of the input distribution, allows for parameter sensitivity analyses [3,4].

THERMAL CONDUCTIVITY OF NANOPAPER FILMS: A CONTINUUM MICROMECHANICS APPROACH

*Pedro Miguel Jesus de Sousa Godinho**[1]

[1]*Vienna University of Technology*

ABSTRACT

Nanopaper films made of cellulose nanofibrils are suitable candidates for heat management in several flexible electronics applications [1]. However, natural, as well as technical and technological variability, often results in nanopaper films exhibiting a wide range of thermal properties. Hence, it is important, from an application viewpoint, to develop theoretical models that can guide empirical activities related to such materials (such as their production, research and development, or use), and assist in reducing present uncertainties. With this purpose in mind, the mathematical analogy, in the context of continuum micromechanics and mean-field homogenization, between the conductivity and the elasticity problems [1], serves as starting point for adaptation of a continuum-micromechanics-based theoretical model for the elasticity of paper sheets, to the case of thermal conductivity of nanopaper films [1]. Thereby, large collections of experimental determinations are used to compute volume fractions of crystalline cellulose Iα, crystalline cellulose Iβ, crystalline cellulose II, amorphous cellulose, and water in “mean” cellulose nanofibrils of various origins [2]; while a selection of thermal conductivity properties of the abovementioned constituents of nanofibrils, enables estimation of respective thermal conductivity tensors [1]. It is important to note that the thermal conductivity of hydrated amorphous cellulose (the material that indeed embeds the cellulose crystals), as a function of water content, is not directly available; and that, satisfaction of separation of scales conditions formally excludes self-consistent homogenization of amorphous cellulose and water, leaving only atomistic or sub-atomistic approaches available. As a remedy, we resort to recent findings on the elasticity of cellulose nanofibrils [2] and employ Mori-Tanaka homogenization of cellulose crystals and water, embedded into a dry, amorphous cellulose matrix, to estimate a reliable thermal conductivity tensor for the corresponding composite. Theoretically predicted relationships between porosity and in- as well as out-of-plane thermal conductivity of corresponding nanopaper films, agree well with respective, experimentally determined relationships [1]. Similar agreement is found for cellulose fibrils [1]. The proposed theoretical model gives access to similar models (for instance, for water diffusivity or permeability), and paves the way to a higher level of control in empirical activities related to such materials.

COMPARING TOPOLOGY-OPTIMIZED REINFORCED CONCRETE BEAMS DESIGNED WITH 0-1 AND VARIABLE THICKNESS METHODS

Jackson Jewett[*1] and Josephine Carstensen*[1]

[1]*MIT*

ABSTRACT

Topology optimization (TO) is a design optimization method known to generate high-performing structures with a limited volume of material. TO is particularly powerful because it does not require an initial layout of structural members from the user. Rather, it places material freely inside a defined design space with known forces and boundary conditions, so the method can algorithmically derive highly efficient results. TO has enormous potential for impact in the construction industry because it can help reduce the use of building materials, which produce approximately 10% of greenhouse gasses worldwide [1].

Within existing research on TO for construction, tailoring algorithms specifically to reinforced concrete (RC) design has received considerable attention [2]. RC is an important structural system for research because it is ubiquitous in the construction industry. It can also be easily formed into shaped molds, allowing it to be adapted to complex optimized geometries. A common approach for TO of RC uses continuum elements that are stiff in compression to represent the placement of concrete struts, and truss elements that are stiff in tension to place steel ties. These two components come together to create a truss-like RC structure following the strut-and-tie method [3].

This research will present a new framework for topology optimization of RC. Continuum and truss elements will be used together as in [3], but the locations of the nodes of the truss elements will be controlled by design variables, and able to move during the optimization process. Also, SIMP penalization schemes will not be used on the continuum elements, so that their respective design variables can take intermediate values between 0 and 1. These values will be interpreted as varying thicknesses in the final design, following the Variable Thickness Sheet method. Several numerical design examples will be presented using this new framework, and mid-scale designs (~1 meter spans) will be fabricated and tested to demonstrate their efficacy.

ABSTRACT

Trochanteric soft tissue thickness (TSTT) is an important factor influencing the probability of a fracture of the proximal femur following a fall [Pretty et al.,2021, Fleps et al., 2019]. To build personalized biofidelic finite element models (FEM) of human hips, we collected whole body DXA scans using Hologic® Horizon W scanner and body shape (optical) scans using TC2® scanner for 188 subjects (109 Females, 79 males). One of the challenges of accurately determining the TSTT from the whole body DXA scans is associated with the fact that the subjects are scanned in supine position which leads to overestimation of the TSTT as the tissue over the greater trochanter (GT) region is pushed outwards due to the subject's body weight. To address this, we developed a novel method which corrects TSTT based on the optical scans. Briefly, this method utilizes open-source python (v3.9.x) packages to measure TSTT from the two scan sources. The average TSTT (TSTT_avg) of both sides was used to minimalize the measurement error due to preferred weight shifting by the subject during the scan. The TSTT in the supine position (DXA scan: TSTT_avg_scanned) and the standing position (optical scan: TSTT_avg_corrected) was compared for the respective 188 subject's body mass index (BMI) and the correction equation was obtained (eq. 1). The scanned and corrected hip width (HW_scanned, HW_corrected) are obtained from eq. 2 & 3.
TSTT_avg_corrected = 0. 6843 x TSTT_avg_scanned - 0.5461 – (eq.1)
HW_scanned = ΔGT_Left&Right + [2 x Avg. (TSTT_avg_scanned)] – (eq.2)
HW_corrected = ΔGT_Left&Right + [2 x Avg. (TSTT_avg_corrected)] – (eq.3)
where, ΔGT_Left&Right = Distance between left and right greater trochanter point (lateral most).
To demonstrate the influence of this correction we subjected 25 biofidelic FEM to a simulated sideways fall at an impact speed of 3.1 m/s. The soft tissue for the biofidelic FEM creation is selected based on subject's gender, hip width, weight, and BMI. Scanned and corrected hip width were used for each subject to create respective models. The number of hip fractures, determined using a strain-based criterion, increased from 11 to 20 after the correction. The average increase in predicted femur force (17.47%), impact force (6.41%) and drop in force attenuation (11.87%) were recorded. Thus, to generate biofidelic FEM for assessing hip fracture risk due to sideways fall, it is critical to correct TSTT measured in supine position.

MULTISCALE MODELLING OF DEFECT KINETICS IN IRRADIATED ZR-SN-NB ALLOYS

Changqiu Ji[*1], *Yang Li*[2] *and Yinan Cui*[1]

[1]*Tsinghua University*
[2]*Shanghai University*

ABSTRACT

The development of fuel cladding material is a core technology that crucially affects nuclear power plants' safety, reliability, and economy. Due to their excellent performance, Zr-Sn-Nb alloys have become the mainstream of future cladding material development. During service, Zr-Sn-Nb alloys are subjected to strong neutron irradiation and high temperature, which significantly changes their microstructure and mechanical properties, resulting in performance degradation such as irradiation growth, seriously threatening the safe operation of nuclear reactors. However, due to the anisotropy and temperature-dependent behaviour of Zr alloys and the complex effects of alloying elements addition, the microstructure evolution and irradiation growth behaviour of Zr-Sn-Nb alloy under irradiation are far from clear.

This work established a systematic cluster dynamics and dislocation dynamics model for modelling defect evolution and predicting the irradiation growth of Zr-Sn-Nb alloys. The model considers the temperature dependence and anisotropy of Zr alloys, and reasonably handles the effect of various alloying elements. The simultaneous evolution of point defects, small defect clusters, and microstructures including dislocation lines and irradiation loops on the prismatic and basal plane, as well as Nb-induced precipitates in Zr-Sn-Nb alloys is obtained. Results of defect density, size and irradiation growth strain from the model and experiments of Zr, Zr-Sn, Zr-Nb and Zr-Sn-Nb alloys are compared and all in good agreement, verifying the proposed model. Based on the model, the effect of Sn and Nb on microstructural evolution and mechanical properties of Zr alloys is evaluated. Further, the irradiation temperature range of 473-673K is studied, which covers the service temperature range of cladding material in the widely used pressurized water reactor and boiling water reactor.The proposed model provides a powerful tool for developing new cladding materials.

DROPLET COALESCENCE ON A SLOPED CYLINDRICAL WIRE

Souradip Chattopadhyay[1], *Leyun Feng*[2], *Kyoo-Chul Park*[2] *and Hangjie Ji**[1]

[1]*North Carolina State University*
[2]*Northwestern University*

ABSTRACT

Transporting droplets along cylindrical wires is an emerging focus area with various practical applications such as fog collection and filtration. Recent experiments by Feng et al. (2022) have revealed a wealth of new droplet coalescence dynamics on a superhydrophilic cylindrical wire, illustrating the need for more advanced theory. In this study, we present a mathematical model using lubrication theory and weighted residual modeling techniques for a thin liquid film flowing on a tilted superhydrophilic cylinder. This model incorporates key physical factors such as gravity, low-to-moderate inertia effects, surface tension, and disjoining pressure. This model explains the observed phenomenon of directional self-propelled transport during droplet coalescence, where the large droplet moves towards the small one. Moreover, we identify two distinct coalescence modes that result in either droplet oscillations or quasi-static droplet collapses. Stability analysis and numerical simulation agree well against the experimental observations.

TOPOLOGY OPTIMIZATION OF THERMAL MANAGEMENT SYSTEMS WITH CONTROL STRATEGIES

Yonghwa Ji[*1] and Jaewook Lee*[1]

[1]*Gwangju Institute of Science and Technology*

ABSTRACT

Efficient thermal management systems are increasingly vital in the context of electrified mobilities, impacting key components such as batteries and electric motors [1]. Liquid cooling, a widely adopted approach for electrified mobilities, necessitates the design of efficient cooling channels to maximize cooling capacity while minimizing pressure drop. To determine the optimal geometry for enhanced performance, topology optimization has been applied to various fields including structural mechanics, heat transfer, and fluid mechanics [2]. Topology optimization based on the conjugate heat transfer phenomenon has proven effective at the single-part level in prescribed boundary conditions [3]. However, a critical gap exists in the analysis of thermal management system performance under varying conditions, as existing studies only consider prescribed boundary conditions. Consequently, comprehensive evaluation of thermal management system performances requires the incorporation of control strategies to address dynamic environments.

This research aims to validate the enhanced performance of thermal management systems by integrating topology optimization results with control strategies, employing exergy analysis based on the second law of thermodynamics. A cooling channel that maximizes both heat transfer and fluidic performance is designed through the utilization of a multi-objective topology optimization approach. Exergy analysis is facilitated by surrogate models based on machine learning, enabling the calculation of thermal management system performances. The comparison of thermal management systems is conducted between a thermal management system with conventional components and one incorporating components derived from topology optimization.

ABSTRACT

Chloride ingress is a critical cause of reinforcement corrosion in structural concrete. In coastal and snow-belt areas, concrete members are continuously exposed to seawater and deicing salts, which are rich in chloride ions. Driven by water convection and diffusion of ions, chloride migrates into the concrete and gradually reaches the reinforcement. The presence and evolution of microcracks caused by external loads also promote faster intrusion of chloride ions from the surface to the rebars. Under long-term loading, cracking can be further exacerbated by creep, leading to an acceleration in chloride transport. In this context, effective corrosion prediction requires multi-physics modeling strategies, considering both chloride transport and load-induced cracking. However, most current models focus on prescribed cracks and ignore the long-term effects of sustained loads on crack propagation. This work proposes a dual lattice discrete particle model (LDPM) for the simulation of coupled fracture, creep and water-chloride transport. The dual LDPM inherits the advantages of LDPM in simulating concrete fracture, including viscous effects. The water-chloride transport element is then established by exploiting the duality between the Delaunay tetrahedralization and LDPM tessellation. To express the influence of cracking on chloride ingress and mass transport, a nonlinear formulation between mesoscale crack width and effective diffusivity is formulated. Solution for the coupled model is implemented by means of two different strategies. Fracture and creep performance are analyzed using a dynamic explicit solver with central difference scheme, while water and chloride transport are resolved by a dynamic semi-implicit scheme employing Crank-Nicolson and Newton-Raphson solvers. The dual LDPM is calibrated and validated by comparing simulation results with reported tension, compression, and three-point bending experiments available in the literature. Results demonstrate the capability of the proposed dual LDPM in predicting chloride ingress in concrete members subjected to different damage levels under both short- and long-term loading conditions.

SOIL-STRUCTURE INTERACTION EFFECTS IN SEISMIC FAILURE PROBABILITY ANALYSIS OF BRIDGES WITH MULTIPLE LOAD COUPLING

Mingming Jia[*1] and Yijiang Wan*[1]

[1]*Harbin Institute of Technology*

ABSTRACT

Soil-structure interaction (SSI) has a significant impact on the performance of large-scale bridge structures in multi-layered soils, especially under strong ground motions. Quantifying the uncertainty can provide support for structural failure probability analysis. Considering SSI effects in an experimental setting involves cumbersome procedures that are difficult to control and monitor. At present, there are only the Winkle foundation method and the finite element method in numerical models, which makes it hard to balance accuracy and computational efficiency. Therefore, it is essential to develop a new machine learning-assisted numerical method to accurately and efficiently quantify SSI uncertainties. The purpose of this study is to analyze the SSI effects of bridge failure probability under strong ground motions. Focusing on the pile-supported piers, the structure is a single-column group-piles system, connected with the superstructure simply supported. The pile group is anchored to a robust bedrock and comprises end-bearing piles. The Monte Carlo method is used for modeling analysis of multi-layered soil strength uncertainty, structural material uncertainty, and pile-soil contact uncertainty. The linear elastic properties and radiation damping of far-field soil, the plasticity of near-field soil, and the sliding and debonding process of the pile-soil interface are extracted by the cyclic neural network. On the other hand, the time-history characteristics of the inertia load of the superstructure are captured. The failure probability of the pier structure is judged based on the multi-load coupling failure theory.

MATHEMATICAL MODEL FOR THERMAL RUNAWAY PROPAGATION WITHIN CELLS

Yikai Jia[*1] and Jun Xu[2]*

[1]*Northwestern Polytechnical University*
[2]*University of Delaware*

ABSTRACT

Thermal runaway (TR) is one of the dangerous failure modes of lithium-ion batteries (LIBs). In real situations, thermal runaway is commonly initiated within a local heat point and propagates to the entire cell. The propagation behavior, such as front and velocity, determines the energy released rate and temperature distribution. Therefore, it is of great importance to describe thermal runaway propagation efficiently and accurately. Recently theoretical and experimental research indicated that thermal runaway propagates within cells with a around constant velocity. The velocity is also found to be related to the reaction rate and thermal conductivity. In this work, we further investigate more general cases that consider the anisotropic and jellyroll structure of cells. Our theoretical derivation shows that the thermal runaway propagation velocity will also tend to be a constant value when the front is far away from the initial heat source. The theoretical propagation velocity and propagation front were derived. The results are validated both by numerical simulation and TR triggering tests of commercially used 18650 cylindrical cells from the NERL Battery Failure Databank. The theoretical front shape is consistent with experiment speculation. Based on this theory, the energy release rate during the TR propagation was discussed. Cells would have the highest energy release rate when their normalized dimensions were proportional to the thermal conductivity in the corresponding directions. Furthermore, the effect of preheating is discussed based on the hypothesis of point heat source and infinite space. In this case, the TR propagates with the maximum velocity first and quickly convergence to a stable lower value. The results will provide insights for thermal runaway modeling and safety design.

ANOMALOUS FRACTURE BEHAVIOR OF SOFT LAYERED MATERIALS

Zheng Jia[*1]

[1]*Zhejiang University*

ABSTRACT

Soft layered material systems are ubiquitous in nature and engineering – from natural biological tissues to engineered devices. However, from the mechanics perspective, why soft layered materials are favored by natural selection and engineering design remains largely unexplored. Here we study the fracture mechanics of heterogeneous soft layered materials. We develop a theoretical framework for analyzing the co-evolving channel cracking and interfacial delamination in soft film/substrate systems, which is then applied on investigating the fracture of bilayer hydrogels – a representative soft layered material. Through both experiment investigation, theoretical analysis and numerical modeling, we find that the heterogeneous soft layered materials exhibit anomalous size-independent fracture behaviors with fracture strains independent of the flaw size and overall structural dimensions, in stark contrast to ordinary homogeneous materials whose stretch at break reduces undesirably with increasing flaw size and structural dimensions. The size-independent fracture behavior leads to notable toughening of soft layered materials. The findings hold for a broad range of hyperelastic soft materials, from biological materials to hydrogels and elastomers, opening potentially new avenues for the development of fracture-resistant soft materials, and motivating new investigations of the development and applications of heterogeneous soft materials.

STUDY ON THE ANNEALING BLISTERING BEHAVIOR OF IRRADIATED U-10MO/AL MONOLITHIC FUEL PLATE

Xiaobin Jian[*1] and Shurong Ding*[1]

[1]*Fudan University*

ABSTRACT

U-10Mo/Al monolithic fuel plate is composed of U-10Mo fuel foil, Al alloy cladding and Zr diffusion barrier layer, which has delightful application prospects in the research and test reactors due to its high uranium density and stable irradiation performance under normal conditions. It is very important to ensure its safe operation under accident conditions. The blister threshold-temperature obtained by the annealing experiments on the irradiated fuel plates, can be utilized to test the ability of the fuel plated under accident conditions. Compared to the experimental methods, which are expensive and time-consuming, it is an economical and efficient approach by utilizing numerical simulation techniques to study the annealing blistering behavior of U-10Mo/Al monolithic fuel plates combining experimental data.

The annealing experiments of U-10Mo/Al monolithic fuel plates indicate that the blistering behavior of fuel plates is closely related to their irradiation history, which is thermal-mechanical coupling behavior. As the nuclear fission progresses during irradiation, fission gas is generated inside the U-10Mo fuel grains, forming and growing the fission gas bubbles at the grain boundaries, leading to a pressurized porous structure of U-10Mo fuel foil. The fission gas swelling is related with the temperature and macroscale hydrostatic pressure. The material properties of U-10Mo fuels including the elastic constants, thermal conductivity and materials strength will be degraded owing to the porosity and the irradiation damage. The temperature changes during the annealing process cause both thermal stress and pore pressure variations of the U-10Mo fuel foil, and the thermal creep behavior of cladding. The crack will occur in the U-10Mo fuel foil with the interaction of fuel foil and cladding, and pore pressure. A cavity pressure will take place due to the release of fission gas atoms, accelerating the propagation of cracks. The macroscale deformation of Al alloy cladding will happen with the effect of temperature and cavity pressure, resulting in the local blistering behavior.
In this study, a three-dimensional incremental constitutive relationship will be established comprehensively considering the thermal-mechanical properties for the whole irradiation-annealing process. A cohesive zone model considering the porosity effect will be developed to describe the initiation and propagation of cracks for U-10Mo fuels, together with the coupling model of fission gas release-volume-cavity pressure. The blistering behavior of U-10Mo/Al monolithic fuel plates will be analyzed, and the underlying annealing blister mechanism of fuel plates will be revealed.

STATE SPACE BASED MIXED FINITE ELEMENT METHOD FOR LAMINATED STRUCTURES

Jiaqing Jiang[*1] and Weiqiu Chen*[1]

[1]*Zhejiang University*

ABSTRACT

Laminated structures are widely used in various engineering fields. Using combination of different materials, they can achieve excellent mechanical characteristics, such as high strength-mass ratio and adjustable stiffness. Numerous methods are therefore proposed to analyze their mechanical performances [1]. However, as elastic modulus and Poisson's ratios are different across the thickness direction, shear deformation distributions become complex and it requires high-order shear deformation theories to give accurate displacement predictions for those laminated structures. The state space method is suitable for composite structures with arbitrary multiple layers. It preserves both displacement and stress continuities across the thickness direction. But it requires simple material distribution and loading conditions on other directions, which limit its applications. In order to make this method more flexible, finite element discretization on those directions are introduced in this paper, with nodal displacements and their energy-conjugated stresses as state variables, which conveniently handles continuity requirements and various transfer characteristics at the interfaces. The differential quadratic method (DQM) is further introduced to improve calculation stability.

Under such framework, static and dynamic behaviors of partially-connected composite beams are analyzed. The analyses of interlayer slip, stress distributions and natural frequencies of composite beams under different support conditions, loading arrangements and span combinations verify the correctness of the present method. Based on finite element meshing, non-uniform shear stiffnesses can be set along the longitudinal direction between layers to simulate spaced studs connection, which shows the advantage of this method to consider detailed structure configurations [2].
As finite element method provides flexibility for various boundary conditions and arbitrary in-plane shapes, laminated plates are further analyzed. Displacement and stress distributions of simple-supported laminated plates are analyzed and verified. Other boundary combinations of clamped and free edges are also calculated. Zero shear stress distributions on free boundaries are accurately satisfied using this method, and the calculation cost is significantly low comparing to ANSYS. Analyses of irregular plate shapes with holes on opposite sides shows geometric flexibility of the present method, and influences of holes on stress redistributions are clearly and accurately demonstrated.

FINITE ELEMENT SIMULATION ON INSTABILITIES OF DIELECTRIC ELASTOMERS CONSIDERING NONLINEAR MATERIAL VISCOSITY

Heng Feng[1] *and Liying Jiang**[1]

[1]*Western University*

ABSTRACT

Dielectric elastomers (DEs) have attracted great research interests due to their unique features such as softness, flexibility, large deformation capacity and electromechanical coupling properties. However, the applications of DE-based devices have been limited by various potential instability modes including electromechanical instability (EMI) and some other stimuli-induced structural bifurcations. When undergoing large deformation, DEs exhibit nonlinear material viscosity, which makes it more challenging to accurately predict their instabilities. To fill this research gap, a finite element (FE) framework is developed to investigate the electromechanical responses and different instability modes of DE structures with the implementation of the nonlinear field theory and a micro-macro constitutive model that incorporates the deformation-dependent material viscosity. A highly customized user-element subroutine (UEL) in Abaqus is developed for the FE implementation. The material viscosity is modeled to be dependent on the global deformation based on a tube model derived from polymer dynamics. On this basis, the effects of nonlinear material viscosity on different instability modes of VHB 4910 structures are investigated, and the simulated results are compared with existing experimental data and analytical studies to validate the accuracy and robustness of the proposed model. This work provides a general approach for instability analysis of DE actuators with different configurations and can further function as a universal platform for numerical analysis on the electromechanical finite deformation of DE structures with complex configurations, leading to better design and applications of DE-based devices.

IDENTIFYING MATERIAL PARAMETERS OF PRINCIPAL STRETCH-BASED HYPERELASTIC MODELS WITH THE VIRTUAL FIELDS METHOD

Mingliang Jiang[*1] and Zhujiang Wang*[2]

[1]*Hefei University of Technology*
[2]*Guangdong Technion - Israel Institute of Technology*

ABSTRACT

This work deals with parameter identification of principal stretch-based hyperelastic materials using the reformulated virtual fields method (VFM) based on the variation of elastic energy. Traditional VFM framework calculates the internal virtual work (IVW) as a product of one of the three types of stresses (Cauchy stress, the first Piola–Kirchhoff stress, or the second Piola–Kirchhoff stress) and its corresponding conjugate virtual strain, which often involves intricate mathematical derivations and computations. For example, the traditional method requires solving the hydrostatic pressure to obtain the first Piola–Kirchoff stress for incompressible materials [1], introducing an additional layer of complexity. In this study, we develop a reformulated version of VFM termed variation-of-elastic-energy-based virtual fields method (VEE-VFM), where the IVW is considered as the variation of elastic energy caused by virtual displacements, eliminating the need to calculate stress and its conjugate virtual strain [2]. The VFM is reformulated by calculating the IVW through the variation of elastic energy, which is more concise and easier to implement. In the reformulated VFM, an important step in calculating the IVW of principal stretch-based hyperelastic models is the calculation of the variations of principal stretches. Two approaches are proposed in this work: 1) the variations of principal stretches are directly correlated to the virtual deformation gradient based on the chain rule; 2) alternatively, we compute the variations of principal stretches by solving a system of linear equations which are constructed based upon the relation between the invariants and the principal stretches. To illustrate this reformulated framework and the proposed methods of calculating the variation of principal stretches, the first-order Ogden model is selected for this study, and numerical biaxial tensile experiments which give rise to heterogeneous deformation fields are performed on this type of material. Finally, material parameters are successfully extracted using the reformulated VFM framework, and the accuracy and robustness of VEE-VFM are demonstrated through simulated experiments, highlighting its reliability even in the presence of noise.

[2]*Federation University Australia*

ABSTRACT

Structural defect identification is a vital aspect of structural health monitoring used to assess the safety of engineering structures. However, quantitatively determining the dimensions of structural defects is often difficult. Therefore, this study presents an innovative data-driven algorithm that combines the scaled boundary finite element method (SBFEM) and a deep learning framework based on a dilated causal convolutional neural network (CNN) to identify crack-like defects in large-scale structures. The SBFEM is used to simulate different crack-like defects. Mesh generation is significantly simplified by a simple procedure that requires only changing the scale centre at the crack tip and the positions of the nodes at the crack opening. This minimises remeshing and enables simple generation of sufficient data to train the neural network. In addition, an absorbing boundary model based on Rayleigh damping is used to avoid computing the entire model when simulating wave propagation in massive structures. To ensure that sequential data remain ordered and to obtain a large receptive field without increasing the complexity of the neural network, a dilated causal CNN is employed in the deep learning framework. Therefore, more historical information is captured, and the complex mapping relationship between the echo signal and the crack information is efficiently learnt. The proposed model can accurately identify the number, location, and depth of cracks in massive structures. Moreover, it is robust to noise, which is demonstrated via numerical examples. Therefore, the proposed algorithm provides valuable insight into the detection and diagnosis of structural defects, which can ultimately improve the safety of engineering structures.

EFFICIENT NONLOCAL-TO-LOCAL COUPLING

Shuai Jiang[*1] and Christian Glusa*[1]

[1]*Sandia National Laboratories*

ABSTRACT

In this talk, we propose a non-intrusive and simple "splicing" method for local-to-nonlocal (LtN) coupling with variational methods. This is in contrast to the established splicing approaches of using particle methods. Furthermore, we rigorously show that our approach is in fact equivalent to a optimization-based LtN coupling method, and inherits many valuable theoretical properties such as convergence while still being cheap to solve.

COMPUTATIONAL MODELING OF TRANSPORT PHENOMENA IN FLUIDS AT SMALL SCALES

Xikai Jiang[*1]*

[1]*Chinese Academy of Sciences*

ABSTRACT

Transport phenomena in fluids at small scales play vital roles in science and engineering. Numerical modeling and fundamental understanding of these phenomena are crucial for improving performance of technologies in areas such as biology, medicine, and energy storage, to name a few. This talk will discuss recent research progress made in the Micro/nanofluidics Group at Institute of Mechanics, Chinese Academy of Sciences. The topics we worked on include particulate transport in low-Reynolds-number fluids under general geometries, ionic transport in room-temperature ionic liquids in confined and unconfined spaces, and contact angle hysteresis at electrified ionic liquid-solid interfaces. Computational tools used to investigate these transport phenomena will also be discussed. Our research reveals that hydrodynamic interaction, electrostatic interaction, ion-ion correlation, and the structure and energetics at interfaces are main factors of the observed phenomena. In the end, we will discuss future research interests and possible opportunities to explore collaboration.

A UNIFIED STRAIN ENERGY DECOMPOSITION STRATEGY UNDER THE LOCAL COORDINATE SYSTEM FOR PHASE FIELD FRACTURE MODELING

Yang Jiang[*1] and Jianguang Fang*[1]

[1]*University of Technology, Sydney*

ABSTRACT

The various currently existing phase field decomposition approaches exhibit efficacy in capturing mechanical behaviour within their preferred stress state regions. This study aims to propose a novel unified phase field decomposition model capable of appropriately decomposing strain energy across arbitrary stress states. The total strain energy is decomposed into three non-negative components, namely tensile, shear and compression parts on the local coordinate system (LCS) considering the Poison effect. The LCS is determined by the three normal stresses on it to achieve the maximum F-function energy, which drives the fracture propagation in this model. This local coordinate system decomposition (LCSD) model could recast to the common-adopted spectral, V-D and crack-surface-based strain energy decomposition strategies for specific stress state regions, which has proven to be related to the ratio between shear and tensile crack energy release rate as well as the Poison ratio. Furthermore, a unified strength criterion is incorporated for the update of the LCS to ensure the stability of the original damaged surface. The proposed model is implemented via ABAQUS explicit code with VUEL and VUMAT subroutine. Verification of this proposed LCSD phase field model is conducted by comparing its simulation results with the isotropic, spectral and V-D decomposition model through a comprehensive series of numerical examples, encompassing uniaxial tension and compression test on the dogbone specimen, triaxial compression test on the pre-cracked cylinder specimen and the perforated asymmetric bending test, which cover various stress states including tension, compression, shear-compression and shear-tension stresses. Additionally, the performance of this model under dynamic loading is also validated through the renowned Kalthoff–Winkler impact test.

TOPOLOGY OPTIMIZATION DESIGN OF UNDERWATER PRESSURE HULL FOR SUBMERSIBLE

Yuanteng Jiang[*1] and Min Zhao*[1]

[1]*Shanghai Jiao Tong University*

ABSTRACT

As the key component of submersible, the design of underwater pressure hull is particularly important. In this work, based on a parameterized level-set method using radial basis functions, a topology optimization method is proposed that can account for the design of underwater pressure hull for submersible. The optimal design of underwater pressure hull is studied by using the buoyancy factor minimization as the objective function, the critical buckling factor and the yield strength as the design constraint. To provide clear and continuous mathematical expressions for the normal velocities, the theory of the shape derivative and bifurcation analysis are used to obtain the normal velocities in the parameterized level-set method, and we propose an easily implemented method to discretize normal velocities to every nodal point in the design area. An augmented Lagrange multiplier is given to realize stable transitions of both optimization problems during the convergence process. The effectiveness of the proposed method is validated by numerical examples, and it has engineering application value for the exploration of new underwater pressure hulls.

A COMPUTATIONAL STUDY OF THE INFLUENCE OF CARDIAC MECHANICS IN DESMOPLAKIN CARDIOMYOPATHY

Javiera Jilberto[*1], Renee Miller[2], Adam Helms[1] and David Nordsletten[13]*

[1]*University of Michigan*
[2]*GE Healthcare*
[3]*King's College London*

ABSTRACT

Desmoplakin Cardiomyopathy is a genetic disease that compromises the sub-cellular structure responsible for mechanically linking cardiomyocytes. Unlike other cardiomyopathies, patients with this disease present a unique pattern of fibrosis that focalizes in the subepicardial layer of the left ventricle (LV) [1]. The heterogeneous mechanical loading of the left ventricular wall is thought to be responsible for this pattern. To investigate this hypothesis, we use image-based biomechanical modeling to build a virtual cohort of patients (n=17) with different levels of disease severity. The models are generated using a modification of a previously developed pipeline [2], which uses machine learning and image processing tools to extract structural and functional data from magnetic resonance images (MRI) of the patients' hearts. In this pipeline, we also implemented a process to identify fibrotic areas from late gadolinium enhancement MRI. This information is merged into the biomechanical models using universal ventricular coordinates [3]. By analyzing the data of the virtual cohort, we define the trends of LV wall thinning, fibrotic patch increasing, and the changes in pressure and volume traces.

To understand how mechanics are related to the observed disease progression, we used a healthy patient geometry as a baseline and simulated the mechanics for five stages of disease severity. The myocardium is modeled using a Holzapfel-Ogden model, with the fibrotic patch being stiffer and non-contractile. We utilize a data-assimilation process [2] to estimate the cardiac activation levels given the pressure-volume loop. Mechanical quantities such as strain, strain rate, and stress are quantified and correlated with the spatial maps of fibrosis. We observe that strain and strain-rate values are exacerbated in the subepicardium, especially during isovolumic contraction, and the presence of fibrosis exacerbates the mechanical loading of neighboring areas. This study provides a comprehensive investigation of how mechanics are related to the progression of Desmoplakin Cardiomyopathy and provides key knowledge that can help clinicians design better treatments for these patients.

METAMATERIAL COUPLED WITH HELMHOLTZ RESONATOR FOR ENHANCED ACOUSTIC PIEZOELECTRIC ENERGY HARVESTING

Feng Jin[*1]*

[1]*Xi'an Jiaotong University*

ABSTRACT

To achieve high-performance acoustic piezoelectric energy harvesting at lower frequencies, this study proposes a metamaterial and Helmholtz resonator coupled structure. The metamaterial incorporates periodically arranged composite resonant pillars within a perforated thin plate. By designing a point defect in the metamaterial, vibration energy can be intentionally confined to the defect location under the defect band frequency. This design results in a more substantial energy localization for the coupled structure, leveraging the characteristic of amplified acoustic pressure in the Helmholtz resonator. Initially, the mathematical model for calculating the first resonant band gap is established. The band gap and corresponding defect band frequency are then validated by comparing finite element simulation with experimental results. Subsequently, numerical simulations are conducted to investigate the influences of hole size and coupled structure on acoustic piezoelectric harvesting energy. The results demonstrate a significant improvement in vibro-acoustic localization and piezoelectric conversion efficiency with an increase in the hole size of the perforated metamaterial plate. Furthermore, the synergistic effect of local resonance and acoustic pressure amplification generated by the coupled structure further enhances the performance of acoustic piezoelectric energy harvesting. At an acoustic incident amplitude of 2Pa and a defect band frequency of 1068.5Hz, the coupled structure attains the maximum output voltage and power of 5.94V and 39.10μW, respectively. These values are 2.65 times and 2.80 times higher than those of the uncoupled metamaterial structure. This study offers guidance for designing piezoelectric energy harvester applications in self-powered sensors and small electrical devices.

FINITE ELEMENT-FINITE VOLUME COUPLED ASYMPTOTIC TIP ENRICHMENT FOR HYDRAULIC FRACTURE PROPAGATION

Tao Jin[*1], Joshua White[2] and Randolph Settgast[2]*

[1]*University of Ottawa*
[2]*Lawrence Livermore National Laboratory*

ABSTRACT

Numerical strategies suitable for field-scale fluid-driven fracture simulations have significance in advancing the scientific understanding of natural phenomena in geoscience and disrupting the status quo of geological techniques. The accuracy and robustness of numerical strategies largely hinge on the appropriateness of fracture propagation criteria in different regimes and the capability to locate the fracture front position in discretized computational domains. We address the above topics in the context of a fully coupled finite element-finite volume computational framework. Based on the fracture tip asymptotic solutions, we solve the Eikonal equation using the fast marching method to calculate the signed distances at element nodes. The signed distance field is used as the fracture propagation criterion, where element nodes are split when the calculated distances change signs. This feature enables us to overcome the limitations associated with the conventional stress intensity factor-based approach in the viscosity-dominated propagation regime. From the signed distance field, we can also locate the fracture tip in partially opened elements, providing accurate fluid volume and transmissibility estimations to enforce the fluid mass conservation. This feature overcomes the numerical difficulties encountered in the fracture element initialization during a propagation time step, therefore facilitating the convergence of the tightly coupled finite element-finite volume solver.

APPLICATIONS OF THE FAST FOURIER TRANSFORMS TECHNIQUE FOR CONTACT ANALYSIS OF HETEROGENEOUS MATERIALS

Kuanyu Liu[1], Zhizhen Jiang[1], Hengxu Song[2], Pu Li[3], Feodor Borodich[1] and Xiaoqing Jin[1]*

[1]Chongqing University
[2]Chinese Academy of Sciences
[3]Sichuan University

ABSTRACT

Contact problems are widespread in engineering applications, posing significant challenges due to the intricate interactions associated with diverse impurities[1, 2]. The complexities arise from the diversity in shapes and material properties of the inhomogeneities, contributing to the computational intensity associated with the discretization of numerous elements[3]. This necessitates innovative solutions to address the intricacies of these problems and improve computational efficiency. In response to these challenges, this paper introduces an innovative solution for solving the contact problems, leveraging the Fast Fourier Transform (FFT) algorithm.

The present approach not only addresses the complexities introduced by the diverse impurities but also capitalizes on the FFT algorithm's efficiency in handling the associated contact problems. By deriving the analytical solutions for stress in a semi-infinite medium, the work presents a structured methodology[1] that significantly enhances computational efficiency. The present approach not only streamlines intricate calculations but also mitigates the computational load, making it an attractive alternative for engineering analyses[2].

Furthermore, the proposed method's versatility is demonstrated through its application across different inclusion shapes and materials. The FFT-based algorithm proves to be a powerful tool in handling the diversity of contact problems, showcasing its potential to revolutionize computational methodologies in engineering applications[2, 3].

In essence, the utilization of FFT principles in contact problems not only enhances accuracy and computational efficiency but also offers a versatile and powerful solution. This approach represents a significant advancement in addressing the complexities of these problems, providing valuable insights for engineers and researchers in various fields.

DISCRETE RITZ METHOD

Zhao Jing[*1], Lei Duan[1] and Siqi Wang[1]*

[1]Northwestern Polytechnical University

ABSTRACT

In the past century, the Ritz method could not be applied to complex geometric problems due to the complexity of constructing a global trial function to approximate structural behaviours and the difficulty of numerical integration in complex geometric domains. This fact has led to a large number of literatures examining the problems of two-dimensional (2D) and three-dimensional (3D) structures having regular geometries. Reddy[1] indicated that the Ritz method is a true "meshless" method because it uses a global trial function for solving the problem, thus eschewing the necessity for meshes or nodes in the solution process. However, engineering problems are significantly more complex with irregular geometries, preventing the Ritz method from being applied, despite the fact that it is "meshless", efficient, and accurate.

To resolve this problem, this study presents a novel numerical method, discrete Ritz method (DRM), for the static, stability and vibration analysis of 2D and 3D structures with arbitrary geometries[2-3].

The problem is formulated in a standard geometric domain (rectangle for 2D and cuboid for 3D problems), and arbitrarily shaped structures can be simulated by assigning cutouts within the standard geometric domain. Geometries of structures are characterized by using level set functions. By combining the extended interval integral, Gauss quadrature, variable stiffness characterization, the strain energy of the structure is modelled in the standard geometric domain, discretized using Gauss points, and is characterized by variable stiffness, which characterizes the material distribution and structure geometry simultaneously. In this manner, DRM transforms the problem into a discrete energy system which allows the geometric boundary of the structure to vary in the standard geometric domain. The orthogonal polynomials are used as the global admissible function to approximate structural behaviours. The deformation of arbitrarily shaped structures can be numerically simulated by setting the stiffness and thickness of Gauss points within the cutouts to zero. New formulations in DRM have resulted in completely standard energy functionals and computation procedures for arbitrarily shaped 2D/3D structures.

FLOW AND TRANSFER LAWS IN SOLID FOAMS: REGIME TRANSITIONS AND STABILITY

Yann Jobic[*1], Frédéric Topin[1] and Marc Médale[1]*

[1]*Aix-Marseille University*

ABSTRACT

Optimal design of industrial systems such as reactors, columns or heat exchangers using foams as medium requires accurate prediction of transport properties, and remains a major concern today. Those porous media can be too complex for studying individual morphological features as we can not control individually each parameters (e.g., strut shape, pore elongation, etc). We have then chosen a simplified model consisting in a tri-periodic kelvin cell with varying strut size and cross-section.

The approach of numerical simulations at pore scale has become a popular criterion with the development of high performance computational power, used here to determine intrinsic macroscopic hydraulic properties on porous structures. The recent development of innovative scheme like Lattice Boltzmann (LBM) to overcome the classical drawback of commercial softwares (Finite Volume, Finite Element) in achieving high accuracy, shows the potential of kinetic based methods for producing efficient and accurate solvers. An alternative vector kinetic method is proposed to solve incompressible Navier–Stokes equations at pore scale and eventually determine permeability tensors of complex porous media. A moment based (vs discrete velocities), non-diffusive, explicit, parallel implementation was implemented and successfully used on several totally different complex geometries. Excellent results at low Reynolds number were obtained, the method is thus well suited for permeability tensors determination of complex heterogeneous media (e.g. sandstone, redwood samples).

We are also interested in the flow stability, studies being performed with homemade numerical tools, using Finite Element Methods. The first one uses a steady-state continuation algorithm, based on the Asymptotic Numerical Method (ANM) that enables to determine critical points along the continuation parameter path (here the pressure drop) where there is a steady-state bifurcation. The second tool studies the linear stability of the steady-state solution given by the ANM, and determine the critical pressure drop where the Hopf bifurcation (unsteady and periodic solutions) occurs. Using the above numerical methods, we have shown in recent results ([1]) the bifurcation diagram of a periodic Kelvin cell made up of triangular struts. Moreover, we have linked both (dynamical and state-state) bifurcation types to the macroscopic flow regimes (Darcy, transition, Forchheimer).

INTERPOLATION BASED PARAMETRIC MODEL ORDER REDUCTION USING MODIFIED COMPONENT MODE SYNTHESIS

Lokesh Jogi[*1] and Amar K Gaonkar[1]*

[1]*Indian Institute of Technology Dharwad*

ABSTRACT

Model Order Reduction (MOR) techniques are widely used in reducing the computational time associated with simulating high-dimensional models, enabling faster analysis and optimization processes [1,3]. Projection-based methods are generally used for MOR of dynamical systems. In these methods, the governing equations in the high dimensional space are projected onto a lower dimensional subspace using a transformation matrix which consists of projection bases. Component Mode Synthesis (CMS) is a very popular method frequently used for structural systems along with substructuring. The information loss of CMS is mainly associated with its part-static nature due to static condensation. We propose a Modified Component Mode Synthesis (MCMS) method based on the highly efficient method [2] that considers the dynamic nature of the model. The ease of computing the transformation matrix with the help of a recurrence formula makes the method more computationally efficient than iterative schemes. This paper presents an interpolation based parametric model order reduction (pMOR) with the application of MCMS along with substructuring. Heavy computational resources are required to investigate the parameter dependency of the entire system having multiple parameters. Therefore, the offline sampling is done at the substructural level to save computational time [3]. Each substructure is reduced using MCMS scheme. A congruence transformation matrix is also computed to retain the accuracy of the ROM while interpolation. In the on-line stage, the ROM is constructed by interpolating the already sampled ROMs at the subdomain level. Global assembly is done ensuring the compatibility of substructures. The interface degrees of freedom of the ROM are also reduced enabling the construction of two-level semi-parametrized ROM [3]. The accuracy and efficiency of the proposed method is demonstrated by computing the relative eigen-value errors and comparing the transient response of one dimensional and two dimensional structural systems at some random parameter within the sampling range.

GENERALIZED PARAMETRIC MODELING AND ISOGEOMETRIC ANALYSIS OF STENTED MEDICAL DEVICES

Emily Johnson[*1] and George Pan*[1]

[1]*University of Notre Dame*

ABSTRACT

Stents are an essential therapeutic intervention approach to address various medical conditions and diseases across the entirety of the human anatomy, including the heart, vascular system, brain, lungs, and kidneys. Even with the maturity of many stent technologies, device designs across different physiological environments exhibit immense variability despite experiencing relatively similar mechanical conditions. Stent structures can be utilized for specific shunting or drug-eluting purposes. These stents are typically made from biocompatible materials such as stainless steel, cobalt-chromium alloys, or advanced polymers for bioresorbable variants. The technical complexities of stent design include various considerations. One such aspect is the interlocking pattern, which impacts each device’s stress distribution, manufacturing difficulty, and durability. Another critical factor is the strut thickness, which influences the stent’s radial strength and flexibility during the crimping and expansion processes. Additionally, the inter-strut angles are crucial for ensuring sufficient friction with the vessel walls while minimizing blood flow disturbance. This study develops parametric models for stents referencing real-world cases based on a novel, bio-inspired, unit-cell-based platform for a generalized stent model. Each "cell" shape is modified locally, and the height, width, and orientation are adjusted to generate a stacked unit-cell column that is revolved radially about a central axis to generate the full stent model. This method allows for straightforward localized modification, customized geometry extension in multiple directions, and more optimization choices. This model enables various developments in modeling stents using the proposed approach, including assessing multi-directional unit cell combinations, creating unit cell patterns with unique shapes, and exploring performance differences between open and closed cell structures. The proposed methods aim to enhance the versatility and effectiveness of stented devices through efficient computational modeling using isogeometric analysis. Future investigations will also integrate these modeling approaches with performance-based assessments to improve the function and long-term performance of stented devices.

A PSEUDO-DIFFERENTIAL SWEEPING METHOD FOR THE HELMHOLTZ EQUATION USING HIGH ORDER SPECTRAL ELEMENTS

Sebastian Acosta[1], *Jesse Chan*[2], *Raven Johnson**[2] *and Benjamin Palacios*[3]

[1]*Baylor College of Medicine*

ABSTRACT

Ultrasound-guided medical procedures often experience complications when imaging heterogeneous tissue. Computer simulations of the ultrasound field offer a workable solution to this heterogeneity problem, but the computational methods required for these simulations tend to be either highly accurate and computationally slow or computationally quick and inaccurate. We propose a sweeping numerical method for solving the Helmholtz equation which is built from a truncated pseudo-differential expansion. We discretize this expansion using high order spectral element methods in space and an explicit time-stepping method in time. Numerical experiments examine the behavior of the proposed method in 1D and 2D under different numerical parameters. We demonstrate that the proposed sweeping method is not only accurate but increases in accuracy as the angular frequency increases.

ADAPTIVE AND SCALABLE DOMAIN DECOMPOSITION PRECONDITIONERS

Pierre Jolivet[*1] and Hussam Al Daas*[2]

[1]*CNRS*
[2]*Rutherford Appleton Laboratory*

ABSTRACT

Recent advances in adaptive domain decomposition methods have made it possible to solve large systems of equations that where previously challenging for both algebraic multigrid (because of lack of robustness) and exact factorization (because of large FLOP count and memory cost). In this presentation, I will highlight some recent improvements and developments in PETSc, the Portable Extensible Toolkit for Scientific computations, and one of its preconditioner, PCHPDDM, a framework for defining efficient domain-decomposition based preconditioners. Numerical results for solving large coupled systems of various types (such as indefinite or nonsymmetric) will be showcased.

A MACHINE LEARNING APPROACH TO FAST STATISTICAL MICROSTRUCTURE PREDICTIONS IN LASER POWDER BED FUSION WITH ARBITRARY PROCESS PARAMETERS

Mason Jones[*1], Jean-Pierre Delplanque[1], Theron Rodgers[2], Daniel Moser[2] and Brian Weston[3]*

[1]*University of California, Davis*
[2]*Sandia National Laboratories*
[3]*Lawrence Livermore National Laboratory*

ABSTRACT

The laser powder bed fusion (LPBF) additive manufacturing process produces complex microstructures, which have been shown to vary with process parameters and print geometry. Because the process is slow and multiscale, it is not feasible to tune the process parameters for every new part geometry via experimentation or traditional computational modeling. A previously introduced fast machine learning based microstructure model can reliably predict statistics about LPBF-produced microstructures orders of magnitude faster than equivalent simulations. This work analyzes the effectiveness of this fast machine learning based microstructure model by assessing the model's predictive power and the minimum viable training dataset. Efficient strategies for making part-scale predictions are explored.

[1]Sandia National Laboratories
[2]The University of Texas at Austin
[3]Cornell University

ABSTRACT

Multiscale simulation is needed in cases where a single representative constitutive model cannot be constructed for the material of interest due to inherent or designed inhomogeneities in the microstructure. Classical multiscale methods rely on subgrid/mesh solves for microstructual samples which are coupled by an equilibrium equation for the full structure. Machine learning via convolution neural networks enable the accurate and efficient encoding of these microstructural response functions. This talk will describe the particular architecture and demonstrate the efficacy of neural networks designed to model the response of microstructural samples. In addition, the models are incorporated in a large-scale simulator that enables material uncertainty quantification and design under uncertainty. Representative boundary value problems will demonstrate the utility of the approach and its correspondence with direct numerical simulation of large-scale structures with microstructural details.

VARIATIONAL HYDROACOUSTIC FORMULATION FOR MOVING BOUNDARY PROBLEMS

Shreyas P.[1], *Kevin S. Swamy*[1] *and Vaibhav Joshi**[1]

[1]*Birla Institute of Technology & Science Pilani*

ABSTRACT

Motivated by the stealth-like low acoustic signature in the flapping motion encountered in fishes, the current study focuses on developing a computational framework for modeling hydroacoustics in moving boundary problems. Several acoustic formulations based on integral methods (FW-H and Curle's method) and perturbation equations (Linearized Euler Equations, Perturbed Compressible Equations [1] , Acoustic Perturbed Equations [2]) have been proposed in the literature. However, either these methods are inaccurate or computationally expensive due to the increase in variables in the form of perturbed quantities. Hybrid techniques decompose the flow variables into incompressible and acoustic components so that a solution from an incompressible solver can be coupled with an acoustic solver. Moreover, implementing the acoustic solver is complicated, and higher-order methods are generally used for discretization.

For hydrodynamic problems, the flow can be assumed to be at low Mach number, and temperature variations can be neglected. This simplifies the governing equations such that pseudo-compressibility can be incorporated into mass and momentum conservation equations [3] . These equations circumvent the need for perturbed equations and lead to fewer unknowns for the problem. The current study implements the pseudo-compressible Navier-Stokes equations in the moving mesh arbitrary Lagrangian-Eulerian framework for moving boundary problems. The equations are discretized using stabilized finite element methods with equal interpolation for the flow variables. Benchmarks test of flow across a stationary cylinder at Reynolds number of 200 and Mach number of 0.3 is conducted to verify the acoustic propagation. The study then demonstrates the ability of the solver to predict the acoustic signature of a rigid passively flapping foil at a Reynolds number of 1100.

THE EFFECT OF BOUNDARY CONDITION FORMULATIONS ON BULK DEPOSITION PROPERTIES FOR 3D CONCRETE PRINTING USING THE MATERIAL POINT METHOD

Johannes Joubert[*1], Daniel Wilke[1] and Patrick Pizette[2]*

[1]University of Pretoria
[2]IMT Nord Europe

ABSTRACT

Additive manufacturing (AM) is fast becoming a disruptive technology in the manufacturing space. AM promises to provide engineers and designers with increased flexibility in their designs, allowing for the manufacturing of objects that are impossible with conventional manufacturing techniques. While most AM technologies target small-scale plastic or metal parts, 3D concrete or earth-based material printing is a niche AM technology that aims to print large-scale 3D concrete structures by following a similar process to the classic extruded material method (EMM) using custom concrete compositions designed to control the material properties and setting behaviour.

Tuning of the printing process is typically required to produce high-quality prints with both the desired macroscopic mechanical properties and the required final shape. Simulations can reduce the number of iterations necessary for tuning, which is especially important for concrete printing due to the time and repreparation cost of the process. The EMM process naturally benefits from a Lagrangian description, especially when considering the multiphysics nature of this process.

The material point method (MPM) [1] is a numerical scheme that discretises a system as Lagrangian material points. Mapping material point properties to an underlying Eulerian grid enables resolving differential operators. The grid state is updated and mapped back to the particles. These two system representations naturally enable two domains to develop and enforce boundary conditions: grid- [2] and particle-level [3] boundary schemes.

For 3D concrete printing, the formulation and implementation of boundary conditions can affect the final predicted footprint and shape. However, the implications of particle-based or grid-based boundary condition enforcement require further investigation. This work addresses this by presenting a multiphysics MPM formulation for 3D concrete printing that allows for comparisons between different particle-based and grid-based boundary condition schemes. This study simulates, verifies, and conducts a sensitivity study of process parameters on a single concrete layer's deposition.

ON MODELLING THE FREQUENCY DEPENDENCE OF UNFILLED AND FILLED ELASTOMER BLENDS

Daniel Juhre[1]*

[1]*Otto-von-Guericke-University Magdeburg*

ABSTRACT

Elastomer blends are of high interest for tailoring materials with specific mechanical behaviour. However, while for the pure components the experimental characterization of the temperature dependent viscoelastic properties is usually well feasible, doing this for the blends is often difficult or impossible.
One reason is that the blend components often have different glass transition temperatures which makes the resulting behaviour quite complex.
In most cases when blending elastomers, heterogeneous morphologies are formed consisting of different regions with (nearly) pure components and finite interphases in between. In addition to the pure phases, especially these interphases influence the resulting viscoelastic properties significantly. For such cases, material modelling and numerical simulations can help to better understand the interactions between phases and interphases and to forecast the resulting viscoelastic properties.
In this contribution we model and simulate an RVE of a binary blend consisting of natural rubber (NR) and styrene butadiene rubber (SBR). The modelling and the simulations are performed in the small strain regime, using linear viscoelasticity. A phase field variable is used to describe the blend morphology within the simulation. The blend morphology is based on microscopic images and the dependency on the field variable is derived from an energy formulation allowing sharp and diffuse interphases between the NR and SBR phases. Both, sharp and different diffuse interphases are numerically investigated and their influences on the mechanical behaviour are compared to elaborate experiments.

UV-IRRADIATION EFFECT ON ATOMIC OXYGEN RESISTANCE OF POLYMER MATRIX IN LOW EARTH ORBIT ENVIRONMENT

Jiwon Jung[*1], Jongkyung An[1], Seunghwan Kwon[1] and Gun Jin Yun[1]*

[1]*Seoul National University*

ABSTRACT

In the low earth orbit (LEO), polymer matrices in spacecraft structure experience harsh environments including atomic oxygen (AO) collision, ultraviolet (UV) irradiation, thermal cycle, high vacuum, etc. Especially, highly reactive AOs lead polymer matrices oxidized and eroded at the surface, resulting in degradation of mechanical properties of structures and critical failure of electrical systems. Therefore, several researches were conducted improve atomic oxygen resistance of the polyimide (Kapton) and epoxy, which are thermal insulation coating material and structure material in LEO satellites, respectively. However, not only in-flight experiments but in-ground experimental simulations are also costs high economic and temporal resources in describing environments in LEO (high-UV, high-vacuum, AO, extreme temperature cycles, etc.) and long duration of the experiments. Thus, molecular dynamics simulations with reactive force fields which are able to describe active formation of chemical bonds during oxidation by AO collisions, had been conducted. Evaluation of AO resistance through reactive MD simulations of Kapton nanocomposites, epoxy, silicon carbide, etc., were reported for last decades. To simulate polymer degradation by UV-irradiation, density functional theory (DFT) studies were reported to predict dissociation of crosslinking bonds in epoxy. The synergetic effect of UV and AO erosion were consistently investigated by experiments that up to 400% increase in erosion rate by AO were observed when 172nm vacuum UV were exposed on polyimide films. However, such synergetic effects between UV and AO collision had not been reported through molecular simulations. Therefore, in this study, acceleration of the AO erosion by chemical bond degradation in polymer matrix through UV irradiation will be discussed through multi-scale scheme combining DFT and reactive MD simulations.

SPACE-TIME MODELING OF MATERIALS WITH DISSIPATIVE MICROSTRUCTURE EVOLUTION VIA STATIONARY PRINCIPLES

Philipp Junker[*1] and Thomas Wick*[1]

[1]*Leibniz University Hannover*

ABSTRACT

Material modeling is a core task in the research of mechanics of materials. Starting from the experimentally observed phenomena, appropriate variables have to be defined which enable us to describe the material behavior. These variables are usually referred to as internal variables and complete the set of thermodynamic state variables. There exist different methods to derive equations which describe the evolution of the internal variables and thus, the evolution of microstructure. In the end, the (numerical) solution of the resultant coupled system of algebraic-differential equations, often with inequality constraints, paves the way for in-silico experiments and, consequently, improve our understanding of the physical processes in material behavior and offers the possibility to design construction parts with tailored properties.

Usually, the system of equations is the starting point for a space-time description: this strong form is then multiplied with appropriate test functions and integrated over space and time to receive the weak form. Appropriate discretization schemes can be invoked for numerical solution. Here, it might be unclear which function space is needed for the test functions in the respective equations.

In this talk, we present a different approach for holistic space-time material modeling: by careful analysis of Hamilton’s principle, which contains as special case the principle of least action, the space-time formulation of arbitrary material models can be obtained from a stationarity principle. This, for instance, directly solves the issue of appropriate function spaces. We present that Hamilton’s principle is not restricted to elastic problems. In contrast, it can be used for materials with ordinary and partial differential equations or inequalities as evolution equations. We furthermore showcase that also Navier-Stokes equations directly follow from this principle which then enables us to make use of the concept of internal variables also for modeling of non-Newtonian fluids. Exemplarily, we demonstrate this for fluids with fading viscosity which models the bidirectional laminar/turbulent transition.

GENERALIZED STRUCTURE TENSOR-BASED SWITCHLESS CONSTITUTIVE RELATIONS FOR ARTERIAL TISSUES

Arvind K[1] and Krishna Kannan*[1]

[1]*Indian Institute of Technology Madras*

ABSTRACT

The collagen fibers which provide mechanical reinforcement to the arterial wall cannot sustain compressive loads. The existing Generalized Structure-Tensor (GST) based formulations emulate this through a tension-compression switch criterion based on the fiber stretch. This approach, however, has the following drawbacks:
1. discontinuous stresses at the switch point,
2. inconsistent predictions of the fiber stretch due to the conditional constitutive relations, i.e., the fibers predicted to be in compression according to the anisotropic terms can be in tension after the switch is employed, and
3. identical responses in longitudinal and transverse shear of unidirectional fibers, contrary to experimental observations.

To address these concerns, we introduce a matched invariant based on the Seth-Hill strain measure that auto-annihilates the contribution from fibers in pure compression. This leads to a unitary & switchless constitutive relation. The matched invariant inherently contains the I5 invariant and, consequently, the different shear modes yield distinct responses. The definition of the matched invariant is generalized for distributed fibers using the GST approach.

A vanishing matched invariant-based GOH (Gasser-Ogden-Holzapfel) constitutive relation with the same number of material parameters is obtained as a particular case corresponding to the Green-Lagrange strain. The constitutive relation with the general Seth-Hill strain resembles an anisotropic Ogden-like relation that can better control the relative magnitude of normal and shear stresses. For deformations devoid of shear, the proposed relations exclude the compressed fibers in a manner similar to that of the angular integration-based model proposed by Li et. al [1]. As evidenced by extensive fitting to planar biaxial and uniaxial data for various arterial tissues, the resulting unitary constitutive relations have significantly improved descriptive and predictive capabilities. The proposed switchless constitutive relation solves the discussed issues with little added complexity. This formulation is equivalent to using a modified and deformation-dependent structure tensor instead of the conventional GST, thereby eliminating the major hurdles associated with the use of a switch criterion.

ABSTRACT

In this work, we develop an algorithm to build a mapping between two geometries based on elastic deformation. While many elasticity-based approaches exist in the literature, the proposed method can be used for non-parametric geometries. The aim of this tool is its use in some surrogate modeling techniques or projection based model order reduction, where we are interested in accelerating the computation of solutions for complex parametric physical models with geometric variabilities. Many of these methods require each new domain to be mapped to a reference domain where the prediction/calculation can be performed. However, very often in practice, we don't have access to a domain parametrization, and only a mesh for a new geometry is available. In this case, our method can be used to construct such a mapping.

First, given a family of target domains, we start by applying the method to build a mapping between a common reference domain and each target domain. The mapping takes into account geometric features such as labeled lines and points, like the position of application of boundary conditions, so that each label in the reference geometry is aligned with its correspondence in each target geometry. Since we are interested in surrogate modeling, and to achieve online efficiency, all these calculations are performed during the offline phase. Then, for the online phase, we propose a reduction technique to efficiently build the mapping for a new unseen geometry, making our method effective for online use for surrogate modeling or projection-based model order reduction.

AN ARBITRARY ORDER CONTACT FORMULATION USING LAGRANGE MULTIPLIERS FROM RAVIART-THOMAS SPACE

Lukasz Kaczmarczyk[*1], Chirs Pearce[1] and Adnrei Shvarts[1]*

[1]*University of Glasgow*

ABSTRACT

We will present an approach for the analysis of contact in the context of elastic and elastoplastic materials. In the case of elastoplastic materials, we will use the multifield plasticity formulation [1]. The advantages of the presented finite element technology will be shown as examples of deformation of meta-materials, incremental cold forming of metals, and deformation of the rough multi-scale surface of Triboelectric generators. However, the focus of the talk will be dedicated to the core problem, stability of contact formulation of Lagrange multipliers, and solution schemes and efficiency for saddle point problems.

One established approach to enforce contact conditions is via the Lagrange Multipliers (LM) field, which is robust and implementation-independent from chosen material models. A consistent approximation of the LM field for h-refinement approaches has been developed and investigated [2, 3, 4]. However, p-refinement approaches are gaining popularity with the standardisation of hierarchical basis functions and a proper choice of basis functions to meet the needs of different functional spaces. For the case of contact problems, the space H^{−1/2}(Γ_c) is the LMs for contact when displacements are sought in the H^{1/2}(Γ_c) space. In the present work, a so-called dual approach for modelling contact of a deformable solid coming into contact with a rigid surface is proposed and is the first step towards a mortar contact formulation. The discrete functional space for LMs, H{−1/2}(Γc) defined on contact surfaces, Γ_c, emerges from the trace of Raviart-Thomas space, RT ⊂ H(div; Ω), defined in the deformable discretised body domain Ω^h. This enables us to evaluate some terms present in contact formulation both on the boundary and within the volume via the Gauss theorem, providing stability to the discrete solution.

IMPROVED NEURAL OPERATOR WITH GRAPH CONVOLUTIONAL NETWORKS AS A REDUCED ORDER MODEL

Teeratorn Kadeethum[1], Birendra Jha[2], Stephen Verzi[1], John Jakeman[1] and Hongkyu Yoon[1]*

[1]*Sandia National Laboratories*
[2]*University of Southern California*

ABSTRACT

A Reduced Order Model (ROM) provides a viable alternative to Full Order Models (FOM) for large-scale optimization or real-time control tasks. However, ROMs, particularly Machine Learning (ML) -based, face challenges in large-scale industrial settings due to a scalability. To elaborate, each degree of freedom (DOF) corresponding to the discretization of the domain serves as input features. This leads to a significant increase in computational resource requirements as the problem domain expands, a common scenario in large industrial reservoir models, rendering the training process impractical.

To address this, we have developed the Improved Neural Operator (INO), an advanced neural operator that effectively divides the computational area into smaller segments for each training step [1]. This approach involves sampling our computational domain at each forward pass, leading to much smaller training sets compared to using the entire domain. The INO framework can adapt to training with various DOFs, even with limited portions of the computational domain. For instance, in the Illinois Basin – Decatur Project, INO achieved an average relative error below 1% for pressure predictions on the test set, using just 90 training samples over four years, a count considerably lower than standard deep-learning datasets.

Despite these advancements, INO encounters challenges in gaining a comprehensive global understanding due to its approach of subsampling. While INO's training speed is impressive, it assumes that the state of a Partial Differential Equation (PDE) is determined only by localized conditions. This assumption is limited in geological contexts that require understanding solution states over a broader area. For example, the INO model's random subsampling method does not provide a full view of a heterogeneous permeability field, exposing the model to different segments of the domain rather than the whole, simultaneously. This results in a partial understanding of the permeability field's values and connections, potentially leading to inaccuracies in predictions.

To enhance INO's capabilities, we propose integrating Graph Convolutional Networks (GCNs). GCNs utilize graph structures, like those in heterogeneous permeability fields, to extend the model's global perspective while maintaining localized training samples. This integration is designed to boost INO's overall performance and realism, offering a more accurate depiction of the intricate interactions within the permeability field.

UNDERSTANDING AGENT ACTIONS UTILIZING ACTOR-CRITIC ALGORITHM IN DEEP REINFORCEMENT LEARNING

Rintaro Kai[*1] and Kazuo Yonekura*[1]

[1]*The University of Tokyo*

ABSTRACT

Reinforcement learning has been applied to a broad range of problems and has achieved remarkable results, especially when combined with deep learning. However, such high-performance AI often leads to complex black-box models. That is the reason why explainable AI, which aims to make the predictive process of AI understandable to humans, is gaining attention.
In this research, we propose a method to visualize the rationale behind the actions of reinforcement learning agents by applying the Actor-Critic algorithm. Specifically, this involves estimating the rewards for the actor's actions based on the value inferred by the Critic, which evaluates actor's actions. Additionally, we developed a method for extending this approach to multi-objective optimization problems by creating a critic for each objective function. Sub-rewards, which were traditionally aggregated before being passed to the critic, are now explicitly passed to the critic. This allows the critic to learn the value function for each sub-reward and calculate sub-reward estimations.
To verify the usefulness of this method, we applied it to the pendulum problem, a benchmark problem in multi-objective optimization. Furthermore, we applied it to multi-objective optimization of turbine blades as an engineering application. For evaluation, we used the explanations derived from traditional reinforcement learning metrics such as loss and reward transitions and SHAP, a representative method of Explainable AI, as comparison targets to confirm an improvement in explainability. As a result, explanations that could not be provided by traditional methods were achieved with the proposed method. Remarkably, some of the results make it possible to definitively identify agent actions as mistakes, which could not be conclusively determined by means of traditional methods. Moreover, the results from this proposed method were often interpretable not only by developers and designers but also by non-professional.

FLOW-BASED QUANTIFICATION OF THE EPISTEMIC UNCERTAINTY OF SIMULATION PREDICTIONS

Bryan Kaiser[*1] and Kyle Hickmann*[1]

[1]*Los Alamos National Laboratory*

ABSTRACT

We demonstrate how normalizing flows (NFs), a class of generative deep learning problems, can be applied to simulation predictions to quantify epistemic uncertainties. NFs use invertible deep learning architectures to solve the change of variables equation for probability densities. One density is prescribed (a.k.a. the “base” density, usually a high dimensional isotropic Gaussian) while the other density of the “target” data is learned. Crucially, the probability density of the target data is explicitly and tractably quantified. If the target data is, for example, a set of proton radiographs predicted by a simulation then the NF will “learn” an arbitrarily complex high dimensional target density in which the predicted radiographs are maximum likelihood. Then, if proton radiographs from an experiment are passed through the NF, the NF will compute the likelihood of the experiment radiographs within the density of the simulated radiographs. In other words, NFs quantify epistemic uncertainty by quantifying of the likelihood of any new sample within the learned target density. Provided sufficient numbers of training samples, this unsupervised method can be applied to high dimensional data.

GEOMETRIC OPERATORS & GENERIC PARAMETRIC MODELING FOR AI-BASED SHAPE OPTIMIZATION IN MARITIME ENGINEERING

Panagiotis Kaklis[1], Shahroz Khan[2] and Konstantinos Kostas[3]*

[1]*University of Strathclyde*
[2]*BAR Technologies*
[3]*Nazabayev University*

ABSTRACT

Despite the recent spectacular successes of Artificial Intelligence (AI), the degree of its acceptance by the Engineering Design communities remains limited. This is especially true for Shipping, a conservative sector partially due to the long life-cycle of ships (25-30 years). In fact, the dominant design practice in Maritime Engineering, based on Parametric Modelers, which generate thin Design Spaces around a baseline design with costly, e.g., CFD and FEM simulations, has a limited capability for novelty.

Our work aims to strengthen AI's role in Engineering Design by deriving novel physics-informed and low-cost geometric functionals, acting as: (i) stabilisers versus the criteria of geometric-validity and shape-richness, and (ii) shape-optimisation accelerators in the Design Spaces and their latent subspaces involved. Our investigation covers so far a variety of application areas, such as flows around ships, propellers and hydrofoils, with very encouraging results, see, e.g., [1] and [3].

Furthermore, our recent research activities contributed towards establishing a novel paradigm in the area of Ship Design via a Generic GAN-based Parametric Modeler [2], which increases dramatically the capacity of generating novel shapes, while securing geometric-validity along with high-quality and low computational cost of the adopted shape encoding.

ACCELERATED DEVELOPMENT OF MATERIALS USING HIGH-THROUGHPUT STRATEGIES AND AI/ML

Surya Kalidindi[1]*

[1]*Georgia Institute of Technology*

ABSTRACT

The dramatic acceleration of the materials innovation cycles is contingent on the development and implementation of high throughput strategies in both experimentation and physics-based simulations, and their seamless integration using the emergent AI/ML (artificial intelligence/machine learning) toolsets. This talk presents recent advances made in the presenter's research group, including: (i) a novel information gain-driven Bayesian ML framework that identifies the next best step in materials innovation (i.e., the next experiment and/or physics-based simulation to be performed) that maximizes the expected information gain towards a specified target (e.g., optimized combination of material properties, refinement of a material constitutive response), (ii) computationally efficient versatile material structure analyses and statistical quantification tools, (iii) formulation of reduced-order process-structure-property models that enable comprehensive inverse solutions needed in materials design (e.g., identifying specific compositions and/or process histories that will produce a desired combination of material properties), and (iv) high throughput experimental protocols for multi-resolution (spatial resolutions in the range of 50 nm to 500 microns) mechanical characterization of heterogeneous materials in small volumes (e.g., individual constituents in composite material samples, thin coatings or layers in a multilayered sample). These recent advances will be illustrated with case studies.

APPLICATION OF PHYSICS-AUGMENTED NEURAL NETWORKS TO MULTISCALE PROBLEMS

Karl Kalina[*1], Jörg Brummund[1], Steve WaiChing Sun[2] and Markus Kästner[1]*

[1]TU Dresden
[2]Columbia University

ABSTRACT

Due to the recent development of machine learning, constitutive models based on neural networks are becoming increasingly popular. Thereby, a promising field of application is the usage of such models for the acceleration of multiscale simulations [1].

Herein, we present an approach based on physics-augmented neural networks (PANNs) [2,3] that are applied as macroscopic surrogate models. PANNs are designed to fulfill as many conditions as possible from constitutive modeling by construction and are very flexible at the same time. Our approach allows the efficient simulation of materials with complex underlying microstructures which reveal an overall anisotropic and nonlinear behavior on the macroscale. Thereby, we restrict ourselves to finite strain hyperelasticity problems in the first part of the talk. By using a set of problem-specific invariants as the input of the PANN and the Helmholtz free energy density as the output, several physical principles are fulfilled a priori [2,3]. The invariants are formed from structure tensors and the right Cauchy Green deformation tensor. Necessary data for the training of the PANN surrogate model are collected via computational homogenization of representative volume elements (RVEs). Besides the network parameters, the structure tensors are automatically calibrated during training so that the underlying anisotropy of the RVE is reproduced in the best possible way. The developed approach is exemplarily applied to several descriptive examples. Finally, an extension of the approach to magneto-hyperelasticity is shown [3].

PHASE-FIELD MODELLING OF DUCTILE FATIGUE FRACTURE

Martha Kalina[1] and Markus Kästner*[1]

[1]*TU Dresden*

ABSTRACT

Phase-field modelling of fatigue fracture has been approached by many different models in recent years. Yet due to the high number of load cycles involved, computational time remains one of the main challenges, especially for fracture in ductile materials such as metals.

In this contribution, we revisit our efficient phase-field model for fatigue fracture [1] with a simplified consideration of cyclic plasticity. We combined the phase-field method for brittle fracture with the Local Strain Approach [2], a traditional fatigue concept from structural durability. It involves assumptions for the stress-strain behaviour including local plasticity and the damaging effect of load cycles, based on experimental material data.

Now, we improve the model by refining both the approximation of the stress-strain behaviour and the evaluation of the damaging effect of the load cycles with a new damage parameter. In a second step, we introduce a comprehensive phase-field model with elastic-plastic material law [3]. This we use to evaluate the two efficient models with the simplified integration of plasticity. The range of application of the three models is discussed, compromising between accuracy and computational time.

THE MICROLAYER MODEL – A NOVEL APPROACH TO DESCRIBE MATERIALS WITH RIGID PARTICLES EMBEDDED IN A MATRIX

Jakob Platen[1], *Johannes Storm*[1] *and Michael Kaliske**[1]

[1]*TU Dresden*

ABSTRACT

Concrete is one widely utilized material. Due to its heterogeneous mesostructure, it exhibits specific material characteristics. Firstly, concrete can withstand larger loads in compression than in tensile regime. Secondly, under multiaxial loadings, concrete shows a significant influence of the secondary loading directions. Significant differences in the directional stiffness along the different loaded directions are typical for concrete. To overcome the limitations with respect to load bearing characteristics under tension, reinforcements are utilized.

In computational mechanics, concrete is often modelled by the so-called microplane material model, which is based upon linking the behavior of a material point with a representative volume element. In the microplane framework, unit spheres are chosen for representing the material behavior of concrete. Also, this model is not based upon the Principle of Multiscale Virtual Power according to the authors knowledge. The utilization of the aforementioned principle results in better agreement with reality.

In the contribution at hand, a new approach to model concrete, the microlayer model, is detailed and applied in numerical simulations. The formulation can be generalized to all materials, which consist of rigid particles embedded in a deformable matrix. One main advantage of this modelling strategy is, that anisotropy, which is induced by loading, can be captured in a closer alignment with experimental data. In the microplane material model, the directional stiffness is shown to only exhibit small differences, while for the microlayer material formulation significant differences can be observed. Another class of models, which rely on the concept of homogenization, are FE^2 formulations. In the microlayer model, the smaller scale is solved analytically, which results in significantly reduced computational effort.

The capabilities of the microlayer material formulation are shown for different numerical examples. Firstly, numerical simulations are conducted to compare the behavior of the microplane and microlayer material model. Subsequently, experiments on concrete are simulated to validate the microlayer model.

DISCRETIZATION ERROR ESTIMATION FOR FLOW SIMULATIONS USING GENERAL HYBRID GRIDS

Yannis Kallinderis[*1]*

[1]*University of Patras*

ABSTRACT

The discretization error is a primary component of the numerical error in flow simulations. Use of general hybrid meshes is of importance due to the complexity of both the geometry and the field of modern computational fluid dynamics applications. The meshes can consist of a mix of hexahedra, prisms and tetrahedra with pyramids being transitional elements. The different elements are arranged in local areas of different grid density and directionality according to the dominant flow feature there. The discretization error arises not only from the local density of the mesh, but also from its "distortions", namely the local size variation (stretching), the shape of the individual elements (shear, skewness, twist), as well as the local change in their type (grid interfaces).

Two distinct approaches have been followed in order to estimate and control the discretization error: the a priori methods are employed during grid generation and its assessment (e.g. [1]) and the a posteriori ones monitor the simulated flow field and guide grid improvement (adaptation) (e.g. [2]).

The a priori approach utilizes a second order finite volume discretization. It derives expressions of the truncation error for the most commonly encountered "distortions" of the mesh and works with the terms that multiply the solution derivatives (grid metrics or error coefficients). The magnitude of those terms is used to guide grid generation and post-processing of the initially created grid.

The a posteriori error estimation monitors approximations of the magnitude of the flow gradients ("sensors"). Those are then applied to guide adaptation of the grid to the simulated flow field. This typically includes local divisions of the elements or entire zones, grid point / element redistribution or local change in the order of discretization.

ABSTRACT

Physics informed neural networks (PINNs) has emerged as a surrogate modeling method garnering considerable attention. It incorporates the governing equations of physical phenomena into the loss function, enabling efficient and highly accurate learning with minimal observation data. Consequently, PINNs has been applied in various fields where there is a lack of observation data and real-time predictions are essential, including aerospace, mechanical engineering, architecture, civil engineering, and the medical field. In design problems, parametric PINNs is expected to facilitate rapid and precise uncertainty quantification and optimization, with growing research interest in this area.

In this study, we focus on the learning of parametric PINNs with limited observation data along the parameter axis, aiming to enhance efficiency. We propose introducing a new loss function term, the "parameter gradient loss," which derives from the parameter derivative of the governing equation. To assess the impact of this new term, we explored how the weight during learning and the number of observation data along the parameter axis affect performance using a simple static one-dimensional Euler beam problem as a case study.

Our results indicate that the proposed method can reduce prediction error in the interpolation range, even under challenging learning conditions, such as sparse observation points along the parameter axis and the absence of evaluation points of the governing equation between observation points, compared to traditional approaches. We observed that increasing the learning weight reduced the prediction error of the interpolation range. However, the error increased beyond a certain weight threshold. Conversely, the effectiveness of the proposed method was limited with a relatively higher number of observation points along the parameter axis than in our other computations or when evaluation points of the governing equation were placed between observation points.

This study introduces a novel loss function for efficient learning in parameteric PINNs, demonstrating its potential even with sparse observation data in the parameter direction. This approach is anticipated to lessen the need for extensive numerical analyses and experiments for each parameter set before learning in parametric PINNs, offering significant benefits in practical computational settings.

[2]*Purdue University*

ABSTRACT

High Entropy Alloys (HEAs) have shown potential to improve on the performance of legacy materials, thus characterizing the relationships between the composition, material properties, and microstructure of HEAs is of great interest. However, predicting these characteristics presents significant challenges due to the complex, multi-component nature of HEAs and the resulting large design space. To address this challenge, a multi-physics simulation framework and data-driven surrogate modeling approach are implemented, to provide a method to rapidly assess how changes in HEA composition will lead to changes in material properties and microstructure. The physics-based framework sequentially couples CALPHAD for material properties, CFD for thermal conditions during solidification, and Cellular Automata for microstructure. A data-driven surrogate model, which can reconstruct microstructure statistics from the thermal conditions, is trained via a reduced-dimensional form of the microstructure output of the physics-based framework. Dimensionality reduction is achieved in two steps. First, Angularly Resolved Chord Length Distributions (ARCLDs) are extracted from microstructures by sampling the distance between grain boundaries at various angles. ARCLDs provide a thorough statistical characterization of microstructure morphology and are a robust representation of microstructure as a result. Second, the ARCLDs are reduced via Principal Component Analysis (PCA), resulting in identification of the significant modes of each Chord Length Distribution. The coefficients of these modes are the final reduced form of the microstructure and are the output for which the surrogate model is trained. The coefficients which are output from the surrogate model are used with the significant PCA modes to reconstruct the ARCLDs of the microstructure, providing insight into how thermal conditions will affect microstructure characteristics without having to run a slow microstructure simulation. This surrogate modeling approach provides a significant speedup to characterizing the relationships between HEA composition, thermal conditions, and the final microstructure. This combination of physics-based and data-driven approaches with a reduced-dimensional representation of microstructure can significantly speed up the development of HEAs, increasing their adoption rate in practical applications. Additionally, the ability of the present surrogate model to reconstruct a statistical representation of the microstructure lays the groundwork for future endeavors to reconstruct the microstructure itself.

A FINITE ELEMENT INFORMED NEURAL NETWORK (FINN) FOR ELASTOGRAPHY

Sahil Kamath[*1], Zhiqi Mao[1], Ganesh Sankaranarayanan[2] and Dong Qian[1]*

[1]*The University of Texas at Dallas*
[2]*UT Southwestern Medical Center*

ABSTRACT

Elastography is an imaging technique utilized for extracting tissue elastic modulus from various imaging modalities like ultrasound, MRI, and video cameras. While in practice, the application of elastography has encountered challenges in achieving accurate quantitative analysis within computational mechanics. These challenges stem from human factors, ad hoc assumptions, and image quality issues, limiting broader applications. Current data-driven models in elastography heavily rely on large datasets, leading to statistical sensitivity. In response to these limitations, we propose an innovative approach that integrates physics-based models using the Finite Element Method (FEM) with Deep Neural Networks (DNN). We term the approach Finite Element Informed Neural Network (FINN). Our method incorporates mechanistic understanding of physics principles into deep learning, enabling precise capture of ultrasound deformation without the need for extensive training datasets. The algorithm demonstrates robustness across diverse scenarios, displaying an error margin of less than 5% compared to ideal conditions. Validation of the algorithm against ultrasound testing on tissue-mimicking phantoms further confirms its efficacy. This new approach in elastography has the potential to significantly enhance patient care by advancing the accuracy and reliability of tissue elasticity assessments.

A MECHANISTIC MODEL FOR ICE DEPOSITION IN FREEZE DRYER CONDENSERS USING COMPUTATIONAL FLUID DYNAMICS

Blaž Kamenik[*1], Matjaž Hriberšek[1] and Matej Zadravec[1]*

[1]*University of Maribor*

ABSTRACT

This work presents a novel model for the deposition of ice in the condenser of a freeze dryer based on a computational fluid dynamics. The efficiency of the condenser has a significant impact on the efficiency of the overall process and the product quality. Therefore, a comprehensive understanding of ice deposition is essential for freeze-drying processes. The proposed condensation model integrates fundamental heat and mass transfer principles with the specific interactions that occur at the solid-vapour interface during ice deposition and further integrates these with transport phenomena in the condenser, including fluid flow, heat and vapour transport, which influence ice deposition kinetics. This is necessary because the pressure in the drying chamber can increase under various conditions, e.g. if the flow in the connecting duct is choked, if there is too much inert gas in the system or if the water vapour in the condenser is not sufficiently removed.

The vendor code Ansys Fluent with custom user-defined functions (UDF) were used to simulate the ice deposition, which was modelled as a volumetric sink of mass, momentum and energy. The ice deposition process is modelled as the one-way diffusion of water vapour. The numerical model was validated by an experimental comparison, which showed a high degree of agreement between the model predictions and the experimental data. The proposed model allows a comprehensive investigation of all potential causes and their mutual effects, making it a valuable tool for understanding and controlling the pressure dynamics in the system.

Using the validated model, a parametric study was performed by varying the temperature of the condenser walls, the mass flow rate of the sublimate and the mass fraction of the inert gas in the system. This study showed that energy consumption can be reduced in certain cases by selecting the optimum condenser wall temperature, as increasing the pressure in the condenser only slightly increases the pressure in the drying chamber.

The developed mechanistic model thus provides a deeper insight into the kinetics of ice deposition during freeze drying and enables process engineers to improve the design and operating parameters of the condenser to increase performance and product quality.

INVESTIGATION OF RESIDUAL STRESS MECHANISMS ON IRON SUBSTRATES DURING THE FORMATION OF DLC FILMS BY MOLECULAR DYNAMICS STUDY

Noritsugu Kametani[*1], Morimasa Nakamura[2], Kisaragi Yashiro[3] and Tomohiro Takaki[1]*

[1]*Kyoto Institute of Technology*
[2]*Doshisya University*
[3]*Gifu University*

ABSTRACT

Due to their characteristics of low friction, high hardness, and wear resistance, diamond-like carbon (DLC) films are some of the hardest thin films expected to be applied to the mechanical sliding parts of automobiles. However, the poor adhesion of DLC films to substrates has caused delamination problems, particularly when used in high dynamic friction environments, and this limits the scope of their application. One of the main causes of delamination is high compressive residual stress, which originates from the deposition process. This cause-effect relationship is critical in understanding the practical application of DLC films. However, direct experimental observation of the generation of residual stress is difficult, as the phenomenon occurs at an atomic scale. In addition, the amorphous structure of DLC films precludes stress measurements by X-ray diffraction. To predict the local stress state of a film, a numerical simulation must be conducted. Accordingly, in this study, the residual stresses and structural changes of carbon bonds on iron substrates during the formation of DLC films were investigated through molecular dynamic simulations. Specifically, we conducted a detailed investigation of the manner in which carbon atoms form carbon bonds such as sp2 and sp3 on Fe-BCC substrates during the film formation process and how they contribute to the development of compressive residual stresses. Simulations showed that iron atoms ejected from the substrate penetrated the film and transformed the sp2 bonds into sp3 bonds in amorphous carbon, resulting in increased residual stress. The effects of the substrate material on the DLC-film bond structure and residual stresses are also thoroughly discussed through comparisons with previous studies.

MINIMAL SURFACES: WHAT ARE THEY GOOD FOR?

*Randall Kamien**[1]

[1]*University of Pennsylvania*

ABSTRACT

“Economics, we all recite, deals with allocation of limited resources towards satisfaction of unlimited wants” [1]. But does that mean a good deal for you is a good deal for me? Minimal surfaces, so-called because of their local area minimization, are used as models in liquid crystals, foams, and block copolymers. Are they also energy minimizers? I will give examples of their use in these systems and raise the question, “are these really the best or are they just the best we can think of?”

PHYSICS-INFORMED NEURAL NETWORK VS FINITE ELEMENT METHOD FOR MODELING COUPLED WATER AND SOLUTE FLOW IN UNSATURATED SOILS

Hamza Kamil[*12], Azzeddine Soulaïmani[1] and Abdelaziz Beljadid[23]*

[1]*École de technologie supérieure*
[2]*Mohammed VI Polytechnic University*
[3]*University of Ottawa*

ABSTRACT

Precise simulation of water and solute movement in unsaturated porous media is crucial in a variety of applications, including precision irrigation, and environmental conservation. The coupled model of water and solute flow involves integrating the Richards equation with the equilibrium advection-dispersion equation. The high nonlinearity of the Richards equation limits the availability of analytical solutions for the coupled system, especially with complex geometries and boundary conditions. Consequently, various numerical and data-driven approaches have been proposed (e.g., Haruzi and Moreno, 2023). In this study, we present physics-informed neural network (PINNs) solvers for the coupled system and provide a comparative analysis with the widely adopted finite element approach (FEM). The inputs for the PINNs solver consist of time and space coordinates, while the output provides the solution for the coupled system, encompassing water content and solute concentrations. To train PINNs solvers, random points are generated to calculate various loss functions, including the residual loss connected to the partial differential equations (PDEs), as well as initial and boundary losses. Two approaches are employed to satisfy the initial conditions: a soft approach, where the initial loss is integrated into the objective function for minimization, and a hard approach, where the output of the solver is transformed to fulfill both the initial conditions and the PDEs. Additionally, a comparison is made between a standard PINNs solver with a fixed activation function and an adaptive-based PINNs solver.

Numerical tests, encompassing both 1D and 2D scenarios, were conducted to assess the performance of the PINNs solver and its variants in comparison with the FEM. The PINNs solver exhibits a substantial increase in training time as the spatial dimension expands, in contrast to the FEM, which delivers results within minutes. Notably, the PINNs solver with adaptive activation and the hard implementation of initial condition constraints proves to be the most efficient in terms of accuracy. Conversely, the PINNs solver without adaptive activation requires more iterations to achieve comparable results. Soft implementation of initial conditions, in general, struggles to predict the initial condition near boundaries where Neumann conditions are applied. This underscores the need for further research to enhance the efficiency of PINNs solvers, enabling them to match the efficacy of standard numerical methods.

[3]AIRBUS

ABSTRACT

Recent developments in progressive failure simulation methods, based on increased computing capacities, provide the framework within which substantiation through numerical analysis, supported by experiments, can be envisaged. Nowadays, progressive damage models for the prediction of failure and failure modes are used [1, 2] and 3D finite element simulations are performed to describe and quantify composite material damage and to decrease the number of experiments required in the building block approach.

Here, a 3D multi-scale progressive failure approach developed at ONERA [3] has been implemented in the commercial calculation code Abaqus/Explicit, with an explicit solver. Explicit dynamics offers advantages over implicit modelling in solving large nonlinear problems. Different sources of non-linearities are considered by the OPFM model at the scale of the UD ply: (i) non-linear elasticity in the fibre direction, (ii) non-linear viscoelasticity of the matrix, (iii) matrix damage based on continuous damage mechanics and (iv) description of the sudden failure of the fibres with a softening law in the fibre direction regularised by a delay effect and delamination is described with cohesive zone elements. The model has been evaluated on different configurations provided by Airbus in order to predict accurately the final failure of composite structures subjected to in-plane or triaxial loading. First, some basic failure modes have been investigated on different configurations such as plain specimens and open-hole specimens in tension and compression on a CFRP thermoset UD Tape 194 gsm under prepeg format to evaluate the model. Then, damage and failures modes have been predicted on different composite laminate bolted joints in tension and compression. The simulation results will be compared with a large database coming from experiments provided by Airbus.

PROBABILISTIC ENTROPY AND DISTANCE IN HOMOGENIZATION OF RANDOM MULTI-COMPONENT COMPOSITES

Marcin Kamiński[*1]

[1]*Lodz University of Technology*

ABSTRACT

The main issue is to use the apparatus of probabilistic entropy, and also probabilistic distance to perform uncertainty quantification related to effective characteristics of random composites built up with a few constituents. It is well known that uncertainty quantification is usually delivered in the literature using a few basic probabilistic characteristics like expectations, variances, and so on, so that a single function such as a probabilistic entropy may be an attractive alternative. Shannon entropy has been selected for this purpose, which is directly based on the given probability density function and which can be determined using a classical Monte-Carlo simulation scheme. Random composites under consideration have a perfect spatial distribution of the constituents, show some statistical scattering of the elastic characteristics, and also may exhibit some probabilistic interface defects in between the matrix and its reinforcements. Calculation of the effective composite characteristics is carried out with the effective modules method implemented in some Finite Element Method program, whose extension towards stochastic analysis is programmed using simulation, perturbation, and semi-analytical approaches. Additionally, probabilistic distance is analyzed in-between original material characteristics of such composite constituents and their effective parameters and this is completed using a relative entropy approach; the Bhattacharyya distance is selected for this purpose. Probabilistic distance enables us to determine the closest and the most distant material characteristics' probability distribution for the given component of the effective tensor. Therefore, it may serve as an alternative to traditional sensitivity analysis, not only for the homogenization procedure but as a general tool in stochastic computational mechanics.

ABSTRACT

Recently, there is active research on rotor blades in various fields such as advanced air mobility(AAM), wind turbine, military rotorcraft and more. In the structural design process of these rotor blades, dynamic characteristics analysis for the blades are necessary. This analysis process requires the cross-sectional stiffness of the blade, and the result of the analysis is utilized for assessing the structural integrity of the blade[1,2]. However, in the design process, recursive analyses are necessary whenever there is a change in the cross-sectional design. Therefore, the use of deep learning technique can be effective in reducing computational costs. Consequently, we are in the process of designing a prediction model that predicts the dynamic characteristics of the blade, and currently, we have developed two types of prediction models that predict the cross-sectional stiffness via structural properties of the blade cross-sections. The first prediction model, using multi-layers perceptron(MLP), has developed to investigate the feasibility of using deep-learning technique for predicting the cross-sectional stiffness of the blade. The input variables for the prediction model consider the position and thickness of the cross-sectional members, and the output variables are the cross-sectional stiffness terms. As an example problem for the training and verification of the prediction model, the r/R=0.3 cross-sectional geometry of IEA 15MW reference wind turbine blade[3] is used. The second model is developed to extend the predictive range along the spanwise direction of the blade in the MLP-based prediction model. Therefore, to additionally consider the cross-sections at r/R=0.1 and 0.5 in the example of the MLP-based model, graph neural network(GNN) is utilized. To evaluate the prediction results of the models, the coefficient of determination(R^2) is used. As the results of the MLP-based prediction model, the R^2 values for all stiffness terms are above 0.95. Also, the R^2 values of GNN-based prediction model are above 0.99 for all stiffness terms. As the future research, the development of blade dynamic characteristics prediction model via cross-sectional structural properties will be conducted.

CONTROLLING POISSON'S RATIO AND THERMAL EXPANSION IN A ROTATING RECTANGLE STRUCTURE COMBINED WITH BI-MATERIAL STRIPS

Duhwan Kang[*1], Jeong Min Hur[1] and Do-Nyun Kim[1]*

[1]*Seoul National University*

ABSTRACT

Mechanical metamaterials have garnered significant attention due to their extraordinary properties surpassing natural limits, including negative Poisson's ratio (NPR) and negative coefficient of thermal expansion (NTE). Metamaterials with NPR contract laterally under axial compression, while those with NTE shrink when heated. Their unique properties make them promising for various applications including shape-morphing [1, 2].

Recently, various multifunctional metamaterials with both tunable Poisson's ratio (PR) and coefficient of thermal expansion (CTE) have emerged, rather than single-functional ones, to handle the complex thermo-mechanical loads. A common approach to achieving both properties involves combining auxetic structures with bi-material lattices. For instance, connecting a re-entrant structure auxetic to a bi-material triangle has shown tunable NPR and NTE [3]. However, prior works faced limitations in fully independent control of PR and CTE from negative to positive values, as the physical mechanisms for tuning PR and CTE are highly interrelated. The advent of solution to solve this problem will expand the potential uses in a wide range of applications and introduce novel functionalities.

This work introduces a novel meta-structure with independently tunable PR and CTE across a spectrum from negative to positive, demonstrating its controllability numerically and experimentally. Specifically, a rotating rectangle unit combined with alternating bilayer beams enables fully independent control of PR and CTE. Strategy for isotropic and anisotropic thermal expansion is also explored. Furthermore, we propose a novel application concept, the meta-surface, which offers diverse shape-morphing behaviors by exploiting the multi-functionality of the metamaterials when exposed to thermo-mechanical loads. Our advancements in the field of metamaterials may offer a robust foundation for applications capable of handling both mechanical and thermal loads, including shape morphing, stress mitigation, and smart actuation.

SUBSURFACE IMAGING OF STRUCTURES BY AN ELECTRICAL IMPEDANCE TOMOGRAPHY METHOD

Jun Won Kang[*1] and Ju Hyeon Jo*[1]

[1]*Hongik University*

ABSTRACT

This study presents an electrical impedance tomography (EIT) method for subsurface imaging of structures in two dimensions. The proposed EIT method seeks to reconstruct the electrical conductivity profile of structures using measured electric potential differences at the boundary. The EIT method is based on a partial-differential-equation (PDE)-constrained optimization approach, which takes a complete electrode model (CEM) comprising the Laplace equation and boundary conditions for the electric potential difference as constraints. The finite element method was used to calculate the electric potential difference described by the CEM, and the accuracy of the forward solutions was validated by comparing them with ANSYS solutions. The inverse EIT problem seeks the optimal solution of the domain's electrical conductivity profile to minimize a Lagrangian functional consisting of a least-squares objective functional and a regularization term. By enforcing the stationarity of the Lagrangian, Karush-Kuhn-Tucker conditions comprising the state, adjoint, and control problems are derived. The three problems are iteratively solved in the reduced space of the control variable, the electrical conductivity, to image the structure. Numerical results show that electrical conductivity profiles, whether homogeneous or layered, could be effectively reconstructed using measured electric potential differences at the boundary. The relative error of the measured and calculated electric potential differences after the inversion was less than 1%, demonstrating the successful inversion of the measured data using the proposed EIT method.

LATTICE BOLTZMANN SIMULATION OF REACTIVE TRANSPORT IN COMPLEX FRACTURES

Qinjun Kang[*1], Richard Larson*[21] and Hari Viswanathan*[1]

[1]*Los Alamos National Laboratory*
[2]*The University of Texas at Austin*

ABSTRACT

Fractures play an important role in providing preferred flow pathways in low-permeability formations. They can improve gas production for shale reservoirs but can also increase the risks for leaking of carbon dioxide from geological storage sites. In addition, recent studies have shown that continuously created fractures are required to generate new mineral surfaces for sustainable carbon mineralization or subsurface clean hydrogen generation.

The fluid-mineral reactions, including dissolution or precipitation, can cause the alteration of fracture wall. Particularly, mineral dissolution (precipitation) can increase (decrease) the aperture size and hence the fracture permeability. While there have been a lot of two-dimensional studies on mineral dissolution in porous or fractured media considering resultant pore-structure, high-resolution pore-scale modeling study of reactive transport in three-dimensional fractures with evolving fracture geometry is scarce. Consequently, the complex coupled processes including fluid flow, solute transport, dissolution, precipitation, and evolution of pore structure are not well understood.

We are developing a high-performance computer code for simulating coupled fluid flow, solute transport, and chemical reaction in a single lattice Boltzmann method (LBM) framework. This allows for more accurate treatment of the coupled processes and improved computational efficiency. First we use LANL-developed open-source python library, Pysimfrac1, to create realistic fracture realizations of varying properties (e.g., fracture aperture and roughness). Then we perform a series of simulations of dissolution of the fracture wall by a reactant introduced at the entrance. We cover a wide range of Pe and Da numbers by varying flow rate and dissolution rate constant. Our preliminary results have shown that dissolution patterns highly depend on the combination of Pe and Da numbers. The results have also shown that roughness causes more surface area but lower velocity leading to the non-linear relation between roughness and effective reaction rate. We are carrying out more quantitative analysis of the effect of fracture characteristics on the effective dissolution rate and will present the results at the conference.

SHAPE IDENTIFICATION OF SCATTERERS USING PERIDYNAMICS AND B-SPLINE PARAMETERIZATION

Sehyeon Kang[1], Hyun-Seok Kim[2] and Seonho Cho[1]*

[1]*Seoul National University*
[2]*Korea Research Institutie of Ships & Ocean Engineering*

ABSTRACT

In this paper, we proposed a new shape identification method without a priori information about the scatterer. Shape identification, an inverse problem finding the configuration of scatterers by minimizing the discrepancy between real wave data with scatterers and estimated wave data, is investigated employing peridynamic theory and gradient-based optimization in plane elastic medium. To quantitatively measure the discrepancy, an error functional is defined as the L2 norm error obtained at several sensors located around the scatterers. The particle-based and non-local characteristics of the peridynamic theory enable the direct modeling of interface between scatterers and the medium, avoiding remeshing difficulties when employing conventional domain-based methods [1]. The boundary of scatterers is parameterized using a zero level of B-spline surfaces and determined by bond parameters in peridynamics material. The B-spline surface based parametrization enabled the precise boundary expression of the scatterers and topological changes during the identification process. Control points of the B-spline surfaces on the fixed grid are set as design variables. The design sensitivity of the error functional is efficiently obtained through an adjoint variable method, requiring only the solution of one additional adjoint equation to obtain the sensitivity [2]. The peridynamic adjoint sensitivity involving history-dependent variables in transient peridynamics is accurately obtained by using an identical path in both adjoint and response analyses. A gradient-based optimization scheme with an efficient adjoint variable method is utilized to determine the boundary of scatterers that minimize the error functional of discrepancy. Numerical examples of various geometry are presented to verify the accuracy and efficiency of the proposed method. The accuracy and efficiency of the proposed method could be further enhanced by implementing a multi-optimization scheme by increasing frequency inputs. This method can be extensively used in various fields (e.g. medical imaging, geometrical exploration, non-destructive testing) for accurate shape identification.

[3]*Universidad de Sevilla*

ABSTRACT

For the last few decades, a host of partitioning methods has been proposed for a parallel iterative solution algorithm. However, application of those for a heterogeneous system is still cumbersome, sometimes falling into a non-convergence. This paper suggests an alternative iterative algorithm based on the displacement-only partitioning (DP) formulation [1] for a highly heterogeneous material component. DP formulation handles the partitioned displacement as a fundamental variable, but does not include the interfacial variables, e.g., Lagrange multiplier. In addition to an implementation simplicity, such solution variable will maintain superiority in convergence and accuracy for the heterogeneity. The quasi-static structural analysis procedure based on the DP iterative algorithm will be demonstrated along with application of the various preconditioners, including the coarse space construction. Additionally, comparison against the traditional saddle-point and allied methods will be shown.

ENHANCING LOW-ORDER DISCONTINUOUS GALERKIN METHODS WITH NEURAL ORDINARY DIFFERENTIAL EQUATIONS

Shinhoo Kang[*1] and Emil Constantinescu*[1]

[1]*Argonne National Laboratory*

ABSTRACT

The growing computing power over the years has enabled simulations to become more complex and accurate.
However, high-fidelity simulations, while immensely valuable for scientific discovery and problem solving, come with significant computational demands. As a result, it is common to run a low-fidelity model with a subgrid-scale model to reduce the computational cost, but selecting the appropriate subgrid-scale models and tuning them are challenging. We have developed a novel continuous-in-time hybrid method that reduces the errors introduced by classical low-order discontinuous Galerkin (DG) discretizations. Our approach learns the missing scales of the low-order DG solver at a continuous level and hence improves the accuracy of the low-order DG approximations as well as accelerates the filtered high-order DG simulations. We demonstrate the performance of our approach through Taylor–Green vortex examples at different Reynolds numbers and times, which cover laminar, transitional, and turbulent regimes. The proposed method not only reconstructs the subgrid-scale from the low-order (1st-order) approximation but also speeds up the filtered high-order DG (6th-order) simulation by two orders of magnitude.

MULTISCALE MODELING FRAMEWORK USING ELEMENT-BASED GALERKIN METHODS FOR SIMULATION OF THE MOIST ATMOSPHERE

Soonpil Kang[*1], James Kelly[2], Anthony Austin[1] and Francis Giraldo[1]*

[1]*Naval Postgraduate School*
[2]*U.S. Naval Research Laboratory*

ABSTRACT

Atmospheric flows involve a broad spectrum of spatial and temporal scales and their multiscale interactions, encompassing large-scale convective processes and small-scale moist processes. Therefore, one of the main challenges for simu- lating atmospheric flows is to resolve the processes across various scales, ranging from global circulation to precipitation microphysics. The multiscale modeling framework (MMF) [1, 2] uses local fine grids to explicitly resolve phenomena at distinct scales using different grid resolutions within a global circulation model (GCM).

This talk adapts the MMF approach to model moist atmospheric limited- area (mesoscale) simulations. The MMF resolves the large-scale convection us- ing a coarse grid while simultaneously resolving local features through numerous fine local grids, and seamlessly coupling them. Both large- and small-scale processes are modeled using element-based Galerkin methods [3] with high-order basis functions. Coupling of the two models are achieved in either a column- based or block-based manner. Consequently, the atmospheric flow model is informed by the local microphysics. The proposed method is tested in 2D and 3D limited-area weather problems involving storm clouds, i.e., squall line and supercell simulations.

AN IMPLICIT DISCONTINUOUS GALERKIN METHOD FOR TWO-DIMENSIONAL SHALLOW WATER EQUATIONS

Younghun Kang[1], Mark Loveland[2], Corey Trahan[2] and Clint Dawson[1]*

[1]*The University of Texas at Austin*
[2]*U.S. Army Engineer Research and Development Center*

ABSTRACT

Two-dimensional shallow water (2D SW) equations are widely applied for various physical phenomena such as global tides and storm surges. Numerical models have been developed using various discretization schemes. This work focuses on the 2D SW Adaptive Hydraulics (2D SW AdH) model, which is developed by U.S. Army Corps of Engineers ([1]). The 2D SW AdH model is an unstructured, implicit, Petrov-Galerkin finite element method model. As the name implies, the AdH model is capable of adaptivity in both space and time, and the performance of AdH has been demonstrated with various test cases (see [1]). In this work, we develop an implicit discontinuous Galerkin method for 2D SWE (2D SW AdH-DG) within the 2D SW AdH framework. In the 2D SW AdH-DG model, 2D SW equations are spatially discretized using local discontinuous Galerkin method and Local Lax-Friedrichs flux is utilized for numerical flux. The 2D SW equations are temporally discretized using finite difference method, which is between first- and second- order scheme based on user-defined parameter. The model is verified with fully wet domains and the results are compared with 2D SW AdH model.

A METHOD OF SUCCESSIVE ITERATION OF ANALYSIS AND DESIGN FOR LARGE-SCALE DYNAMIC TOPOLOGY OPTIMIZATION

Zhan Kang[*1], Yixiao Zhu[1] and Xiaopeng Zhang[1]*

[1]*Dalian University of Technology*

ABSTRACT

Large-scale dynamic topology optimization of structures and metamaterials considering natural frequencies, transient responses or wave propagation properties is a challenging task due to the high computational cost required by the iterative computation of the dynamic performances and their sensitivities. This presentation introduces recent developments of a new framework based on successive iteration of analysis and design (SIAD) for finding high-quality solutions at affordable computational costs. In the original SIAD method for natural frequency-related topology optimization problems, the eigenvalue solution routine is integrated into the optimization iterations to achieves sequential approximations of the eigenpairs along with the structural design evolution, thus avoiding the time-consuming eigenpair analysis in each optimization iteration. A multi-step relay approach has been developed to further enhance the computational efficiency, in which the optimization process starts from a relatively coarse finite element discretization, and then gradually refined meshes are used to improve the design resolution. For a given level of mesh resolution, by sequentially solving the optimization problem and projecting intermediate designs and the corresponding approximate eigenmodes from a coarser mesh onto finer meshes, the proposed multi-step relay method can further reduce the computational cost and yield high-resolution solutions in the final design. This method can be used to solve natural frequency maximization topology optimization problems with millions of degrees of freedom on a desktop workstation, and is much more efficient than the conventional double-loop method. The SIAD method has also been combined with a quasi-static response-enhanced mode displacement method and thus extended to topology optimization of transient responses, in which the approximate eigenmodes and quasi-static responses are used as the model reduction basis for each intermediate design. Numerical examples show that the method significantly improves the efficiency of dynamic topology optimization.

ABSTRACT

Monolithically coupled partial differential equations for thermo-poro-elastic deformation of fractured rocks are solved using the finite element method. The rock matrix is assumed to be linear elastic and isotropic, Darcy fluid flow is assumed in the matrix, and laminar fluid flow is assumed in the fractures. The volume is discretised by tetrahedral and hexahedral meshes, using quadratic or mixed Taylor-Hood elements for improved stability. Fractures nucleate in response to the local accumulation of damage. Fractures are sub-dimensional features represented by NURBS surfaces to capture the geometry; on these, a hybrid sub-dimensional isogeometric solution is embedded and coupled with a volumetric finite element solution. These solutions locally interpolate the fields, yielding a dual representation on the fracture surface and leading to smoother approximation of stress intensity factors around the fracture tips. Growth angles are computed using the Richard method based on the stress intensity factors, resulting in crack propagation vectors that modify the discrete geometry of the resulting non-planar fractures. After each growth event the geometry and discretisation are regenerated and optimised to the new geometry. Examples of coupled deformation and crack growth are shown in the context of fracturing under coupled thermo-poro-elastic processes. Resulting fracture patterns are compared against experimental and field observations.

DIGITAL TWIN INFERENCE FROM MULTI-PHYSICAL SIMULATION DATA OF ADDITIVE MANUFACTURING PROCESSES: PROOF OF CONCEPT STUDY

Maximilian Kannapinn[*1], Felix Rutsch[1] and Oliver Weeger[1]*

[1]*Technical University of Darmstadt*

ABSTRACT

A digital twin is a virtual representation that accurately replicates its physical counterpart, fostering bi-directional real-time data exchange throughout the entire process lifecycle. This study explores the integration of digital twins into additive manufacturing processes, particularly focusing on lattice structures. In additive manufacturing, digital twins help to control the process better and progressively react to unplanned processing results. Employing faster-than-real-time and highly accurate surrogate models enables the prediction of altered structural properties, facilitating on-the-fly re-optimizing the ongoing manufacturing process to still achieve desired structural outcomes. Consequently, this approach contributes significantly to realizing the first-time-right paradigm in additive manufacturing.

The foundation of successful digital twin derivation lies in the physics-based modeling of the additive manufacturing process. Predicting final structural properties necessitates mapping input parameters to potentially non-linear material properties [2]. However, a challenge arises from the need to provide faster-than-real-time replications of these mappings through simulations, particularly as the complexity and computational cost of multi-physical simulation models increase. This study addresses the aforementioned challenge by presenting an efficient training methodology for digital twins, utilizing only minimal training datasets extracted from multi-physical simulation models. An efficient design of experiments aids in selecting representative training data, ensuring minimal test error on the twin when applied to pertinent test data. The proposed solution includes a comprehensive software suite that automates simulation model management, training data selection, reduced-order model derivation, and integration of digital-twin-based control techniques into a unified framework. The versatility of this framework, specifically designed for seamless integration with various simulation models, was initially exemplified through its application in autonomous thermal food processing [1]. Remarkable efficiency gains are achieved. Computational efficiency is demonstrated by characteristic solution times of one-tenth of a second, imposing negligible processing costs on a single-core processor. The framework showcases practical viability by predicting field data with 4649 spatial points and one hour of real-time processing outputs within less than 0.5 s.

ABSTRACT

Hydrogen (H2) is considered a potential energy carrier for the next generation due to its high energy density, high combustion efficiency with zero emission, and nontoxicity. Among the various explored catalysts, two-dimensional (2D) transition metal dichalcogenides (TMD) have emerged as the state-of-the-art candidates for electrocatalytic H2 production beyond the traditional noble metal catalyst (Pt, Pd) owing to their intriguing electronic properties, large surface area, and relatively low fabrication cost. However, the insufficient utilization of active sites (edge), low electrical conductivity, and poor durability limit their intrinsic activity and the developed potential. To overcome the aforementioned issues, introducing atomic-scaled intercalation in the layered 2D materials is a powerful strategy. In this study, we introduce lithium (Li) as intercalant to promote the hydrogen evolution reaction (HER) activity and the structural stability for both the 2H- and 1T-MoS2 materials, which are revealed by the density functional theory (DFT) calculations. Our calculation results show that Li intercalation will enhance adsorption strength of H* on 2H-MoS2 basal plane, and the optimal adsorption site of H* will be changed by the position of intercalant. The computed Gibbs free energy of the HER (ΔGH*) indicates drastic enhancement of the HER reaction activity at the basal planes by Li intercalation. As for 1T-MoS2, the HER performance at the basal plane will also be promoted under the certain intercalant concentration. Such an activity enhancement can be attributed by the charge transfer between the host material and intercalant, and subsequently the rearrangement of electron density distribution for the surface atoms. Moreover, the intercalation energy demonstrates the structural stability of both the 2H- and 1T-MoS2 are improved after Li intercalation, especially for 1T phase. Even for the maximum intercalant concentration (LiMo2S4), it still yields the negative value of intercalation energy (-0.702 eV and -1.714 eV for 2H- and 1T-phase, respectively), implying that intercalated MoS2 are thermodynamically stable. In summary, both the HER activity at the basal plane and structural stability of layered MoS2 materials can be substantially promoted via Li intercalation. Hence, we demonstrate that intercalation is the effective methodology to enhance the HER performance on the basal plane of 2D material as the alternative way to the defect engineering.

CONCEPTUAL DESIGN FOR PREDICTIVE DIGITAL TWINS: CONCEPTS, TOOLS, AND TECHNIQUES TO ENSURE FITNESS FOR PURPOSE

Michael Kapteyn[1] and Karen Willcox*[1]

[1]*The University of Texas at Austin*

ABSTRACT

Advancements in computational technologies, including reduced-order modeling (ROM), uncertainty quantification (UQ), and scientific machine learning (SciML), offer significant potential for improving the accuracy, efficiency, and robustness of digital twins. However, adopting a systems engineering perspective reveals that the design of a digital twin is a multi-objective optimization problem, with inherent tradeoffs across multiple axes such as investment in technology development, computational costs, implementation complexity, accuracy, reliability, and robustness [1]. Thus, the challenge lies in making data, modeling, and algorithmic choices that align with the application area, decision-support context, and computational constraints, so as to ensure that the resulting digital twin is “fit-for-purpose” [2].

In this presentation I will discuss the above challenges, highlighting the understudied conceptual design phase in digital twin development and drawing parallels to the multidisciplinary engineering design optimization of physical systems. I will then present ongoing work to address these challenges by developing conceptual design tools for digital twins. First, I will build upon the mathematical abstraction for digital twins established in prior work [3] to develop a definition language for digital twin architectures. I will then discuss tools and techniques for assessing the performance characteristics of different digital twin architectures. The goal of this work is to empower digital twin designers to navigate and explore tradespaces over various architectural decisions, develop a fit-for-purpose digital twin architecture, and derive requirements for the various models and algorithms that comprise the digital twin. Such requirements can then drive the research, development, and adoption of computational technologies such as ROM, UQ, and SciML. I will illustrate these concepts and developments in the context of ongoing work within the Willcox Research Group, showcasing digital twin applications ranging from cancer patients to space satellites.

MECHANICS OF 3D INTERTWINED LATTICES

Konstantinos Karapiperis[1] and Dennis Kochmann*[1]

[1]*ETH Zurich*

ABSTRACT

Architected truss lattice materials have recently enjoyed popularity due to advances in 3d-printing, and they are being increasingly used in several applications. In particular, intertwined lattices have emerged as a new family of architected materials, which replace conventional struts with intertwined or woven strands. By extending principles of weaving, typically found in two-dimensional fabrics, to bulk three-dimensional architectures, these materials promise interesting properties.

First, we an efficient an efficient numerical framework for computing the effective mechanical response of periodic intertwined materials, relying on a nonlinear beam formulation, and a conforming frictional beam-to-beam contact algorithm, embedded into a computational homogenization framework. Next we discuss how we can explore the design space of such materials, specifically the generation of the topology and geometry of intertwined unit cells, by casting it into an optimization problem. We quantify the effect of unit cell topology on the effective mechanical response of an inertwined unit cell, and present additional applications where we design architectures with properties such as tunable elasticity and high energy absorption. Lastly, we cover the experimental calibration and validation of the model, with experiments on 3d-printed intertwined materials.

RELATIONSHIP BETWEEN PERFECTIONISM TENDENCY AND SPORTS INJURIES

Satsuki Karino[*1]*

[1]*Toyo University*

ABSTRACT

Most of the world's top athletes have a “perfectionist mindset," which suggests a relationship with poor health and maladjustment. Additionally, as Japan's Internet usage rate (SNS usage rate) continues to increase, opportunities to compare oneself with others in SNS activities will increase significantly. Therefore, it is suggested that in the future in Japan, the number of young people with “perfectionist thoughts" will increase, as well as the number of athletes with perfectionist thoughts. Furthermore, “sports injuries" are one of the events that can disrupt an athlete's competitive life, and even these “sports injuries" can be seen to be associated with poor health and maladjustment. However, there is currently very little research linking “perfectionist tendencies" and “sports injuries." A survey was conducted among athletes and former athletes affiliated with University A. There were three scales/questionnaires used: one was the four factors that emerged from a multifaceted view of "self-oriented perfectionism," which is one of the perfectionist ideologies, "setting high goals for oneself." The “new multidimensional self-oriented perfectionism scale (MPPS) " includes “desire for perfectionism ", “personal standard", “concern over mistakes ", and “doubting of actions ". The second is the “scale for Assessing in injured Athletes," which includes “development of self-understanding" and “expanding and deepening subjective considerations," which are two important factors for returning to competition. Finally, we used “sports-related questions" that asked participants about their competitive history, whether they had ever been injured, the details of their injuries, and the causes of their injuries. As a result, the “personal standard " included in the “new multidimensional self-oriented perfectionism scale " was found to be positively correlated with “development of self-understanding" and “expansion and deepening of the scope of consideration. In addition, in a question related to sports, it was suggested that one issue with club and sports activities in Japan is that injuries are increasing due to “over-practicing." In the future of athlete education in Japan, it will be necessary not only to focus on athletes' physical aspects and performance, but also to conduct psychological tests and understand their personality traits. As a future issue, what kind of research results can be obtained when there is a strong tendency for other perfectionism such as "other-oriented perfectionism" or "socially-oriented perfectionism"? Both findings suggest an increase in knowledge about how to avoid "over-training" and improve athletes' abilities.

A COMPUTATIONAL PRESTRESSING ALGORITHM FOR BIOLOGICAL TISSUES: APPLICATION TO THE AORTA AND CONSEQUENCES ON GROWTH AND REMODELING

Ali Akbar Karkhaneh Yousefi[*1] and Stéphane Avril*[1]

[1]*École des Mines de Saint-Étienne*

ABSTRACT

In computational biomechanics, accurately modeling biological tissues presents a unique challenge, particularly for patient-specific applications. Classical continuum mechanics and finite element methods usually rely on known stress-free reference configurations, a condition not met when modeling tissues reconstructed from in vivo medical images. The identification of the stress-free configuration is an inverse problem with high computational costs, especially when applying the constrained mixture theory, which considers varied material properties and homeostatic stretches in different tissue constituents [1]. Addressing this, we propose a novel prestressing methodology designed to approximate the in vivo residual stress field or identify its stress-free configuration.

Our approach, inspired by thermal contraction principles, innovatively updates the deformation gradient incrementally at each integration point, to minimize deviation of the loaded geometry from the actual in vivo geometry. Implemented in the commercial finite element solver Abaqus through the UMAT subroutine, our algorithm demonstrates rapid convergence in complex patient-specific geometries, including human ascending and abdominal aortas.

By successfully identifying the in vivo residual stress map as an initial condition, we explored arterial wall growth and remodeling under various mechanical stimuli. By maintaining the mechanobiological equilibrium in our finite element simulations [2], we measured changes in wall morphology and tissue composition in response to alterations in internal pressure and axial tension. Notably, our findings highlight the importance of incorporating residual stresses in simulations, as evidenced by comparing results obtained with and without prestressing.

This research advances computational biomechanics and paves the way for more precise patient-specific simulations, essential for understanding and predicting tissue behavior under both physiological and pathological conditions.

Keywords: Inverse finite element, Prestressing, Constrained mixture, growth & remodeling, Patient-specific modeling.

IMPLICIT GEOMETRIC REPRESENTATION FOR THE CONSTRUCTION OF OCTREE-MESHES FOR FINITE ELEMENT ANALYSIS

Samundra Karki[*1], Mehdi Shadkhah[1], Adarsh Krishnamurthy[1] and Baskar Ganapathysubramanian[1]*

[1]*Iowa State University*

ABSTRACT

Recent advancements in 3D surface representation have witnessed a shift toward using neural implicit surfaces, which exploit the capabilities of neural networks or multi-layer perceptrons (MLPs) to represent complex geometry. Specifically, these implicit representations use the signed distance to query the occupancy information at a 3D location, departing from traditional ray tracing methods used in mesh-based geometry. MLP-based representations can capture geometry with arbitrary topology, provide multi-resolution control, and maintain an efficient memory footprint [1]. Despite the versatility of implicit representations, their application in computational analysis remains largely unexplored.

In this work, we explore using neural network architectures for constructing octree meshes for complex geometries. We explore different loss functions optimized for reconstructing the signed distance fields of complex geometries. The trained MLPs are integrated with an octree-based Finite Element Method (FEM) solver (Dendrite-kt), which can be directly used for fluid flow simulations over complex geometries [2]. We empirically show this methodology is faster than the conventional ray tracing algorithms used for octree construction, especially for geometries consisting of a large number of triangles. The streamlined structure of MLP architectures ensures that they can be efficiently embedded within a single CPU node, markedly enhancing the computational tractability and scalability of high-performance simulations. We have validated these methods to confirm that these MLP-driven models attain a level of precision analogous to that of established ray tracing techniques, thereby preserving the accuracy of previously validated simulation results.

A GENERALIZED HOMOGENIZATION APPROACH TO DESCRIBE THE ORIENTATION DYNAMICS OF FIBER SUSPENSIONS

*Tobias Karl**[1] and Thomas Böhlke*[1]

[1]*Karlsruhe Institute of Technology*

ABSTRACT

Predicting the evolution of fiber orientation during mold filling of fiber suspensions is a computationally challenging task. To keep the computational effort reasonable, the averaging concept of fiber orientation tensors [1] is used in engineering practice. The fiber-induced anisotropic viscosity of the suspension leads to a so-called flow-fiber coupling, i.e. the fiber orientation influences the flow field and vice versa. In this context, the anisotropic viscosity of the fiber suspension must also be considered in the fiber orientation evolution equation beyond the standard kinematic terms in order to model the orientation dynamics comprehensively.

In this contribution, a generalized evolution equation for the fiber orientation tensor of arbitrary order is formulated that takes into account the microstructural anisotropy of the fiber suspension. This computationally efficient coarse-grained formulation is based both on the consideration of a single fiber at the microscale and on an upscaling of the respective local spin tensor. In this context, a previous work [2] is generalized and the corresponding methodology of using a linear homogenization approach is applied. The derived fiber-fiber interaction term is discussed as a micromechanical convergence criterion of the underlying integral operator. It is discussed how the special case of Jeffery's equation [3] follows from this general formulation. Beyond Jeffery's approach, the generalized evolution equation is specified for additional mean-field models. In this context, a novel equation is presented to describe the evolution of the fiber orientation tensor of arbitrary order depending on the spatial fiber distribution.

The prediction of fiber orientation in a shear flow is investigated with respect to different mean-field models. It is shown that the type of mean-field model, the fiber volume fraction, and the spatial fiber distribution significantly affect the orientation dynamics of the fiber suspension. The computational complexity of the considered mean-field models is discussed in terms of constraints on the choice of an efficient closure method and numerical integration on the unit sphere. It is found that there are significant differences between the considered models and that an encapsulated numerical integration leads to an unacceptably high computational cost.

CONSTRAINED OPTIMIZATION OF SENSING IN NUCLEAR REACTORS UNDER UNCERTAINTY

Niharika Karnik[*1], Mohammad Abdo[2] and Krithika Manohar[1]*

[1]*University of Washington*
[2]*Idaho National Laboratory*

ABSTRACT

The optimal placement of sensors with respect to restrictive spatial constraints is essential for the reconstruction of nuclear reactor flow fields and online calibration of nuclear digital twins. We develop a data-driven optimization technique for sensor placement, which aims to minimize reconstruction error of flow fields under sparse, noisy sensor measurements. The proposed greedy algorithm optimizes sensor locations over high-dimensional grids, adhering to spatial and dynamic constraints based on operating tolerances of sensors. We apply the algorithm to the Out-of-Pile Testing and Instrumentation Transient Water Irradiation System (OPTI-TWIST) prototype capsule, which is electrically heated to emulate the neutronics effect of the nuclear fuel. The resulting sensor-based temperature reconstruction within OPTI-TWIST demonstrates minimized error, provides probabilistic bounds for noise-induced uncertainty, and establishes a foundation for communication between the digital twin and the experimental facility.

A NOVEL, CONSISTENCY-BASED METRIC FOR PROBABILISTIC REMAINING USEFUL LIFE MODEL SELECTION

Dongjin Du[1], Pranav Karve[1] and Sankaran Mahadevan[1]*

[1]Vanderbilt University

ABSTRACT

Physics-based, data-driven, and hybrid models are used for remaining useful life (RUL) prediction in various engineering applications. These models are usually calibrated/trained using data obtained from accelerated material failure tests. The calibrated/trained RUL model is, however, used to predict material performance under normal operating conditions. Normal operating conditions are significantly different than the accelerated test conditions, and material failure data under normal operating conditions is not available in many cases. To tackle the problem of choosing the best probabilistic RUL prediction model for such extrapolation situations, a model consistency-based metric is proposed in this research. The proposed metric evaluates the inconsistency in the probabilistic RUL prediction, where inconsistency is measured using the statistical distance between probability distributions of RUL over the probability distribution of normal operating conditions. A two-step approach for model selection is proposed. In the first step, model validation is performed using previously developed metrics and accelerated test data. In the second step, model consistency is evaluated for the normal operating conditions. The model with superior performance in both these steps is chosen to be the best RUL prediction model. The proposed methodology is demonstrated using five RUL models for polyethylene (PE) pipes. Bayesian inference is used to calibrate these models using accelerated test data. The proposed two-step model selection methodology is compared against traditional model selection methods (goodness of fit, model complexity and information theoretic metrics). The proposed methodology is applied to different normal operating conditions, and it is shown how different models could be more consistent in predicting PE pipe RUL under these circumstances. It is shown that the proposed additional consistency criterion is useful for selecting the best RUL prediction model in these, practically relevant, scenarios.

HPC CONSIDERATIONS FOR GLOBAL KM-SCALE EARTH SYSTEM MODELS

Stanley Posey[1] *and Karthik Kashinath**[2]

[1]*NVIDIA Corporation*
[2]*NVIDIA*

ABSTRACT

Efforts are underway in the weather and climate modeling community towards substantial horizontal resolution refinement of global atmosphere GCMs to km-scale in order to explicitly resolve some of the small-scale convective cloud processes and provide more realistic local information on climate change and extreme weather events. At the same time, Exascale HPC systems have arrived and in most cases are powered by GPU accelerator technology that offers opportunities in practical simulation turn-around times balanced with efficiency in energy consumption. High-resolution model developments driven by the need for global storm-resolving simulations featured in projects such as DNA Climate, DYAMOND, SCREAM, nextGEMS, and EXCLAIM have motivated NVIDIA collaborations in GPU development of Exascale-ready AGCMs for next-generation Earth system models. This talk will describe the challenges and expectations for the directions of accelerator-based programing methods, GPU strong-scaling experiences with km-scale AGCMs, and large data handling for post-processing and visualization; and examine the requirements to develop Earth system digital twins from km-scale models as proposed in programs like the EU Destination Earth and NVIDIA Earth-2.

DATA-DRIVEN EXPLORATION OF STRUCTURE-PROPERTY LINKAGES AND INVERSE DESIGN OF MATERIALS

Markus Kästner[*1], Alexander Raßloff[1], Paul Seibert[1] and Karl Kalina[1]*

[1]*TU Dresden*

ABSTRACT

Being able to design, e.g., the microstructure of a material to achieve a desired behavior is a key enabler for innovation. To achieve this goal, knowledge about the influence of the local material structure on the mechanical properties of the material, e.g. measured in terms of stiffness, strength or ductility, must be acquired. Ideally, experiments and simulation results are combined to build structure-property linkages. The key challenge is then to invert this knowledge to find a material structure for a desired set of material properties. This process is known as inverse design.

While surely inverse design is challenging, even the forward prediction of SP linkages using multiscale simulations of complex microstructures is still a demanding task. The difficulties lie in (i) describing the features of the local material structure, (ii) reconstructing plausible 3D statistically representative volume elements (SVEs), e. g., from 2D slices like microscopy images, (iii) modeling the complex and non-linear effective constitutive response and (iv) using it in an efficient multiscale scheme.

In this contribution, we present recently developed methods that aim at addressing these issues and it is shown how to integrate them in an efficient workflow. Descriptors are employed to characterize complex microstructures. Examples of such descriptors are volume fraction, generalized spatial n-point correlations or Gram matrices of pre-trained convolutional neural networks. Corresponding SVEs are generated using differentiable microstructure characterization and reconstruction (DMCR). An advantage of DMCR over similarly efficient reconstruction algorithms is that it allows to prescribe generic high-dimensional microstructure descriptors as long as they are differentiable. The reconstructed structures are then used for numerical simulation and effective properties are obtained from homogenization techniques. Together with the descriptors of the local material structure, SP linkages are set up.

As engineering data, including the SP linkages, are generally costly to generate, inverse design has to cope with scarce data. We therefore employ a Bayesian optimization approach and it is shown that significantly less data are needed in comparison to classical sampling procedures and alternative inverse design methods which is due to the iterative data augmentation. The approach is demonstrated for spinodoid metamaterials. In future work, the active learning augmentation loop could be applied to a broader range of materials.

DATA-DRIVEN TOPOLOGY OPTIMIZATION FOR NON-RELAXED STRESS MINIMIZATION PROBLEMS

Misato Kato[1], Taisei Kii[1], Kentaro Yaji[1] and Kikuo Fujita[1]*

[1]*Osaka University*

ABSTRACT

In structural design, stress concentration is a crucial consideration due to its significant influence on the strength of the structure. Consequently, there are many studies related to topology optimization for the maximum stress minimization problem. However, the following issues remain with conventional topology optimization methods.
Firstly, gradient-based methods are commonly employed for topology optimization, but they require transforming the original problem into any differentiable pseudo-problem through relaxation techniques. These relaxation techniques include grayscale, approximation of maximum stress, and relaxed stress. Although these techniques are essential for the gradient-based methods to solve maximum stress minimization problems, these methods only solve a pseudo-problem.
The second difficulty is stress concentration caused by structured mesh. The structured mesh is generally used in topology optimization, but it creates staircase-like boundaries that will have stress concentrations. Generally, after optimizing with structured mesh, post-processing such as smoothing is applied to the optimized designs, and they are evaluated by stress analysis using body-fitted mesh. However, the maximum stress values can change significantly with slight structural modifications through these post-processing steps.
To overcome these issues, we propose a new approach to treat the non-relaxed maximum stress minimization problems and optimize them based on evaluation using body-fitted mesh. In this study, we focus on data-driven multifidelity topology design (MFTD) [1], which is a non-gradient topology optimization approach using a deep generative model. Its concept involves dividing the design problem into low-fidelity optimization and high-fidelity evaluation, iteratively updating solutions based on Evolutionary Algorithms (EAs). We generate multiple diverse and reasonable initial solutions through conventional gradient-based topology optimization using relaxation techniques as the low-fidelity optimization model. Their objective values are evaluated with the exact analysis model using body-fitted mesh as high-fidelity evaluation, and iteratively update the solutions by using a deep generative model as a crossover-like operation in EAs.
We apply the proposed approach to L-bracket and compliant mechanism design problems. We obtain initial solutions by solving the gradient-based topology optimization using the p-norm stress measure and solve the non-relaxed maximum stress minimization problems. The optimized designs obtained through data-driven MFTD are more rounded structures that alleviate stress concentration and completely dominate the initial solutions, demonstrating the effectiveness of our proposed approach.

DENSITY-BASED TOPOLOGY OPTIMIZATION FOR ITR-FREE THERMAL CLOAK

Seitaro Kato[1], Kohei Takejima[1], Yugo Kondo[1] and Garuda Fujii[1]*

[1]*Shinshu University*

ABSTRACT

Thermal cloak was proposed as an analogy to invisibility cloak in thermotics and it has been developed as a metadevice to make an obstacle thermally undetectable by controlling temperature distribution around the obstacle as if nothing is present. Thermal cloaks are usually composed of thermal metamaterials with artificial microstructures that provide the anisotropic/isotropic heat conduction required by transformation thermodynamics. Besides, a thermal cloak composed of naturally available isotropic materials has also been proposed such as bilayer cloaks. Topology optimization is promising numerical approach to optimize the distribution of isotropic materials around an obstacle for designing thermal cloaking structures. Topology optimization based on level set, density, and homogenization methods have been implemented, respectively, for the optimal design of thermal cloaks.

The above previous works attempted to compose thermal cloaks more than two materials with different thermal conductivity. It is well known that the effect of interfacial thermal resistance (ITR) between two different materials increases as the scale decreases and has a significant impact on device performance in nanoscale heat transfer. Similar problems have been reported for thermal cloaking, and it is necessary to construct a thermal cloak using only one material to prevent degradation of thermal cloaking performance due to ITR.

To overcome the problem on the ITR, ITR-free thermal cloak was proposed. Effective thermal conductivity in two-dimensions is adjusted by changing the height of the host material. The height distribution is set based on the bilayer scheme to achieve a two-dimensional thermal cloak.

In this work, we attempt to optimize the structural topology of ITR-free thermal cloak by a density-based topology optimization. Thermal cloaks are usually composed of more than two materials, but the presented ITR-free thermal cloak is composed of single material by changing the structural height of the host material. The local height of the host plate is optimized as continuous design variable, and hence, grayscales are interpreted as a structural height of host structure. Optimal configurations obtained exhibit good cloaking performance, and we investigate how the cloaking performance changes when the maximum height of the host material and volume constraint in the fixed design domain are changed.

LARGE-SCALE UNSTEADY FLOW TOPOLOGY OPTIMIZATION WITH HIERARCHICAL CARTESIAN MESH METHOD AND ITS PARALLEL PERFORMANCE EVALUATION

Ryohei Katsumata[*1], Koji Nishiguchi[1], Hiroya Hoshiba[1] and Junji Kato[1]*

[1]Nagoya University

ABSTRACT

In recent years, topology optimization methods have been applied not only to structural problems but also to fluid flow problems. Most of the previous studies assume steady flows or two-dimensional flows. In contrast, this study focuses on topology optimization for unsteady flows[1], which are more general from an engineering point of view. However, topology optimization for unsteady flows involves solving the governing and adjoint equations of a time-evolving system, which is computationally more expensive than for steady-state flows. Thus, a method suitable for large-scale computation, i.e., a numerical method with high parallel efficiency, is indispensable to perform topology optimization with a finer computational mesh. Therefore, we propose a large-scale unsteady flow topology optimization method based on the building-cube method (BCM)[2], which is one of the hierarchical Cartesian mesh methods. The BCM is suitable for massively parallel computing and has been confirmed to have excellent scalability[3]. The governing and adjoint equations are discretized by a cell-centered finite volume method based on the BCM. The sensitivity of the objective function is obtained by the continuous adjoint method. In the presentation, we discuss the applicability of the proposed method to large-scale computation through several examples of topology optimization and evaluation of computational efficiency by weak scaling.

COMPUTATIONAL MODELING OF NANOPARTICLE-COATED SURFACES FOR RENEWABLE ENERGY APPLICATIONS

*Chao-Cheng Kaun**[1]

[1]*Academia Sinica*

ABSTRACT

Using first-principles calculations based on density functional theory, we investigate the efficiencies of hydrogen evolution reaction (HER) and CO2 photoconversion on nanoparticle-coated surfaces. Effects of hydrogen spillover, nanoparticle-substrate interaction and material configuration are addressed. Particularly, our calculations show that the Pt/ZnO heterostructure has a good performance for the HER process [Int. J. Hydrogen Energy 47, 40768 (2022)], the adsorption energies of H and CO on TiO2 can be the electronic structure-based descriptors of Pt/TiO2 heterostructures for photocatalytic CO2 conversion to distinguish between H2 evolution and CH4 formation [Appl. Surf. Sci. 635, 157678 (2023)], and the synergistic effects of multiple-oxides/metal composition enhance the disassociation of H-OH and the evolution of H* to gaseous H2, thus achieving high activity of a composition design for noble metal free catalyst [ChemSusChem 16, e202300820 (2023)].

A COMPACT SIXTH ORDER FINITE DIFFERENCE SCHEME FOR THE 3D POISSON EQUATION

Chris Kavouklis[*1]

[1]*Lawrence Livermore National Laboratory*

ABSTRACT

We present a sixth order finite difference scheme for Poisson's equation when discretized with the compact 27-point stencil based on Mehrstellen corrections of the forcing function term f. Our approach results in a sixth order accurate solution error as opposed to a fourth-order error imposed by the classical Mehrstellen correction for the 19-point and 27-point stencils. The present study is a continuation of former work of Spotz and Carey (1996) on compact finite difference schemes for Poisson's equation where sixth order convergence may be obtained under the assumption that the fourth order derivatives of f are determined analytically. Specifically, we show that sixth order convergence can still be attained when only values of f at grid points are available. The sixth order Mehrstellen scheme is further coupled with a Method of Local Corrections (MLC) 3D Poisson solver improving to sixth order accuracy the results reported in Kavouklis and Colella (2019). The MLC test case considered involves an adaptive grid that comprises 7.5 billion cells.

AUTONOMOUS TRAJECTORY GENERATION AND CONTROL OF WELDING ROBOT MANIPULATOR FOR TUBULAR WORKPIECES USING DIGITAL TWIN

Abreham Kebede[*1] and Asheber Wagshum*[2]

[1]*Data Science and Machine Learning*
[2]*National Taiwan University of Science and Technology*

ABSTRACT

Industrial robots are undergoing rapid evolution within the manufacturing sector. Two primary methods for programming robots include online programming via pendants and offline programming. However, employing the conventional online teaching method via the robot teach pendant for programming industrial robots is a laborious and time-consuming process that demands skilled expertise and disruption of the production line. A digital twin serves as a virtual representation of a physical object and process. This study aims to utilize a digital twin to facilitate offline autonomous welding path generation and advanced autonomous control of KUKA 6 Degree of Freedom (DOF) industrial welding robot manipulator for various tubular workpieces within the ROS environment and Python programming. The system's architecture incorporates sensors' data input, 3D models, model reduction, end effector trajectory generation and robot control. The publishing component of the digital asset enables individual joint motion controls of the robot to maneuver the end effector to the optimal position and orientation relative to the workpiece. A welding operation is simulated to illustrate the data exchange between the robot within its workspace and its digital version. The acquired data is stored and manipulated to establish a base for generating optimal welding trajectories for tubular workpieces. For the most effective and reliable welding application on tubular workpieces, detailed dimensional information along the generated end effector trajectory is essential. The point cloud models of tubular specimens are generated through 3D scanning. The MIG welding torch path planning is derived from the 3D model of the workpiece and instrumented workpiece positioner system. The point cloud model of the tubular workpiece is simplified to a skeletal line to reduce model complexity. Furthermore, to enhance welding quality, cross-sectional shapes and dimensions of the workpiece are autonomously identified along the generated welding torch path using the 3D model and a shape signature algorithm. Subsequently, specific welding tasks are applied to each segment of the workpiece based on autonomously identified cross-sectional dimensions, shape types and generated trajectory.

PROXIMAL GALERKIN: A STRUCTURE-PRESERVING FINITE ELEMENT METHOD FOR POINTWISE BOUND CONSTRAINTS

Brendan Keith[*1] and Thomas Surowiec*[2]

[1]*Brown University*

[2]*Simula Research Laboratory*

ABSTRACT

The proximal Galerkin finite element method is a high-order, low iteration complexity, nonlinear numerical method for solving variational inequalities that arise from pointwise bound constraints in infinite-dimensional function spaces. This talk will introduce the proximal Galerkin method and demonstrate how it preserves the geometric and algebraic structure of pointwise bound constraints, leading to robust, mesh-independent algorithmic solutions to solve free boundary and optimal design problems. This talk is based in part on [1] but will include new results and applications.

[1]*Brown University*
[2]*Lawrence Livermore National Laboratory*
[3]*Stony Brook University*

ABSTRACT

Engineering design involves estimating and optimizing immediate and long-term performance, manufacturing and maintenance costs, system response, levels of damage, and numerous other quantities of interest. In such environments, practical decisions are regularly made with significant aleatoric uncertainty, incomplete system knowledge, and various physical or financial constraints. In order to characterize a safe, reliable, and cost-effective product, a careful assessment of risk must be incorporated into the decision-making process.

Low-probability, high-consequence events can be mitigated by specifying a target quantile and optimizing for the associated tail expectation, also known as the conditional value-at-risk (CVaR) [1]. However, most techniques for CVaR optimization become prohibitively expensive for large quantiles because of the low frequency of drawing samples in the tail. In this talk, we present an efficient stochastic algorithm for CVaR optimization where the sampling distribution is adapted at every iteration to increase the probability of drawing samples in the tail. In turn, an optimal sampling distribution is found hand-in-hand with an optimal design variable. We use various design problems in engineering, particularly topology optimization under uncertainty, to illustrate the approach.

IMPROVING ALGEBRAIC MULTIGRID PERFORMANCE FOR HIGH-ORDER FINITE ELEMENTS WITH MULTIPOINT CONSTRAINTS

Máté Kelemen[*1], Roland Wüchner[1] and Suneth Warnakulasuriya[1]*

[1]*Technische Universität Braunschweig*

ABSTRACT

The main goal of high-fidelity structural analyses is recovering a detailed stress field, which makes high-order element formulations particularly appealing. In an effort to reduce the complexity of large assemblies, multipoint constraints are often used to represent subcomponents. Since these large problems are too big for direct solvers, they are usually solved with iterative algebraic multigrid solvers [1]. However, traditional AMG (algebraic multigrid) solvers are ill-equipped to handle linear systems produced by high-order finite elements efficiently. An option to improve their performance is exploiting the high-order formulations to perform optimal coarsening on the first few levels [2, 3]. Nevertheless, such methods have limitations, such as failing to handle multipoint constraints.

In this work, we extend the hybrid geometric-algebraic multigrid linear solver with support for multipoint constraints. Benchmark cases comparing the performance of existing methods to the proposed one are studied.

A CRYSTAL PLASTICITY MODEL TO STUDY STRESS LOCALIZATION AND SIZE-DEPENDENT TENSILE PROPERTIES OF ADDITIVELY MANUFACTURED NICKLE-BASE SUPERALLOY: HAYNES 214™ AT ELEVATED TEMPERATURE

Mohammad Keleshteri[*1], Subhadip Sahoo[1], Jason Mayeur[2] and Kavan Hazeli[1]*

[1]*The University of Arizona*
[2]*Oak Ridge National Lab*

ABSTRACT

Microstructures found in additively manufactured (AM) components often display unique characteristics in contrast to those produced using conventional manufacturing processes. Generally, these differences stem from the specific thermal histories experienced at the local level during the additive manufacturing build process. Previous research has illustrated that the mechanical properties of AM thin-walled structures (TWSs) can experience significant variations in response to changes in wall thickness, and this variability is dependent on temperature. The impact of temperature on these variations becomes more pronounced, particularly at elevated temperatures. The goal of this research is to investigate the nature of this size effect on tensile properties, such as yield strength, strain hardening rate, and ductility, for AM HAYNES 214 particularly under conditions of elevated temperature. To explore the size effect, thin-wall structures were fabricated with four different thicknesses: 1.0mm, 1.5mm, 2mm, and 2.5mm. To obtain the constitutive response, initially, we developed a robust approach to generate a representative volume element. Commencing with electron backscattered diffraction (EBSD) images of sections, the technique generates distributions of various morphological and crystallographic parameters, such as grain sizes, texture, and twin fraction. The effectiveness of the entire methodology is confirmed through a successful comparison of different statistics derived from the simulated microstructures with the actual EBSD data. Subsequently, we employed the Crystal Plasticity Fast Fourier Transform (CPFFT) based spectral method and relying on the phenomenological hardening law. We have successfully established a correlation between the local stress analysis conducted at the grain level and the global mechanical behavior observed in experimental results. This comprehensive examination of stress and strain at the micro level has uncovered variations in mechanical properties that are directly linked to the thickness of the TWS. Additionally, we explored how the local stress state, influenced by grain neighborhood effects, contributes to the observed localization behavior. Variations in the arrangement and properties of neighboring grains can lead to different stress distributions at the micro level. We explored the factors that drive the non-uniform distribution of mechanical responses within the HAYNES 214 by addressing how the local stress state, influenced by these grain neighborhood effects, contributes to localization behavior. The manufacturing-induced plastic anisotropy in grain distribution discovered through this study opens avenues for future research. Specifically, it provides opportunities to modify the microstructural grain topology and solidification parameters, thereby influencing not only the mechanical behavior of TWs but also that of other load-bearing critical structures across various applications.

A TWO-SCALE PHASE-FIELD MODEL FOR TWO-PHASE FLOW IN POROUS MEDIA

Mathis Kelm[*1], Carina Bringedal[2] and Bernd Flemisch[1]*

[1]*University of Stuttgart*
[2]*Western Norway University of Applied Sciences*

ABSTRACT

Two-Phase flow in porous media is relevant for many applications and accurately capturing interfacial effects in an effective model is central to its modeling. The flow morphology can vary significantly for different physical settings and impact the behaviour on the macro scale. In order to better capture the effects of microscopic interface behaviour on the larger scale, we determine effective parameters from pore-scale information instead of relying on relative permeability curves. We use phase-fields to model two-phase flow on the pore scale with an advective Allen-Cahn formulation coupled to a Navier-Stokes equation. Using periodic homogenization we arrive at macroscopic equations and microscopic cell-problems that yield effective parameters [1]. Through numerical experiments we investigate the effects of saturations and pore-scale fluid morphologies on the computed tensors and the coupled two-scale simulation. We implement our phase-field model for two-phase flow in DuMux, using a finite volume discretization. It features staggered control volumes and a combination of cell- and facecentered variables, which communicate using a multidomain coupling manager. This serves as a solver for cell-problems in the two-scale formulation that results from upscaling. The coupling between scales is achieved using preCICE and the associated Micro Manager [2].

A BAYESIAN NEURAL NETWORK APPROACH TO MULTI-FIDELITY SURROGATE MODELING

Baptiste Kerleguer[*1]

[1]*CEA, DAM*

ABSTRACT

This talk deals with the surrogate modeling of computer code results that can be evaluated at different levels of accuracy and computational cost, called multi-fidelity. We propose a method combining Gaussian process (GP) regression on low-fidelity data and a Bayesian neural network (BNN) on high-fidelity data, see [1]. The novelty, compared with the state of the art, is that uncertainties are taken into account at all fidelity levels. The prediction uncertainty of the low-fidelity level is transmitted by Gauss-Hermite quadrature to the high-fidelity level. In addition, this method takes into account non-nested designs of experiment and non-linear interactions between levels. The proposed approach is then compared to several multi-fidelity GP regression methods on analytic functions and on a mechanical computer code.

ABSTRACT

Carrying out a Direct Numerical Simulation (DNS) of a heterogeneous structure seems expensive in terms of computational time and generally infeasible due to the high dimension of the system to be solved. The application of homogenization methods such as asymptotic homogenization [1], used in multiscale analysis of heterogeneous structures, allows not only a reasonable computational time but also a good efficiency. However, obtaining the local fields by straigthforward techniques like linear relocalization can induce discontinuties accross macro elements boundaries and low accuracy in presence of microstructure and strain gradients

We propose a novel approximation to estimate local fields in heterogeneous structures exhibiting a mesostructure gradient in the context of non scales separation. It improves the relocalization step by ensuring the continuity of the relocalized fields within a finite element framework for linear elastic heterogeneous materials.

The methodology involves the following steps. First, the structure is divided into non-periodic sub-domains. For each of these, a classical first-order homogenization is performed and the effective properties associated with that subdomain are calculated. A first spatial regularization of the effective properties is then performed on the structure. The macro problem is then solved using these macro effective properties. The resulting macro-deformations are regularized and used to perform a differential Kruch relocation process [2].

As a result, spurious discontinuities across macro-elements are reduced and the effects of deformation gradients can be captured even when using a first-gradient homogenization scheme.

Applications to composites or heterogeneous materials with microstructure gradients are presented to demonstrate the potential of the technique.

DEVELOPING A FORMULATION OF STRUCTURAL DESIGN OPTIMIZATION PROBLEMS FOR QUANTUM ANNEALING

Fabian Key[1] and Lukas Freinberger*[1]

[1]*TU Wien*

ABSTRACT

We develop a formulation of structural design optimization problems, which aims to be solved by quantum annealing (QA) on currently available devices. In structural design optimization, the goal is to improve the performance and efficiency of structures by finding the best design, e.g., a choice of component dimensions, that meets specific criteria, such as maximizing strength. This process typically involves computational optimization methods to explore various design possibilities. Here, a recently evolving strategy based on quantum mechanical effects is QA. In this context, a suitable problem needs to be provided in a specific formulation, e.g., as a quadratic unconstrained binary optimization (QUBO) model. Therefore, we present a corresponding formulation for structural design optimization problems. In such a problem, an analysis model is required to evaluate the structure's performance. For this purpose, we use energy minimization principles to determine how a structure behaves under applied loads. This allows us to merge the analysis problem with the optimization problem as one overall minimization problem. Finally, mapping this problem to a QUBO problem enables us to solve it with QA.

We apply this approach to a one-dimensional sizing problem of a compound bar under self-weight loading [1]. In this course, we study how specific aspects of the formulation influence the number of required qubits. The accuracy of the obtained results is evaluated by means of analytic solutions. In conclusion, we show that the presented formulation can be used to solve structural design optimization problems by QA on existing hardware.

[1]*Lawrence Livermore National Laboratory*

ABSTRACT

A multi-scale ALE3D high fidelity model is developed to simulate directed energy deposition additive manufacturing. The model aims at capturing at a high fidelity the powder transport from the coaxial nozzle to the work piece as well as the effect of the carrier gas and laser ray tracing heating and reveals a new kind of air-cushioned or shell-like pores as well as the advantages of ring laser beam profile. The high cost of modeling is brought down by using deep learning and data driven reduced order modeling at different scales. The end goal is to combine modeling with a data driven approach for “first time right” also referred to here as intelligent feedforward (IFF). We showcase how IFF is used to optimize laser power and scan speed to print complex large parts with overhang geometries, such as the Menger sponge, and obtain high geometric accuracy.

FAST MULTIPLE SCATTERING ANALYSES IN REDUCED SPATIAL DIMENSIONS

Tahsin Khajah[1] and Sebastian Acosta*[2]

[1]*The University of Texas at Tyler*
[2]*Baylor College of Medicine*

ABSTRACT

Volume discretization methods face multiple challenges when used for exterior scattering analyses including high computational cost, need for artificial domain truncation and accurate boundary representation. These challenges are more pronounced in multiple scattering analyses where the wave moves back and forth between multiple obstacles. Conventionally such problems are solved by meshing the space between obstacles and truncating the domain with a fictitious boundary enclosing them. This makes mesh generation even more challenging and considerably limits the flexibility to move, rotate, and reshape the scatterers which are required for design and optimization of devices relying on wave propagation phenomena. Hence, spatial dimension reduction is highly desirable. Methods relying on boundary integral equations allow spatial dimension reduction, however, these methods introduce new challenges such as the need to treat singular integral kernels and lead to dense and possibly ill-conditioned matrices limiting them to low- to mid-frequency analyses. Like boundary integral methods, On Surface Radiation Conditions (OSRC) require boundary discretization only and lead to integral equations with smooth kernels. We demonstrate possibility of enhancing the accuracy OSRC for single and multiple scattering analyses and adopt it to develop a well-conditioned method based on fundamental solution. These developments [1, 2] reduce the spatial dimensions by one as the interaction between scatterers are captured analytically; the need for treating singularities is eliminated; and reliable single and multiple scattering analyses can be performed for arbitrarily shaped scatteres in mid- to high-frequency regimes.

ACCELERATING MANUFACTURING PROCESS DISCOVERY IN MATERIAL SCIENCE THROUGH MULTI-FIDELITY NEURAL NETWORKS

Mohammad Khalil[*1], Ankit Shrivastava[1], Matias Kalaswad[1], Habib Najm[1] and David Adams[1]*

[1]*Sandia National Laboratories*

ABSTRACT

Machine learning (ML) is gaining popularity in material sciences to facilitate the optimization of manufacturing processes that deliver materials with desired properties. In such settings, the limited availability of high-fidelity data (e.g. from costly simulations/experiments) is compounded by the need for high-capacity ML models to capture complex underlying physics. When available, lower-fidelity datasets can be exploited to enhance the predictive accuracy of ML models. In this presentation, we will present a recently developed bi-fidelity neural network training strategy that combines low-fidelity synthetic data with costly high-fidelity experimental data to predict high-dimensional quantities of interest. Specifically, we are interested in predicting the crystallographic texture of molybdenum coatings across a range of process conditions. The bi-fidelity neural networks are trained to capture high-dimensional X-ray diffractograms via low-dimensional latent variables obtained through principal component analysis, exhibiting enhanced predictive accuracy in comparison to traditional learning using limited volume of high-fidelity data.

A TERZAGHI BASED APPROACH TO CONSOLIDATION ANALYSIS OF UNSATURATED SOILS

Nasser Khalili[1] and Mahnoush Gharehdaghikhajehghiasi*[1]

[1]*The University of New South Wales*

ABSTRACT

In this work, a framework is presented for the determination of pore pressures dissipation and settlement calculations during the one-dimensional consolidation in unsaturated soils. To this end, two independent diffusion-form partial differential equations similar to Terzaghi's consolidation equation are presented. Modified coefficients of consolidation for water and air phases are introduced to capture the transient flow of water and air phases during consolidation. The coefficients of consolidation are determined according to the initial state of the unsaturated soil. The solutions to these partial differential equations yield the pore water and pore air pressures at any depth and at any time in the soil layer during consolidation. A set of dimensionless curves analogous to those proposed by Terzaghi are presented to illustrate the pore water and pore air distribution during the consolidation of unsaturated porous media, permitting hand calculation of the consolidation process. The validity of the approach is demonstrated through comparison with fully coupled numerical analysis of the problem. The excellent agreement is obtained between hand calculations and the numerical results.

UNVEILING OPTIMAL CONTROL OF DOUBLY DIFFUSIVE FLOWS: NEW INSIGHTS FROM THEORY AND NUMERICAL ADVANCEMENTS

Jai Tushar[1], Arbaz Khan[2] and Manil T Mohan[2]*

[1]Monash University
[2]IIT Roorkee

ABSTRACT

This talk dives into the exciting world of optimal control of doubly diffusive flows, exploring recent theoretical advances and numerical breakthroughs. We'll unveil minimal regularity results for the governing equations, groundbreaking for their relevance beyond this specific field. Next, we'll delve into the $H^{\textrm{div}}$-conforming discontinuous Galerkin formulation, a powerful method for tackling these complex flows. Moreover, we'll establish the efficiency and reliability of residual-based a posteriori error estimators, ensuring accurate solutions at every step. Finally, we'll put these tools to the test, simulating the captivating phenomenon of small particle sedimentation in salinity-driven flows. Witness numerical results that not only validate our theoretical claims but also showcase the power of adaptive solution algorithms guided by our innovative error estimators.

CFD MODELLING OF ARTIFICIAL PLUME DYNAMICS FOR REEF CONSERVATION: UNVEILING BENCHMARKS FOR LARGE-SCALE IMPACT

Saima Bukhat Khan[*1], Joel Alroe[1] and Emilie Sauret[1]*

[1]*Queensland University of Technology*

ABSTRACT

Solar shading through the artificial production of marine fog is an innovative technique to mitigate the impacts of climate change on coral reefs. This process uses more than a thousand nozzles arranged in parallel to atomise sea water. The plume formed from the primary and secondary breakup of the sea water droplets extends over distances of more than 1km, creating a plume that scatters sunlight and shades the reef. To precisely evaluate the quality and extent of the plume to protect the reef, the accurate estimation of the plume characteristics are critical. This, however, depends on the atomisation process to generate minuscule droplets. Computational Fluid Dynamics can become a powerful tool to simulate such multiscale problems.

Past models have tackled urban haze and fire plumes using Computational Fluid Dynamics (CFD) and do not require any length precisions. Artificial plumes which are made from sea water requires precise length for fogging and shading purposes. The breakup of particles contributes to the formation of smaller droplets which are essential for plume formation. While CFD adeptly models the atomisation phenomena of single and multiple nozzles, analysing larger-scale problems remains unexplored.

The purpose of this study is to establish a benchmark for large scale scenarios involving arrays of nozzles. The physical setup consists of 1080 nozzles arranged in parallel with each fogging nozzle manifold of 12 nozzle lines and 15 nozzles per line for 6 nozzle arrays. Each nozzle has orifice diameter of 200 micrometres and nozzle array has dimensions of around 1626mm by 1270mm. The model is divided into two steps: spray breakup using single and multiple (four) nozzles with and without impaction pin configuration and its dispersion in air flow using nozzle array framework. The spray breakup step describes the subsequent breakup of droplets to the position where droplet velocity equals air velocity. This step will help in getting deeper insight into downstream flow. Nozzle spray dimensions and droplet trajectory analysis will provide the boundary conditions for the second step of nozzle array for large scale modelling. Overall, this study presents a systematic evaluation of Lagrangian-Eulerian approach to create a benchmark case for large scale plume modelling using sea water spray with single and multiple nozzle configuration. The evaluation is based on grid-sensitivity analysis with focus on impact of turbulence model for continuous phase (air), the number of particle streams for discrete phase (sea water) and nozzle spray angle.

QUANTIFICATION OF FABRICATION-RELATED UNCERTAINTIES IN TPMS LATTICES WITH IMAGE PROCESSING AND SURROGATE MODELING

Waris Khan[*1], Ece Naz Erulker[2], Gullu Kiziltas[2] and Pinar Acar[1]*

[1]*Virginia Tech*
[2]*Sabanci University*

ABSTRACT

This paper addresses the quantification of fabrication-related uncertainties in Polydimethylsiloxane (PDMS) Triply Periodic Minimal Surface (TPMS) lattice structures using image processing techniques and surrogate modeling. The aim is to develop a Finite Element (FE) model that captures the uncertainties originating from thermal and mechanical fluctuations during the 3-D printing process, enabling the assessment of homogenized mechanical properties crucial for various engineering applications.

The fabrication process often introduces deviations in TPMS lattices such as defects and surface distortions. To quantify these variations, micro-computed tomography (micro-CT) imaging is employed, providing cross-sectional images of the PDMS lattice morphology produced using 3D printed sacrificial molds. Image processing algorithms are then applied to parametrically quantify deviations, laying the groundwork for subsequent analysis.

Next, the image-based data is incorporated into a sophisticated FE model, allowing for a realistic representation of the TPMS structure's mechanical behavior. To validate the prediction accuracy of the FE model, its results for stress and strain fields are compared to the experimental data. Remarkably, a close match is observed between the experimental data and the FE model predictions, affirming the effectiveness of our approach in capturing the intricate interplay of fabrication-related uncertainties. This agreement not only validates the accuracy of the FE model but also underscores the significance of our image-processing methodology in quantifying fabrication-related uncertainties.

Furthermore, we develop a neural network (NN)-based surrogate model to predict the homogenized mechanical properties as a function of the parametric representation of the TPMS lattice structure obtained through image processing. This surrogate model improves the computing times required for the determination of mechanical properties and thus allows for the efficient creation of sufficient statistical data needed for assessing the propagation of the uncertainty on properties. Accordingly, the surrogate model representation is utilized to predict the effects of uncertainty on the homogenized mechanical properties as a function of the variations in the geometric parameters of the TPMS lattices resulting from the fabrication-related uncertainty.

In conclusion, present study contributes to a deeper understanding of lattice behavior under real-world fabrication conditions, advancing the design and application of TPMS lattices in various engineering fields. The study's findings are expected to enhance the reliability and performance of TPMS lattice structures in applications such as lightweight structural components and biomedical scaffolds.

A HYBRID MODEL FOR FLOW-INDUCED VIBRATIONS OF PIPES CONVEYING FLUID SUBJECTED TO EXTERNAL CROSS FLOW

Mahdi Riazat[1], Mojtaba Kheiri[1], Brian Vermeire[1] and Weixing Yuan[2]*

[1]Concordia University

[2]Aerospace Research Centre - National Research Council Canada

ABSTRACT

We present a hybrid analytical-computational model for studying the flow-induced vibration (FIV) of a pipe conveying fluid subjected to an external cross flow. Real-world cylindrical structures subjected to fluid flow (e.g., drilling risers and seawater intake risers) are often arranged such that combined loading with complex interactions between different FIV modes appears. These interactions often result in unexpected, unsafe dynamical behaviour, such as chaotic motions, and amplified amplitude of vibrations. Several attempts have been made so far to study these interactions for drill- and brine-string systems. Dynamics and stability of long pipes conveying fluid, simultaneously subjected to external cross flow were studied by several researchers, such as Dai et al. [1]. They found that self-excited vibration (SEV) and vortex-induced vibration (VIV) caused by axial and cross flows, respectively, may weaken or amplify each other, and that the system may display complex dynamical behaviour, such as inverse period-doubling bifurcations and chaotic motions. All those studies, however, adopted analytical models for examining the stability and dynamics of the system. Although analytical models for SEV of pipes conveying fluid are well-established in the research community, studies have shown that analytical models, such as the wake oscillator model, used for modelling VIV, still need considerable improvement. In this study, we develop a novel model by combining a three-dimensional nonlinear analytical model for SEV of pipes conveying fluid [2] with a computational fluid dynamics (CFD) model for VIV due to external cross flow [3]. This hybrid model obviates the need for a fully computational model where both internal and external flows are solved using CFD, thus significantly simplifying the modelling and reducing the computational time. The numerical results are presented for two configurations: a pipe conveying fluid immersed in a stationary fluid, and a pipe conveying fluid subjected to an external cross flow.

NUMERICAL MODELING OF THE RODENT HEART AND ITS RESPONSE TO PRESSURE OVERLOAD

Vitaly Kheyfets[*1], Ilham Essafri[1], Mengqian Zhang[1], Ella Lyon[21], Kurt Stenmark[1], Kenzo Ichimura[3] and Edda Spiekerkoetter[3]*

[1]*University of Colorado*
[2]*Colorado School of Mines*

ABSTRACT

When the human heart is subjected to pressure overload, it responds to the elevated mechanical stress with a complex concert of changing gene expression, remodeled coronary microvasculature, and altered cardiac tissue structure. This also leads to a disruption of mechanical energy transfer between the left (LV) and right ventricles (RV), which has a profound effect on pumping function. The overall objective of our work is to pair a multi-scale computational model of a rodent heart with ongoing experiments to bridge the gap between transcriptomics, non-Newtonian fluid dynamics in the coronary microvasculature, and changes in tissue structure. This would allow us to identify which aspects of remodeling are beneficial to cardiac pumping function and myocardial nutrient supply, and possibly isolate targets for intervention.

We performed catheterization, cardiac MRI, and deep tissue imaging on 8 healthy rodents and 8 subjected to 7 weeks of chronic RV pressure overload. This data was combined to develop a 0-dimensional (0-D) digital twin of the heart and pulmonary circulation, by optimization, to fully characterize cardiac function and pulmonary arterial impedance. The optimized 0-D model is applied as a boundary condition to a rodent specific 3D finite element model (FEM) of the heart, with contractile mechanics optimized to regional tissue strain (measured by feature tracking applied to cardiac MRI images). Finally, deep tissue images of biopsied heart tissue were used to develop 3-D networks of the coronary microcirculation, which were used for non-Newtonian computational fluid dynamics simulations.

We developed a novel approach for sensitivity and practical identifiability analysis by combining supervised machine learning with game theory, which revealed a subset of identifiable rodent-specific 0-D modeling parameters. Ongoing FEM modeling has revealed that changes to the RV microstructure to a certain degree improve RV pumping function, but at the expense of LV-to-RV mechanical coupling. CFD models of the 3D microvascular network showed that capillary remodeling reduces hemodynamic stress and likely serves to preserve nutrient delivery to the surrounding tissue by maintaining a low capillary resistance.

Leveraging in-silico modeling to study how the rodent responds to pressure overload has yielded invaluable insight into multiple aspects of this response, which were previously inaccessible through conventional experimental approaches. Combining these findings with ongoing bioinformatics analysis offers a promising avenue for bridging the gap between mechanical stress, gene expression, and structural response. Ultimately, when applied to the human, we hope for this technology to project pathways of restoring function by model prediction.

MODELING THE ENHANCED GEOTHERMAL SYSTEMS USING THE EXTENDED–FEM AND AN EQUIVALENT CONTINUUM MODEL

Amir R. Khoei[*1], S.M.S. Mortazavi[1], O. Rezaie Beydokhti[1] and P. Pirmoradi[1]*

[1]*Sharif University of Technology*

ABSTRACT

In this paper, a computational technique is presented for Thermo-Hydro-Mechanical (THM) simulation of Enhanced Geothermal Systems (EGS) based on the local thermal non-equilibrium using the eXtended Finite Element Method (XFEM) and Equivalent Continuum Method (ECM). Heat extraction from Enhanced Geothermal Systems involves several multi-physics coupling processes, including the seepage through the fractured porous media, the thermal exchange between the working fluid and the matrix, and the deformation of fractured porous media, which play essential roles in exploiting the geothermal energy contained in hot dry rocks. The ECM can provide the equivalent tensors of not only fluid permeability but also solid compliance, which is an essential feature for coupled Thermo-Hydro-Mechanical simulation of fracture networks. In the model, the XFEM is employed for large-scale fractures to capture the mass and heat transfer between the fracture and matrix more accurately, while the ECM is applied on the network of small-scale fractures since considering their details explicitly is not usually cost-effective. Hence, the proposed model benefits from the advantages of both methods, and it allows for managing between accuracy and cost. The set of THM equations is solved with both Local Thermal Equilibrium (LTE) and Local Thermal Non-Equilibrium (LTNE) assumptions to find out the impact of each method on the production temperature.

The model is validated against the analytical solutions of heat transfer in porous media as well as single fracture problems. Moreover, its flexibility and applicability are shown by assessing the effects of the connectivity of fractures, characteristics of fracture networks, coupling conditions, and local thermal non-equilibrium assumption on the EGS simulation results. It is observed that the network connectivity and fracture alignment are both influential in the early thermal breakthrough; however, each can take dominance under different conditions. The capability of the proposed computational model is demonstrated for the diagonal arrangement of the injection and production wells with different fracture orientations in-between. The simultaneous effects of fracture connectivity and inclination are investigated between the two injection and production wells. It is observed that the temperature difference between the two cases is higher in the middle of the domain by comparing the results of LTE and LTNE assumptions. Moreover, it is concluded that the LTE model overestimates the fluid temperature in comparison to the LTNE model in cold water injection problems. The results show the proposed computational model is a promising tool for estimation of the heat mining performance of EGS.

APPLICATION OF PARTIAL NODAL STRAIN SMOOTHING IN ENHANCING THE ACCURACY OF THE LINEAR FINITE ELEMENT METHOD FOR COUPLED PROBLEMS OF GEOMECHANICS

Ashkan Shafee[1] *and Arman Khoshghalb**[1]

[1]*UNSW Sydney*

ABSTRACT

In this study, partial nodal strain smoothing is incorporated into the framework of the linear finite element method to develop a novel numerical technique, referred to as partial node-based smoothed FEM (PNS-FEM), for flow-deformation analysis of problems in geomechanics. In the PNS-FEM, the stiffness and permeability matrices of the domain are computed using the formulation of the linear FEM enhanced with partial nodal strain smoothing. The PNS-FEM takes advantage of the contradicting errors inherent in the solutions of the linear FEM and the node-based smooth point interpolation method (NSPIM) to yield close-to-exact solutions. The formulation of the PNS-FEM and the steps required to develop a PNS-FEM code from an FEM code are presented. The performance of the PNS-FEM is then examined through several numerical examples encompassing both linear and nonlinear porous materials subjected to various loading conditions. The results show that partial nodal smoothing is a simple and effective technique to considerably improve the performance of the linear FEM in coupled problems of geomechanics.

PREDICTING SEA ICE BEHAVIOR AND STRESS-STRAIN CHARACTERISTICS: A DATA-DRIVEN APPROACH

Peiman Sharifi[1], Ali Khosravi[1], Jennifer Hutchings[2], Scott Durski[2] and Banafsheh Rekabdar[3]*

[1]Auburn University
[2]Oregon State University
[3]Portland State University

ABSTRACT

The Arctic Sea ice cover is undergoing a profound transformation in response to climate change, leading to a future ocean with open waters in summer and only annual ice in winter similar to the Antarctic. This shifting landscape presents both opportunities and challenges, particularly for offshore infrastructure development. As the Arctic opens up to resource extraction, shipping, and commercial activities, the need for resilient infrastructure that can withstand the unique forces of sea ice becomes increasingly crucial. Sea ice exhibits complex mechanical behavior, with ductile and brittle modes of failure under compression. Capturing these distinct stress-strain signatures and failure mechanisms is critical for predicting ice forces on structures. To address this challenge, this study delves into the intricate mechanics of sea ice behavior, employing data-driven techniques to enhance the understanding and design capabilities. comprehensive stress-strain databases were compiled from sea ice compression tests conducted under various conditions, representing the diverse characteristics of Arctic Sea ice. The databases served as the foundation for developing machine learning models, including deep neural networks and decision trees, capable of distinguishing between ductile and brittle sea ice behavior. These models also predicted peak and residual stress-strain, providing valuable insights into the mechanical properties of sea ice. To gain deeper insights into the factors driving sea ice behavior, an analysis of model variable importance was conducted. This analysis revealed the key parameters that significantly influence sea ice strength and deformation characteristics under varied conditions. The results highlighted the impact of strain rate, grain size, temperature, and peak and residual stress and strain values and sea ice behavior. The developed predictive models and the insights gained from variable importance analysis demonstrate the power of data-driven techniques in advancing sea ice constitutive modeling. These advancements are essential for the design of robust offshore infrastructure that can withstand the dynamic and unpredictable forces of sea ice in the evolving Arctic. As climate change reshapes the Arctic landscape, data-driven approaches will play a pivotal role in enabling safe and sustainable development in this challenging yet promising region.

VARIATIONAL INFERENCE FOR A STOCHASTIC MULTICLOUD MODEL

Boualem Khouider[*1] and Carlos Sevilla*[1]

[1]*University of Victoria*

ABSTRACT

In the backdrop of climate change the evolving weather and climate is posing a challenge to the numerical modellers to predict the observed variability in a realistic manner. The bottleneck in this endeavour is the improper representation of clouds and its feedback to the environment in climate models. The first author and collaborators have proposed in the recent years a stochastic modeling framework to represent the sub-grid variability, in climate models, associated with clouds and organized convection in the tropics. The model is based on a lattice interacting system that mimics the dynamical transitions of coldness between several cloud types as revealed by satellite and radar observations, in the form of a Markov process with transition probabilities that depend on some physical variables via a set of transition time scale parameters than are indirectly learned from radar data, using Bayesian inference. However, due to the model's complexity, the likelihood function is not known in closed form and depends on the solution of the Kolmogorov backward equations which amount to computing an exponential matrix of high dimension (~10^6). To overcome this computational challenge a variational inference algorithm has been adopted for the learning problem and its efficacy and efficiency have been tested in the context of an AR1 model where various blackbox algorithms used in neural network studies have been tested and validated.

COMPOSABLE HPC INFRASTRUCTURE FOR CONTINUUM MECHANICS AND AI WORKLOADS

*Rooh Khurram**[1]

[1]*King Abdullah University of Science and Technology*

ABSTRACT

High-performance computing (HPC) applications like computational fluid dynamics are often compute intensive, but not all scientists have access to such powerful supercomputers. Cloud computing is a viable alternative for running these applications on the cloud without needing large capital expenditure (CAPEX) in high-end parallel computing systems. However, transitioning from a managed supercomputer to a self serviced public cloud is not straightforward for researchers from engineering disciplines. Moreover, the novice user lacks a priori knowledge of performance for continuum applications on cloud. This preparatory phase can sometimes be rather expensive due to unpredictable costs of cloud computing. The aim of this paper is to provide guidelines for running typical continuum mechanics and AI workflows on HPC clusters in the public cloud. The selected use cases are: CFD, CSM, EM, atmospheric science, geoscience and deep learning training and inference. We will also provide the performance comparison of public cloud and supercomputer for all benchmarks selected from a wide range of applications at various spatial/temporal resolutions. We hope to provide guidelines to individual researchers, faculty groups, academic departments and SMEs for selecting specifications for their respective workloads. These specifications include: compute instances (CPUs/GPUs), storage, interconnect, RAM, scheduler, software environment and data management. We believe that unbiased reporting of HPC workloads on cloud is essential for policy makers for making long term planning for HPC infrastructure. A cloud alternative to a managed on-premise supercomputer provides an option to convert capital expenditure to operational expenditure.

MULTISCALE STUDY ON THE THERMAL CONDUCTIVITY OF VITRIMER-BNNT NANOCOMPOSITE.

Nahyun Ki[*1] and Seunghwa Yang*[1]

[1]*Chung-Ang University*

ABSTRACT

With the help of advanced manufacturing and characterization technique in the field of engineering materials, there have been continuous attempts to replace traditional metal or ceramic materials with high performance polymers and composites in various applications. The notable advantage of polymer's durability such as cross-linked thermosets, however, paradoxically leads to non-degradability and eco-friendly issues. The limited recycling of plastic waste reaching approximately 10% naturally sparked interest in lightweight composites that can secure higher recyclability, less toxicity while maintaining excellent mechanical and thermal properties.

Vitrimer is a polymer featuring dynamic and reversible crosslinks between atoms that allow for recyclability while maintaining good physical properties, representing a recyclable alternative. Above all, the vitrimer's distinguishing feature lies in dynamic crosslinking, activated under specific conditions such as heat or light, providing control between polymer chains. Therefore, understanding the vitrimer's stimuli responsive cross link mechanism is of primary concerns for its application.

BNNT(boron nitride nanotube) is a low dimensional tubular structure comprising alternating boron and nitrogen, The BNNT exhibits mechanical and thermal properties comparable to the CNT, along with piezoelectricity, exceptional thermal stability and cytocompatibility. However, experimental research is hampered by its high cost reaching approximately 80 dollars per gram for controlled synthesis with high-purity. Overcoming these challenges necessitates an in-silico simulation study and sequential multiscale modeling approach for the vitrimer/BNNT nanocomposites.

This study demonstrates a sequential multiscale modeling approach for thermal transport properties of virtrimer/BNNT nanocomposites combining classical molecular dynamics simulations and composites micromechanics models. The dynamic cross linking of vitrimer is described using a bond-boosting method and the resultant thermal conductivity of the vitrimer is determined according to the switching of cross links. Interfacial thermal conductance between the BNNT and vitrimer is investigated through a laminated interface model to quantify the phonon scattering and Kapitza thermal resistance. To develop an efficient structure-property relationship model, the constitutive model for thermal conduction of nanocomposites with interphase and Kapitza resistance is derived from the multi-inclusion model with an equivalent filler concept to describe the degradation by the phonon scattering. Finally the vibrational density of state and solubility parameters of vitrimer with varying dynamic cross link density and BNNT were discussed to correlate the process-structure relationships.

COMPUTATIONAL CHEMO-MECHANICS WITH APPLICATION TO MULTIFUNCTIONAL AND HIGH-TEMPERATURE MATERIALS

Bjoern Kiefer[*1], Stefan Prüger[1] and Stephan Roth[1]*

[1]TU Bergakademie Freiberg

ABSTRACT

This presentation gives an overview of our current research activities in the area of chemo-mechanics-based material modeling. Building on experience in theoretical and computational methods for multiphysics problems, our interest here lies in the modeling of nonlinear, dissipative material behavior in which interacting thermo-chemo-mechanical processes play a dominant role. We aim to capture mechanisms such as stress- and temperature-biased phase transitions and chemical reaction-diffusion processes that directly influence, or even enable, the effective behaviors of modern engineering materials. In this general multiscale approach, model formulations may be considered on very different length and time scales. Recent work regarding analytical and computational scale-bridging methods is also briefly discussed.

Three fundamental ingredients are addressed in this talk: (i) the theoretical model development, particularly regarding variational settings, (ii) the numerical treatment of these problems, and (iii) the calibration of thermodynamical properties via the CALPHAD method. Regarding the first aspect, we discuss the advantages and disadvantages of formulations for chemo-mechanical multifield problems through minimization and saddle-point principles. In terms of numerical solution schemes, we elaborate on the finite element implementation of such theoretical frameworks. Our particular approach builds on the flexible and quite general utilization of the UserELement interface (UEL) provided in the FE software package Abaqus. We further discuss ongoing collaborative work on the co-design of the variational model development and parallel solvers for chemo-mechanics problems, for which the MPI-parallel implementation instead is based on the software libraries deal.II, p4est and FROSch (Fast and Robust Overlapping Schwarz). Moreover, a concept is proposed in which thermodynamically informed material models are efficiently achieved via CALPHAD-trained neural networks. Representative numerical examples from a broad spectrum of technologically relevant studies — ranging from hydrogels to multifunctional filters for the cleaning of steel melts — are presented to demonstrate the validity and flexibility of our simulation frameworks.

DATA-DRIVEN MORPHOGENESIS WITH PERSISTENT HOMOLOGY FOR SOLVING TOPOLOGY OPTIMIZATION PROBLEMS

Taisei Kii[*1], Kentaro Yaji[1], Hiroshi Teramoto[2] and Kikuo Fujita[1]*

[1]*Osaka University*
[2]*Kansai University*

ABSTRACT

Topology optimization is a powerful approach for realizing novel structural optimization by solving a material distribution problem under a high degree of design freedom. In exchange for this attractive feature, topology optimization cannot typically avoid multimodality caused by complex physical computational models, where multiple undesirable local optima exist.
Evolutionary algorithms (EAs), inspired by the emergent process of biological evolution, are capable of global solution search and are considered effective for optimization problems like the one mentioned above. However, the search performance of typical EAs is significantly degraded for large-scale problems, making it difficult to solve topology optimization problems.
Focusing on dimensionality reduction with deep generative models to address such challenges, this study proposes a framework based on the previous work [1], in which the design candidates are iteratively updated by a variational autoencoder (VAE). Furthermore, we apply effective crossover operation into the latent space of the VAE to incorporate the essence of EAs [2]. As a key component of the proposed framework in this study, we employ persistent homology to essentially maintain the diversity among structures represented as high-dimensional material distribution data. Persistent homology is one of the topological data analysis methods in which topological features such as the number of connected components and voids and their sizes are extracted from the target complex data into a two-dimensional plot called a persistent diagram. The Wasserstein distance between corresponding persistent diagrams quantifies the difference in topological features between material distribution data. We develop the proposed framework incorporating the selection operation based on the Wasserstein distance and name it data-driven morphogenesis as a new concept of the EA-based optimization method using a generative model.
We apply the proposed framework to topology optimization problems with strong multimodality. Firstly, we confirm the extraction of topological features of the structures using persistent homology. Next, we compare the obtained optimization results with those obtained by conventional topology optimization. The optimized structures improved by the proposed selection operation exhibit comparable or better performance than those by typical topology optimization, demonstrating the usefulness of data-driven morphogenesis for solving topology optimization problems.

STRUCTURAL TOPOLOGY DESIGN FOR FUNCTIONAL MOTION AS WELL AS FUNCTIONAL MECHANICS

*Noboru Kikuchi**[1,2]

[1]*University of Michigan*

[2]*Toyota Konpon Research Institute*

ABSTRACT

Concept of topology optimization has been widely accepted to design mechanical functionality, heat transfer characterization, flow domain for fluid, and material properties. Details and widely spread advanced research results have been published in, e.g., Computer Methods in Applied Mechanics and Engineering.

In this talk, a new notion of topology optimization to generate dynamical motions of a possibly soft structure, will be presented by collaboration with Tsuyoshi Nomura Research Group in Toyota Central Research and Development Laboratories. This study shows an extension of the notion of topology optimization to motion related functional design of a structure that may be applicable to soft robot design, and motion creation of a living creature in gaming software.

ANALYSIS OF COMPOSITE STRUCTURAL LITHIUM-ION BATTERIES AND AN APPLICATION TO A DOOR STRUCTURE OF ELECTRIC VEHICLES

Cheol Kim[*1] and Yeongeun Park*[1]

[1]*Kyungpook National University*

ABSTRACT

The structural lithium ion battery may serve the dual purpose of providing support for loads and storing electrical energy. A composite structural lithium ion battery, which incorporates carbon fibers and a semi-solid matrix exhibiting favorable electrical conductivity and hyper-elastic material behaviors, has been developed for a potential application to electric vehicles. The analysis in this study includes evaluations of mechanical, electrochemical, and crash performances, with optimization of design parameters for this innovative structural battery. A structural battery cell is the basic unit of a structural battery and consists of an anode, a cathode, an electrolyte, a separator, and a current collector. A separator layer is located between the anode and cathode. To prevent the structural battery laminate from warping, all layers are arranged symmetrically with respect to the center layer. Finite element analyses are performed on the RVE model to derive the mechanical properties of the composite lamina of structural battery. After constructing the door of an electric vehicle with a structural battery, a crash analysis is performed to check the crash performance of the structural battery. Parametric studies were conducted on 11 design variables, encompassing factors such as layer thickness, fiber angle, cathode coating thickness, and fiber volume fraction. Bayesian optimization was employed to maximize the electric vehicle range, ensuring compliance with specified mechanical properties. In this study, the effectiveness of structural batteries is demonstrated through one application case, an auxiliary power source for electric vehicles.

FEASIBILITY OF VEHICLE-BRIDGE INTERACTION NEURAL OPERATOR FOR DRIVE-BY BRIDGE DAMAGE DETECTION

Joshua Irawan[1] and Chul-Woo Kim[1]*

[1]Kyoto University

ABSTRACT

Drive-by bridge damage detection using vehicle vibration has been actively studied in recent years, including machine learning-based approaches. However, extracting features related to the condition of bridges remains a challenge. With supervised learning methods, obtaining training data on a bridge's damage state is almost impossible. Unsupervised learning approaches, on the other hand, can only yield relative changes in features rather than physical characteristics related to structural performance. This study aims to propose and investigate the feasibility of a vehicle-bridge interaction neural operator (VINO) for bridge damage detection using vehicle vibrations. The VINO is first constructed using the physically informed training data from numerical simulations of vehicle-bridge interactions considering the damage field of the bridge. Then data-informed fine-tuning of the VINO is carried out using available data from the target bridge. It is noted that no damage data is required in the fine-tuning stage. The feasibility of VINO for drive-by bridge damage detection is discussed using an in-house experiment.

DATA-DRIVEN SHOCK-CAPTURING INDICATOR FOR DISCONTINUOUS GALERKIN METHODS WITH DECISION TREE CLASSIFIERS

Dongseok Kim[*1], Jayeon Joo[1] and Chongam Kim[1]*

[1]*Seoul National University*

ABSTRACT

Much efforts has been put on finite element-based high-order methods for scale-resolving compressible simulations, due to their capability to handle complex geometries with high-order accuracy and cost-efficiency. At the same time, high degree polynomial-based discretizations are susceptible to shock-driven instability, known as Gibbs oscillations. Typically, unphysical numerical oscillations near shock waves are handled by suitable shock-stabilization techniques, such as limiting strategy and artificial viscosity. Before applying any of these techniques, however, the occurrence and location of shock must be identified. Some troubled-cell indicators, such as P1-projected MLP condition [1] and troubled boundary detector [2], have been developed and successfully combined in a hierarchical projection manner. But the precise detection of troubled-cells is non-trivial and there is still a trade-off between accuracy and robustness in high-order CFD solvers.
Recently, a feed-forward neural network to detect troubled-cells [3] showed its potential as a universal troubled-cell indicator without parameter tuning. However, it was also observed that it exhibits some erratic convergence rate for smooth flows, and its performance is not reliable enough to be extended onto realistic configurations with unstructured-mixed grids. To address this issue, we develop an accurate and robust troubled-cell indicator using decision tree classifiers that can handle unstructured-mixed grids. Training data are generated by projecting the smooth and discontinuous analytic functions onto DG polynomial space. In the modal DG framework, we introduce input features that handle unstructured-mixed grid systems by exploiting the information of high-order shock-capturing schemes. Our tree-based models perform the binary classification, i.e. smooth or shock regions, using high-order features defined on compact stencil. Combined with proven limiting algorithms, we validate our tree-based models in terms of accuracy, robustness, and cost-efficiency on various grid systems. Though extensive numerical tests including shock-vortex interaction, we confirm that the proposed data-driven indicator not only provides the expected order-of-accuracy for vortex region but also flags the troubled-cells accurately and robustly for flow problems with shock-vortex structures.

CHARACTERIZATION USING BEAM-SOIL RESPONSES: A FULL-WAVEFORM INVERSION APPROACH

Hongju Kim[*1], Jun Won Kang[1], Woo Young Lee[1] and Min Seong Kim[1]*

[1]*Hongik University*

ABSTRACT

This study presents a full-waveform inversion (FWI) method that utilizes measured deflections to reconstruct the material profiles of a beam-soil system, such as water pipelines supported by the soil. The forward problem for calculating the beam's deflection in the time domain can be formulated by the Euler-Bernoulli beam and the Winkler foundation models. The accuracy of the forward responses was validated by comparing them with ANSYS solutions. The dispersion characteristics of the flexural waves in the beam-soil system were also demonstrated considering various soil stiffness conditions. The inverse problem for reconstructing the material profiles of the beam-soil system can be formulated by a PDE-constrained optimization approach. The target inversion variables are the beam's elastic modulus and the soil's stiffness of the Winkler foundation model. The optimization approach seeks to minimize an objective functional comprising the least-squares misfit between measured and calculated deflections and regularization terms. By enforcing the stationarity conditions of a Lagrangian, Karush-Kuhn-Tucker conditions consisting of state, adjoint, and time-independent control problems are derived. The three problems are iteratively solved in the reduced space of control variables to reconstruct the beam's elastic modulus and the soil's stiffness. In numerical examples, three cases are presented: (1) inversion for the beam's elastic modulus while knowing the soil's stiffness, (2) inversion for the soil's stiffness while knowing the beam's elastic modulus, (3) simultaneous inversion for both the beam's elastic modulus and the soil's stiffness. In particular, it is shown that the two profiles can be simultaneously reconstructed using a single set of measured beam-soil responses. The methodology presented in this study can be used for various engineering applications, such as damage assessment of lifeline structures.

PHYSICS-BASED MANIFOLD REPRESENTATION USING DIFFUSION MODEL FOR COMPUTATIONAL MULTISCALE STRUCTURAL PROBLEMS

Hyejin Kim[*1], Seongwoo Cheon[1] and Haeseong Cho[1]*

[1]*Jeonbuk National University*

ABSTRACT

Computational multiscale homogenization method has proven to be a favorable strategy for characterizing an effective continuum model for heterogeneous composites at the microscopic level. This approach can also be extended to a multilevel finite element method known as the FE2 method. However, the presence of nonlinear behavior in heterogeneous composites introduces significant computational costs and necessitates recursive computation, given the intricate deformation mechanisms that connect different scales. Considering these challenges, implementing a reduced-order model to address the associated computational inefficiencies can be applicable. In this study, we propose a surrogate model designed to efficiently predict both global and local nonlinear behaviors within the microstructure, leveraging a reduced-order model based on a deep learning network model. Additionally, we explore the manifold representation of microstructure exhibiting nonlinear behavior by introducing a diffusion model, which bridges the inherent homogenized macroscale physics data governing microstructure evolution. Specifically, an autoencoder (AE) is applied as part of the deep learning-based reduced order model, effectively dealing with the high-dimensional quantities of interest in microstructure analysis and learning manifold representation. Furthermore, a flow-based diffusion model is employed to describe the relationship between the manifold representation of microstructure and the underlying physics of homogenized macroscale data.

QUANTIFICATION OF CONTRIBUTIONS ON PLASTIC SHRINKAGE CRACK WITH EVALUATION OF BLEEDING AND EVAPORATION

Hyun-Kyoung Kim[*1] and Hyo-Gyoung Kwak*[1]

[1]*KAIST*

ABSTRACT

Plastic shrinkage crack is a early plastic crack of concrete that occurs due to rapid moisture loss from fresh concrete and the tensile shrinkage following after that. Plastic shrinkage crack have a unfavorable influence on not only exterior appearance but also concrete structure in long term by corroding interior of concrete. Despite of the importance of preventing Plastic shrinkage crack in terms of maintenance, the numerical research and precautions on plastic shrinkage crack and its control is insufficient. This study is devoted to numerical analysis of bleeding and evaporation which are two measures of plastic shrinkage crack, and proposed quantification of the effect of each influencing factors including representative concrete curing method for plastic shrinkage crack, windscreen. For this purpose, bleeding was modelled by large consolidation theory, and the bleeding properties of concrete was determined by the regression on concrete mix variables to the normalized bleeding coefficients, together with the bleeding coefficient of reference concrete mix. And to evaluate evaporation, evaporation rate diminishing effect and concentration weighed characteristic velocity by CFD-analyzed wind profile was adopted to get better evaporation estimation than existing ACI nomograph. In the end, the proposed ready-made quantification of each influencing factor on surface dry time is expected to be effectively utilized in keeping plastic shrinkage crack in construction site.

A MULTISCALE BRIDGING APPROACH TO PREDICT FRACTURE TOUGHNESS AND CRACK PROPAGATION CHARACTERISTICS OF POLYMER NANOCOMPOSITES

Jae Hun Kim[*1], Haolin Wang[1], Jihun Lee[1] and Hyunseong Shin[1]*

[1]*Inha university*

ABSTRACT

In this study, we proposed a multiscale bridging approach combined with molecular dynamics (MD) and finite element homogenization (FEH) method to predict fracture toughness and crack propagation characteristics of polymer nanocomposites. It has been reported that the precise characterization of the interphase elasto-plastic constitutive law is critical for predicting fracture toughness, fatigue crack growth, and overall strength of polymer nanocomposites [1, 2]. To characterize the interphase elasto-plastic properties, we employed full atomic molecular dynamics simulations and finite element homogenization analysis with a three-phase equivalent model that reflects the interphase between the nanoparticle and the polymer matrix. The interphase elasto-plastic properties were used to predict the fracture toughness of polymer nanocomposites by considering debonding between the particle and the interphase, as well as void growth. Additionally, we compared mode I and mode II crack propagation characteristics using phase-field finite element method.

PATIENT-SPECIFIC IN VIVO ESTIMATION OF BASILAR ARTERIAL LOCAL WALL DEFORMATION AND STIFFNESS USING A NOVEL IMAGING-IGA COMPUTATIONAL APPROACH

Jaemin Kim[*1], Michael Sacks[1], Kaiyu Zhang[2], Gador Canton[2], Niranjan Balu[2], Kenneth Meyer[1], Reza Saber[1], Chun Yuan[2] and David Paydafar[1]*

[1]*The University of Texas at Austin*
[2]*University of Washington*

ABSTRACT

A comprehensive understanding of the biomechanical behaviors and failure mechanisms of the basilar artery (BA) and its aneurysms is crucial for advancing disease diagnosis and treatment. In the current study we developed an image-based approach for the in vivo direct determination of basilar arterial wall deformation and stiffness. We start by using a novel MRI based imaging technique to extract the BA endoluminal geometry in humans over the cardiac cycle. Using the resulting segmented point-cloud data we reconstructed the three-dimensional endoluminal surface using non-uniform rational B-splines (NURBS). Using the local support mathematical feature of NURBS, we then estimated the BA endoluminal surface strain throughout the cardiac cycle. To determine the corresponding wall stresses, we developed a computational mechanics framework that incorporates membrane shell theory to estimate BA wall tension through the cardiac cycle. This method ignores bending and transverse shear deformation due to the thin wall of the artery. The membrane shell theory exploits static determinacy, allowing wall tension determination solely from considerations of geometry and blood pressure. A significant advantage of this approach is the elimination of the need for a material model or prior knowledge of residual stress and referential state of the BA wall. To numerically solve membrane shell equations and address complex geometry with higher-order continuity, we employ Isogeometric Analysis (IGA). In this process, the NURBS surface serves as input for the analysis, and IGA determines wall tensions from the geometry. We have developed a robust and open-source finite element framework utilizing FEniCS. The integration between FEniCS and NURBS is seamlessly facilitated through tIGAr, which is a Python library to perform IGA within FEniCS environment. Results from three human patients show several interesting features, such as regional large deformations that occurred in a peristaltic fashion, mechanical behaviors in the functional range demonstrated clear anisotropy and anatomical location differences. This imaging-IGA computational approach holds promise for improved insights into the dynamic behavior of intracranial arteries, contributing to enhanced diagnostic capabilities in neurovascular assessments.

ACCELERATED AND STABLE KRIGING SURROGATE MODEL TECHNIQUE FOR TRAINING LARGE-SCALE DATA

Jieon Kim[*1] and Gunwoo Noh[1]*

[1]*Korea University*

ABSTRACT

Surrogate models, rapidly predicting response values based on design variable conditions, are essential for effectively executing engineering design, improvement, and optimization processes. Among these, the Kriging model is widely utilized because it offers both high prediction accuracy and provides statistical prediction uncertainty information at arbitrary locations. When training the Kriging model, it is necessary to solve the global optimization problem of the likelihood function based on the correlation matrix. Hence, when dealing with large-scale data, increasing the size of the correlation matrix leads to higher training costs and a greater unstable training outcome. This is a primary reason why, despite the high accuracy and utility of Kriging, it is not effectively utilized for large-scale data. In this study, we have developed a new approach called ASTEK (Accelerated and Stable Technique for Efficient Kriging) to overcome these challenges, ensuring consistently high accuracy and training efficiency regardless of data scale.

ASTEK consists of two stages: the ‘Preparation: offline’ and ‘Training’. In the ‘Preparation: offline’ stage, it pre-trains the ‘Optimal hyperparameter predictor’ with Artificial Neural Network and additional two more methods, Radial Basis Function Networks and Kriging, based on the data distribution and trends of the prepared sample pool. We applied the Ensemble of surrogates approach to select the most appropriate model for the given data, ensuring the accuracy and robustness of the 'Optimal hyperparameter predictor’.

In the ‘Training’ stage, where, upon input of arbitrary training data, it quantifies the distribution and trends as the same parameters in ‘Preparation: offline’ stage. These parameters are then applied to the ‘Optimal hyperparameter predictor’ and generate the Kriging model instantly.

In this study, we validate the effectiveness of ASTEK in significantly reducing training time while ensuring stable high accuracy for large-scale data through various numerical test problems and engineering examples. This is expected to contribute to effectively training and optimization works for large-scale data, addressing the challenges in ensuring accuracy and training efficiency that were previously encountered with traditional surrogate models.

ABSTRACT

The compaction of powder plays a crucial role in diverse industries, including pharmaceuticals, ceramics, and metallurgy, where it transforms loose powder into a solid compact through mechanical forces. The integrity and quality of the compact are affected by several factors, such as the particle size distribution, compaction pressure, and powder flow properties. This study focuses on optimizing the quality of iron powder compacts. To achieve this, the discrete element method (DEM) and the multi-particle finite element method (MPFEM) were employed. In developing the numerical procedure, the impacts of the finite element size, the dimensions of representative volume elements, frictional forces, and springback were analyzed. The effectiveness of this combined DEM-MPFEM approach was verified for various powder size distributions. Subsequently, the data generated from this procedure was utilized to train an artificial neural network model. A genetic algorithm-based optimization was then applied to identify the most suitable powder size distribution for optimal quality of the compacted iron powder.

TWO-SCALE SHAPE AND TOPOLOGY OPTIMIZATION USING LEVEL-SET AND HEURISTIC METHOD WITH STRESS AND VOLUME CONSTRAINTS

Jinhoo Kim[*1] and Hyun-Gyu Kim*[1]

[1]*Seoul National University of Science & Technology*

ABSTRACT

This paper presents a two-scale shape and topology optimization method using the level-set method and heuristic update scheme under stress and volume constraints. The optimization problem can be expressed as the Lagrange functional consisted with a compliance, linear elastic equilibrium equation and stress and volume constraints with Lagrange multipliers. The p-norm stress is introduced to analyze the sensitivity to stress constraint and the macro scale sensitivity can be obtained by solving adjoint equation. Two level-set function are introduced to define macro and micro structure. The macro structure is created based on the initial macro level-set function and updated by solving the reaction-diffusion equation. The micro structure is defined by a basic level-set function which determine the topology of the micro structure and the height of the macro element which change the shape of micro structure. Each finite element of the macro structure is considered as one micro structure. For each macro element, the energy-based homogenization method is applied to obtain the homogenized elastic tensor. The heights are updated by heuristic updating scheme with the parameter obtained from the optimal condition.

Multiscale computational homogenization for bridging scales in the mechanics and physics of complex materials

MECHANICAL BEHAVIOR ANALYSIS OF ADDITIVE MANUFACTURED CEMENTITIOUS MATERIAL BASED ON MICROSTRUCTURAL CHARACTERISTICS

Jisu Kim[1]*

[1]*University of Seoul*

ABSTRACT

In the construction and building industry, additive manufacturing (AM) or 3D printing of concrete is widely studied. The AM process offers the advantage of rapidly printing irregular structures. Compared to conventional construction methods, AM structures exhibit interfaces between printed layers and filaments, inducing anisotropy. It significantly impacts directional mechanical properties [1]. Consequently, it is necessary to consider the interfacial effects on the responses when evaluating the AM structure behaviors.

This study examines the influence of the additive manufacturing process on the mechanical properties of cementitious materials, focusing on their microstructural characteristics. Micro-CT images facilitate effective investigation of phase distribution without material defects. The spatial distribution characteristics of the printed structure were examined in a probabilistic manner. A 3D microstructure (or virtual model) with the actual features was generated based on the CT images. The model was utilized to examine mechanical properties through simulation.
For the simulation, two types of the virtual models were designed to analyze the interfacial effects on the mechanical properties of the additive manufactured cementitious material: one is inter-layer model, and the other is inter-filament model. Using the crack phase field fracture model based on the finite element method [2], the responses, i.e., stiffness and strength, of each model were examined. The results indicated a strong correlation between the properties of the printed structure and pore distribution characteristics. Directional behaviors were investigated and correlated with microstructural characteristics.

It was found that the inter-layer less significantly affects the tensile behavior of the printed structure. Cracks under loading mainly propagated through inter-filament pores, which is continuously connected along printing direction. By combining microstructural characteristics and mechanical properties via virtual experiments, an optimized printing pattern can be suggested to improve the integrity of the printed structure.

[2]*Myongji University*

ABSTRACT

In recent years, energy scarcity and greenhouse gas reduction have become important global issues. Thermal and nuclear power plants are responsible for a significant portion of energy generation. From a thermodynamic perspective, a 10 degrees Celsius increase in steam temperature results in a 0.5% increase in power generation efficiency. In addition, a 9% increase in power generation efficiency results in a 20% reduction in greenhouse gas. Next-generation power plants aim to increase power generation efficiency and reduce greenhouse gas emissions by increasing steam temperature. However, it is crucial to understand the mechanical properties of structural materials, such as tensile, creep, and fatigue, to safely operate plants with higher steam temperatures for extended periods of time.

Mechanical properties, such as tensile, creep, and fatigue, are typically evaluated through uniaxial test (UT). This method directly stresses the specimen to measure its mechanical properties. The strain value at a given stress is directly derived since the deformation of the specimen occurs under uniaxial stress. Therefore, UT is a useful method for characterizing the mechanical properties of materials. However, it has a fundamental limitation in that it is resource-intensive and time-consuming to obtain test results.

To address the limitations of UT, small punch test (SPT) has been proposed as an alternative. SPT has the advantage of using a very small specimen size, which consumes very little material and requires relatively little time to obtain test results. Unlike UT, which measures strain and stress, SPT measures displacement and load. Thus, to evaluate the mechanical properties of materials using SPT, it is crucial to establish a correlation between the two test methods.

Unlike UT, which applies direct stress to the specimen, SPT applies indirect stress through the punch and punch ball. Additionally, while UT deforms the specimen under uniaxial stress state, SPT deforms the specimen under multiaxial stress state. This difference in loading mechanism makes it challenging to establish a correlation between the two test methods. Although several researchers have established the tensile and creep properties of SPT, its fatigue properties have not been clearly established.

Thus, the objective of this study is to create a method for assessing fatigue damage using SPT. A model for analyzing fully reversed fatigue damage is developed based on finite element analysis (FEA), and S-N curves are derived using only SPT. The study's validity was confirmed by comparing the simulation results with the S-N curves obtained from the actual UT.

ANALYSIS OF CROSS-SECTIONAL LOAD ACCORDING TO ASYMMETRIC FORMATION OF 3-D RC RAHMEN STRUCTURE

Seonghun Kim[1] and Hyo-Gyoung Kwak*[1]

[1]*KAIST*

ABSTRACT

When performing numerical analysis of a 3D structure, the analysis is generally conducted based on symmetrical shapes. However, currently, various structures have asymmetrical shapes. When designing these asymmetric structures, the main structure part of the lower part of the structure and the substructure part of the upper part have different behavior than when numerically analyzing symmetrical structures. Accordingly, the distribution ratio and value of the load received by each structural part also change. This study will analyze the change in load received by structural members when a symmetrical structure changes to an asymmetrical structure. Based on the 20-story structure, analysis of symmetrical and asymmetrical structures will be conducted, and in asymmetrical structures, changes according to the shape and location of the substructure and the ratio of the main structure and substructure will be considered. In this process, numerical analysis will be performed considering the construction sequence of the structures to maximize the behavior of the actual structure. By analyzing asymmetric structures in 3-D considering the construction sequence, we will enable efficient selection of cross-sectional settings of members during construction of the structure.

DATA-DRIVEN MULTISCALE FINITE ELEMENT METHOD USING DEEP NEURAL NETWORK COMBINED WITH PROPER ORTHOGONAL DECOMPOSITION

Suhan Kim[*1] and Hyunseong Shin*[1]

[1]*Inha University*

ABSTRACT

A data-driven multiscale finite element method (FE2) utilizing deep neural network (DNN) and proper orthogonal decomposition (POD) has been proposed to characterize the behavior of composite materials, including nonlinear and heterogeneous materials. The data-driven FE2 approach assigns data to all integration points to satisfy microscopic equilibrium and resolves the macroscopic problem. We enhance the efficiency of database construction by pre-computing the microscopic problem of the representative volume element (RVE) and incorporating POD to develop a precise and efficient DNN model for predicting microscopic behavior. Therefore, we have further improved the data-driven FE2 technique by efficiently generating an available database. In the numerical example, we effectively attained accurate results for both macroscopic and microscopic analyses with sparse dataset. Employing a data-driven FE2 based on the DNN-POD approach, the methodology not only exhibited its ability to overcome data scarcity but also demonstrated a high degree of accuracy in predicting outcomes at both scales. This work is believed to have significantly increased the efficiency of computational structural mechanics.

PERFORMANCE INVESTIGATION OF DIFFERENTIAL OPERATORS IN THE PERIDYNAMICS FORMULATION FOR HEAT CONDUCTION ANALYSIS

Sunwoo Kim[*1], Suyeong Jin[12] and Jung-Wuk Hong[1]*

[1]*Korea Advanced Institute of Science and Technology*
[2]*California Institute of Technology*

ABSTRACT

Differential operators in the formulation of the peridynamics are obtained from the peridynamic functions, and the precision of the spatial derivatives is contingent on the appropriate selection of the peridynamic function. We investigate the performance of the thermal peridynamic formulation by changing the order of peridynamic functions in the form of Taylor series expansions and weight functions. Six different orders of the Taylor series expansions as well as three individual weight functions are tested to evaluate the performance of the peridynamic functions. For each function, m-convergence test is performed by decreasing the peridynamic point spacing while keeping a specific horizon size. For a one-dimensional case, the heat distribution and fluxes are calculated by integrating the peridynamic functions in quasi-static and transient analyses. Subsequently, the function demonstrating the best performance in this one-dimensional case is employed to solve the three-dimensional quasi-static heat conduction problem. The weight function influences the heat flux calculation across all orders, and the effect considerably decreases at the second order, yielding accurate heat fluxes. Furthermore, in the second-order formulation, the chosen weight function enhances the accuracy of heat flux calculations. Utilizing this optimized combination of second-order formulation and weight function, the temperature and heat flux fields in three dimensions are in good agreement with those calculated in the finite element analysis. This peridynamic formulation proves versatile for various thermodynamic problems, offering high accuracy in heat conduction analyses.

ADAPTIVE SUBCELL SHOCK-CAPTURING FOR DISCONTINUOUS GALERKIN METHODS ON SUPERSONIC AND HYPERSONIC FLOWS

Taegeon Kim[*1], Juhyun Kim[1], Hojun You[2] and Chongam Kim[1]*

[1]*Seoul National University*
[2]*Sejong University*

ABSTRACT

A novel subcell shock-capturing approach is proposed to enhance the performance of discontinuous Galerkin (DG) method on supersonic and hypersonic flow simulations accompanying strong physical discontinuities. High-order methods (HOM), receiving much attention in scale-resolving simulations due to low numerical dissipation and high scalability, have the potential to predict heat transfer rate more accurately than the second-order finite volume method (FVM) in hypersonic simulations. This requires an accurate and robust shock-capturing as an essential pre-requisite because HOM are in general much more susceptible to numerical Gibbs oscillations in the vicinity of strong shock waves. While the posteriori subcell limiter [1] demonstrated the robustness favorable to hypersonic flow simulations, it suffers from Gibbs oscillations as well when subcell FVM solutions are directly used to reconstruct a high-order solution, leading to the loss of accuracy especially in steady-state simulations. In order to address this issue, we design a novel oscillation-detecting process to identify Gibbs oscillations in the reconstruction step by analyzing subcell FVM solutions and reconstructed high-order solutions. We then retain the subcell FVM solutions without further proceeding high-order reconstruction if oscillations are detected during the reconstruction step. The subcell FVM solutions are updated via the boundary fluxes reconstructed using the DRM-DG method [2, 3]. This hybrid approach enables the high-order flux-interaction between the subcell FVM solutions and the neighboring DRM-DG solutions. From extensive numerical experiments, it is verified that the proposed method effectively eliminates numerical oscillations during the reconstruction and accurately resolves shock waves on supersonic and hypersonic flow simulations.

FRACTURE STUDY OF SINGLE CRYSTAL SILICON USING ATOMISTIC SIMULATIONS

Woo Kyun Kim[*1] and Syed Iqbal*[1]

[1]*University of Cincinnati*

ABSTRACT

Silicon is the most commonly used semiconductor material and has played a key role in the recent advances in nanotechnology as a building material for MEMS (micro-electro-mechanical systems). As the size of silicon-based devices continues to decrease to sub-micrometer levels, it becomes of critical importance to have a thorough understanding of fundamental deformation mechanisms since materials on small length scales often exhibit completely different behaviors from their bulk counterparts. For example, while silicon is an inherently brittle material, several recent experiments have shown that micrometer-scale devices made of single crystal silicon exhibit plastic deformation at room temperatures. In the present work, the fracture behavior of single crystal silicon is investigated using atomistic simulation methods. Atomistic simulation is one of the most suitable tools to understand the exact nature of silicon, but the outcomes are strongly tied to particular interatomic potentials used in the simulation. In this study, we considered three interatomic potential models for silicon: (1) Stillinger-Weber (SW), (2) Modified Embedded Atom Model (MEAM), and (3) ReaxFF. The simulation mimics the mode-I fracture test for those models in five different crystallographic orientations and with various initial crack sizes as well as the different model sizes. The simulation results show two different failure modes of the crystal: (1) a slip deformation along the (111) plane or (2) a crack propagation in the perpendicular direction to the loading. It is found that the various input parameters as well as the interatomic potential models affect these failure behaviors with the SW silicon model the most ductile among the tested potential models although the SW model also shows the brittle fracture in certain orientations. The mechanisms leading to the different failure behaviors are identified and some material parameters are computed for each potential model to predict the failure behavior.

COMPUTATIONAL INTERPRETATION OF SHAPE MEMORY EPOXY: PROCESSING AND ITS OPERATION

Yeongbin Kim[*1], Hongdeok Kim[1] and Joonmyung Choi[1]*

[1]*Hanyang University*

ABSTRACT

The shape forming and restoration mechanisms of shape memory epoxy originate from the molecular-scale dynamics that epoxy molecules undergo during thermomechanical processes. In this study, the microstructural changes that occur at the molecular scale caused by heat and load during the programming and operation of the epoxy network were investigated using molecular dynamics simulations. The mechanical behaviors of each molecule were analyzed by classifying it into translation, rotation, and deformation based on the classical kinematic framework. Specifically, depending on its structural properties, each molecular component was rearranged to different levels, forming local residual stresses. The principle leading to shape recovery as the subsequent thermal load breaks the equilibrium of residual stresses and resulting changes in the mechanical anisotropy of entire epoxy network were also analyzed through a subcontinuum perspective. This study has the potential to be extended to a method for designing epoxy resins that satisfy desired physical properties and shape recovery performance.

EMPLOYING THE GURSON-TVERGAARD-NEEDLEMAN MODEL TO PREDICT DUCTILE FRACTURE IN METAL ADDITIVE MANUFACTURING

Yonghwi Kim[*1], Sangyeop Kim[1], Min-Kyeom Kim[1], Taeksang Lee[2] and Moon Ki Kim[1]*

[1]*Sungkyunkwan University*
[2]*Myongji University*

ABSTRACT

Metal Additive Manufacturing (Metal AM), commonly known as 3D printing, is a rapidly evolving industry with significant implications across various sectors. This technology is acclaimed for its customization capabilities, cost-efficiency, and environmentally friendly production processes. In particular, Metal AM is revolutionizing the way metallic components are fabricated. However, a notable challenge associated with Metal AM is the potential reduction in durability and strength of parts compared to those produced by traditional manufacturing methods. This weakness is often attributed to defects such as porosity and inclusions in the Heat Affected Zone (HAZ) during the printing process. This study addresses the critical issue of ductile fracture in Metal AM parts by employing the Gurson-Tvergaard-Needleman (GTN) model, a widely utilized numerical method for modeling ductile fracture phenomena. The GTN model is particularly effective in simulating the initiation, growth, and coalescence of microvoids and cavities in metallic materials, leading to fracture. By adapting the GTN model to the specific context of Metal AM, this paper presents a comprehensive approach to understanding and predicting the ductile fracture behavior of Metal AM materials. Our research involved extensive computational simulations and experimental validations, focusing on the microstructural characteristics unique to Metal AM. The findings offer valuable insights into the fracture mechanisms of Metal AM parts and provide a robust framework for predicting their structural integrity. This model not only enhances the understanding of the mechanical properties of Metal AM materials but also serves as a critical tool for optimizing the AM process, thereby contributing to the advancement of this transformative manufacturing technology.

AUTOENCODER-BASED GAPPY DATA RECONSTRUCTION ALGORITHM

Youngkyu Kim[*1], Youngsoo Choi[2] and Byounghyun Yoo[1]*

[1]Korea Institute of Science and Technology
[2]Lawrence Livermore National Laboratory

ABSTRACT

In this study, we have developed a data reconstruction algorithm called Gappy Autoencoder (Gappy AE) to overcome the limitations of digital twins caused by sparse measurements or missing data in the digital twin model. The existing methodology for data reconstruction using Proper Orthogonal Decomposition (POD), known as Gappy POD, is being utilized. However, the Gappy POD approach has limitations in representing solutions with large Kolmogorov N-width due to its ability to predict data only within the linear subspace. On the other hand, utilizing unsupervised learning models based on nonlinear manifolds provides superior data representation capabilities compared to the linear subspace. An autoencoder model is trained and the decoder part constructs the nonlinear manifold that maps low dimensional latent vectors to high dimensional input data. In this research, we propose a more generalized methodology called Gappy AE, which utilizes nonlinear manifolds (i.e., decoder parts of trained autoencoders) to represent data that the conventional Gappy POD approach cannot handle effectively. This can be applied in real-time state prediction based on measured values. Through numerical examples of 2D diffusion and 2D wave equation problems, we have confirmed that Gappy AE outperforms Gappy POD in terms of data reconstruction performance when sparse measurements on boundaries are given. Furthermore, we evaluate how data reconstruction accuracy is influenced by three different sampling algorithms: discrete empirical interpolation method, the S-OPT algorithm, and uniformly distributed sampling.

A MULTI-DIRECTOR CONTINUUM BEAM FINITE ELEMENT FOR WIRE ROPE STRANDS

Yu-Yeong Kim[*1], Hyo-Jin Kim[2] and Gunwoo Noh[1]*

[1]*Korea University*
[2]*Korea Institute of Science and Technology*

ABSTRACT

This study introduces a finite element model for the analysis of wire rope cables, specifically designed to efficiently handle their complex geometry. The model is based on continuum mechanics principles and employs multi-directors and cross-sectional elements to accurately represent the double helical structures of the individual wires within the wire rope strands. The main advantage of this continuum beam formulation is its ability to address intricate wire rope geometries and inter-wire movements within a simplified beam framework, regardless of the number of strands and constituent double helical wires. This approach offers both ease of modeling and efficient analysis while accounting for geometric complexities. Additionally, the proposed beam element model exhibits high accuracy while requiring significantly fewer degrees of freedom compared to traditional three-dimensional solid finite element models commonly used for cable analysis. To validate the effectiveness of our proposed model, we conducted several numerical examples. These examples show the robustness of the model in accurately simulating the physical behaviors of wire rope cables under various conditions. They also demonstrate the efficiency and reliability of the model in analyzing the complexities of wire rope cable systems.

ADAPTIVE MESH REFINEMENT STRATEGIES FOR MELT POOL RESOLUTION IN PART-SCALE AM SIMULATIONS

Kellis Kincaid[*1], John Coleman[1] and Alex Plotkowski[1]*

[1]*Oak Ridge National Laboratory*

ABSTRACT

The computational expense of part-scale laser powder bed fusion (LPBF) simulations can be drastically reduced by leveraging data contained in the prescribed beam scan path. This information provides times and locations where large thermal gradients, melt pools, and other small-scale phenomena are likely to develop as the beam traverses the work piece. The mesh in these regions can be selectively refined and coarsened as the beam passes over, allowing fine resolution of the melt pool dynamics while minimizing the number of cells and resources required for the problem. An adaptive mesh refinement (AMR) technique was developed to exploit this information within the open-source LBPF modeling tool, AdditiveFOAM. The implementation makes full use of existing AMR and load balancing capabilities available in OpenFOAM, upon which AdditiveFOAM is based. The proposed approach uses scan path information to generate a marker field which is provided to the mesh refinement library. This marker field is created by dividing the simulation into a specified number of intervals. At the beginning of each interval, the algorithm marches forward along the scan path and searches for any cells which overlap with the beam spatial dimensions, until the end of the interval is reached. Overlapping cells are marked for refinement, so that the beam behavior is captured on a fully refined grid as it progresses through the interval.

The performance of this approach is examined for small- and part-scale simulations on both HPC and edge computing resources. Time profiling studies demonstrate that for a given case, there exists an optimum number of refinement intervals which balances frequent AMR operations against long linear algebra solves resulting from over-refinement. A preliminary scaling study indicates that the proposed strategy achieves acceptable results on HPC resources; however, the true impact of this approach is to significantly reduce the resources required for a problem. As an example, one non-AMR benchmark case with a fine mesh required 27 minutes to complete on several HPC nodes. The same problem was finished in 8 minutes using an ordinary laptop with the proposed AMR strategy, with minimal difference in results.

HIGH-ORDER BOUNDS-SATISFYING APPROXIMATION OF PARTIAL DIFFERENTIAL EQUATIONS VIA FINITE ELEMENT VARIATIONAL INEQUALITIES

Robert Kirby[*1] and Daniel Shapero*[2]

[1]*Baylor University*
[2]*University of Washington*

ABSTRACT

Solutions to many important partial differential equations satisfy bounds constraints, but approximations computed by finite element or finite difference methods typically fail to respect the same conditions. Chang and Nakshatrala enforce such bounds in finite element methods through the solution of variational inequalities rather than linear variational problems. Here, we provide a theoretical justification for this method, including higher-order discretizations. We prove an abstract best approximation result for the linear variational inequality and estimates showing that bounds-constrained polynomials provide comparable approximation power to standard spaces. For any unconstrained approximation to a function, there exists a constrained approximation which is comparable in the $W^{1,p}$ norm. In practice, one cannot efficiently represent and manipulate the entire family of bounds-constrained polynomials, but applying bounds constraints to the coefficients of a polynomial in the Bernstein basis guarantees those constraints on the polynomial. Although our theoretical results do not guaruntee high accuracy for this subset of bounds-constrained polynomials, numerical results indicate optimal orders of accuracy for smooth solutions and sharp resolution of features in convection-diffusion problems, all subject to bounds constraints.

UNVEILING FULL-FIELD MODULUS AND STRESS USING DIGITAL IMAGE CORRELATION

Joseph Kirchhoff[*1], Dingcheng Luo[1], Thomas O'Leary Roseberry[1], Zixiang Tong[1], Jin Yang[1] and Omar Ghattas[1]*

[1]*The University of Texas at Austin*

ABSTRACT

Digital Image Correlation (DIC) is a widely used technique in experimental labs for assessing full-field displacement. However, its potential extends beyond this setting. This presentation advances the possibilities of characterizing a spatially varying modulus field by integrating DIC with a partial differential equation (PDE)-based inverse problem, forming a unified joint inversion. With images and boundary conditions it will be shown that displacement and modulus fields can be discovered, naturally extending to stress fields. The PDE describes the expected forward physics; this presentation will show examples with linear elasticity and hyperelasticity. Our exploration reveals that handling the joint inverse problem within an infinite-dimensional framework (using adjoint-based gradients and Hessians) allows for the emergence of heterogeneity or defects in the solution. We will present results from various regularization methods, incorporated to mitigate the ill-posed nature of the inverse problem. Notably, total variation (TV) will be highlighted for its effectiveness in preserving sharp interfaces found in various materials like fibers, particles, and grain boundaries. The presentation will elaborate on a primal-dual TV formulation designed to maintain mesh-independence. Finally, we will discuss inversion results obtained from experimental coupons 3D printed via Polyjet, where the as-printed color corresponds to modulus. To the best of our knowledge, the algorithm presented here represents a pioneering effort in inferring modulus as a fully heterogeneous parameter.

A PRESSURE-ROBUST HYBRIDIZED DISCONTINUOUS GALERKIN METHOD FOR THE CAHN-HILLIARD-NAVIER-STOKES SYSTEM

Keegan Kirk[*1] and Beatrice Riviere*[1]

[1]*Rice University*

ABSTRACT

Diffuse interface models are an increasingly popular approach to the simulation of multiphase flow phenomena. From the computational point of view, the advantage of these models is the elimination of the need to track the interfacial dynamics between phases. This advantage, however, comes at the expense of the solution of an additional nonlinear parabolic equation arising from thermodynamic considerations. One such example is the fourth-order Cahn-Hilliard equation describing the phase separation of an immiscible binary mixture, which, when coupled to the incompressible Navier-Stokes equations, can serve as a model for immiscible two-phase flow in porous media at the pore scale.

An effective approach to the numerical solution of the Cahn-Hilliard equation involves transforming it into a coupled system of second order equations and applying an interior penalty discontinuous Galerkin (DG) method. Among many other advantages, the DG method enjoys local mass conservation due to the introduction of numerical fluxes across element interfaces; however, the tradeoff is an increase in computational expense in comparison to conforming finite element methods. On the other hand, much of the recent progress in the numerical solution of incompressible flow problems has concentrated on pressure-robust finite element methods, a class of methods that preserve a fundamental invariance property of the incompressible Navier-Stokes equations. Two essential ingredients are required for pressure-robustness: exact enforcement of the incompressibility constraint, and H(div)-conformity of the finite element solution.

For this reason, we propose and analyze a hybridized interior penalty discontinuous Galerkin (HDG) method to solve the Cahn-Hilliard-Navier-Stokes system wherein additional finite element spaces are introduced on the interfaces between mesh elements. By enforcing a suitable transmission condition on the numerical flux, the degrees of freedom on the interior of each element can be eliminated through static condensation. This reduces the size of the globally coupled algebraic system compared to the standard interior penalty method while preserving its many advantages. Moreover, H(div)-conformity of the discrete velocity solution is enforced through the introduction of a pressure facet variable, ensuring the numerical scheme is pressure-robust. To guarantee unconditional stability of the numerical scheme and unique solvability of the resulting nonlinear algebraic system, we employ a standard convex-concave splitting of the nonlinear chemical energy density and a first order implicit Euler time integration scheme.

MIXED PARTITION OF UNITY METHODS AND STOCHASTIC GILLESPIE ALGORITHMS FOR TRANSPORT-REACTION EQUATIONS

Markus Kirkilionis[*1]*

[1]*University of Warwick*

ABSTRACT

We propose to solve Transport-Reaction Problems in a new partially deterministic (continuum part) and partially stochastic framework (finite size part). We couple a PDE defined on a domain Ω and a Gillespie algorithm solving the discrete finite-size particle system reaction part of the problem.

The idea of discretisation is simple, but novel, and is in both its theoretical and practical aspects of great importance. We interpret the solution of the PDE as a continuum probability distribution L_x in the space part of the problem, i.e L_x determines where in space to find particles at time t. Let $N = N(t) \in \mathbb{N}$ be the number of particles in the system at time t. We assume there exists a distribution transfer function, choosing the position of each particle from the spatial probability function. We allow here memory, i.e. there is knowledge about the previous positions. Note that this setting solves a lot of long-standing theoretical problems, like the property of infinite speed of propagation of the classical diffusion equation. The separation between transport and reaction allows for a number of interesting combinations of numerical methods. The reason for using a finite particle size has several advantages, finite size effects can be effectively investigated. Nonlinear reaction mechanisms are very common in many applications, like chemical reaction systems, biochemistry, epidemiology, population dynamics, opinion formation, mathematical finance, etc. The particles can undergo type transformations as given by transformation rules called reactions. The reaction process then is implemented numerically by the so-called Gillespie algorithm. The discretisation of the full process is a follows. For the transport PDE we could use any common discretisation method, finite differences, finite volumes or finite elements. We then have to attach reaction volumes to this underlying spatial discretisation. In finite differences, the reaction volumes are identical with the discrete mesh points. In finite elements we can define the reaction volumes with the help of basis functions. Here we propose to use generalised finite element methods based on partition of unity methods, as this allows us to cover complex spatial geometries. The discretised transport equation allows the computation of the particle distribution function L_x. The fluxes between reaction volumes can therefore be computed, establishing transport rules. Then we use a Gillespie algorithm for the reaction part. We can be improve the latter by using a generalised Gillespie algorithm with a decision tree relating to the spatial structure of the problem.

HIGH SPEED COMPUTING FOR MIXING OF BI-DISPERSE PARTICLES IN A ROTATING DRUM

Naoki Kishida[*1], Hideya Nakamura[1], Shuji Ohsaki[1] and Satoru Watano[1]*

[1]*Osaka Metropolitan University*

ABSTRACT

Powder mixing is ubiquitous in a wide variety of manufacturing sectors including chemical industries. In the mixing process, multiple components with different physical properties such as particle size are usually treated. In these conditions, powder segregation can occur due to the difference in particle properties. Degree of segregation of powder mixture has a significant impact on the quality of the final product obtained by processing the powders, and thus methods to predict the degree of segregation are required. Computer simulation using the Discrete Element Method (DEM) is a powerful tool for the analysis of powder mixing process. In a DEM, dynamics (position and velocity) of an individual particles are numerically solved. These calculations are performed at extremely small time-step (micro seconds order). Therefore, a large number of iterations are required to calculate the entire powder mixing process, and it is difficult to predict a practical mixing in an actual process.

Recently, we developed an original machine learning model, namely recurrent neural network with stochastically calculated random motion (RNNSR), which allows long time scale powder mixing simulation with low computational cost and high accuracy [1]. RNNSR learns individual particle dynamics from short-time DEM simulation results and predicts a powder mixing for a long time. However, the RNNSR was only verified for mono-dispersed particles and has not been applied to bi-disperse particle systems that exhibit segregation. In this study, we expanded the RNNSR to handle bi-disperse particles and evaluated its effectiveness in simulating segregation phenomena. Development of this model significantly contributes to the implementation of powder simulations at powder properties and time scales closer to actual processes.

EVALUATION OF EFFECTIVENESS OF TRAFFIC JAM ABSORPTION DRIVING USING COMPUTER SIMULATION

Shuya Yamada[1] *and Eisuke Kita**[1]

[1]*Nagoya University*

ABSTRACT

Congestion-absorbing driving is known as an effective driving method for resolving traffic jams. Congestion-absorbing driving is based on the idea of reducing congestion by reducing excessive acceleration and deceleration while driving at low speeds while keeping a relatively large distance between vehicles. In this study, traffic jam absorption driving is applied to traffic simulation and its effectiveness is verified. The simulation results show that the average arrival time of the vehicle has become shorter. This shows that it is possible to increase the average speed in a congested area by not propagating deceleration to vehicles behind by driving to absorb congestion.

BAYESIAN TEMPORAL CONVOLUTIONAL NETWORK FOR EXCHANGE RATE PREDICTION

Yiyang Zhang[1] *and Eisuke Kita**[1]

[1]*Nagoya University*

ABSTRACT

This study proposes Bayesian Temporal Convolutional Network (BTCN) model applied to exchange rate prediction, and the performance of the proposed model is verified by conducting experiments on USD/JPY exchange rate data in 2018. The BTCN model applies the Bayesian neural network approach and Bayes by Backprop to the Temporal Convolutional Network(TCN) model, which improves the performance of the model for exchange rate forecasting compared to the TCN model by introducing an estimation for exchange rate uncertainty. The performance of the BTCN model on the exchange rate prediction task and the effect of the number of Monte Carlo approximation samples on the BTCN model are discussed separately in the experiments. For the exchange rate prediction experiments, the BTCN, TCN-with-dropout, and TCN-without-dropout models are trained separately. For comparing the prediction results of the three models, the BTCN model has a faster decrease in the value of the loss function on the validation dataset compared to the two TCN models, and the value of the loss function after the model is converged is smaller than the other models. The results of the experiments show that the BTCN model fits the true distribution better than the TCN model, and the introduction of uncertainty estimation has improved the ability of the model to search for optimal solutions.

SYMBOLIC REGRESSION AND EXTENDED PHYSICS-INFORMED NEURAL NETWORKS FOR GRAY-BOX MOTION EQUATION LEARNING

Elham Kiyani[*1], Khemraj Shukla[1], Mikko Karttunen[2] and George Karniadakis[1]*

[1]*Brown University*
[2]*Western University of Ontario*

ABSTRACT

Partial Differential Equations (PDEs) are essential in dynamic system modeling across fields such as fluid dynamics, heat transfer, and phase transformations, aiding in understanding and predicting complex behaviors[1]. However, developing comprehensive models remains challenging. Our study introduces a novel framework using eXtended Physics-Informed Neural Networks (X-PINNs) [2] and symbolic regression [3] to reveal hidden components of nonlinear equations from data. X-PINNs, the foundation of our approach, employ a domain decomposition strategy in space- time, improving upon traditional methods by ensuring flux continuity across domain interfaces. The Allen-Cahn equation, pivotal in phase transition studies, validates our method's effectiveness.

Symbolic regression, integral to our framework, efficiently derives accurate mathematical formulas from data, identifying precise equations corresponding to specific datasets. It successfully predicts the explicit formulas of unknown equation terms.

To evaluate our framework's effectiveness in a setting that closely mimics the complexities of real-world data, we introduce random noise into our datasets and demonstrate the resilience of our framework when faced with substantial levels of noise, mirroring the often unpredictable and imperfect nature of real-life data conditions.

A critical finding is the minimal data needed for effective neural network training. We established that using at least 50% of the data is essential for correctly predicting dynamical equations, while a minimum of 60% is required for accurate unknown coefficient predictions.

Our approach, combining X-PINNs with symbolic regression, shows great promise in dynamic system modeling, effectively uncovering hidden equation aspects under challenging conditions of noise and limited data.

MULTISCALE MODELING OF CALCIFIED POLYMER HYDROGELS

Sandra Klinge[*1] and Marc Graham*[1]

[1]*TU Berlin*

ABSTRACT

Hydrogels, a significant group of highly hydrated polymers, represent the best choice for the potential application to bone fracture regeneration, which goes back to their bioactivity, affinity for biologically active proteins and compatibility with the bone tissue. However, this kind of materials also shows a serious disadvantage, namely, it loses its mechanical strength through swelling. This makes its straightforward usage difficult and motivates the development of different enhancement procedures. One of the most modern techniques for this purpose is calcification or, in a more general sense, mineralization. This method is inspired by the natural process of the bone growth where the enzyme alkaline phosphatase causes mineralization of the bone by cleavage of the phosphate from organic molecules. An analogous process induces homogeneous mineralization of a hydrogel and increases its mechanical strength. Recently, optical and electron microscopy has revealed that calcification yields different types of microstructure dependent on the type of the underlying polymer, and thus has clearly indicated that computational modeling can significantly contribute to the targeted investigation of effective behavior and material parameters. The current contribution uses the multiscale finite element method to simulate the effective material behavior of calcified hydrogels. Within this framework, representative volume elements (RVEs) are generated to depict the biphasic material microstructure consisting of the organic hydrogel and anorganic calcium phosphate [1]. Most commonly, the anorganic phase appears in the form of spherical inclusions or honeycomb grids where the characteristic size of a typical unit might vary. The approach proposed treats the calcified regions as linear elastic material and assumes the Ogden model for the hydrogel. Diffusivity is another important aspect in this context [2]. Its study requires a profound knowledge on the processes on the nanoscale. This time, the effective behavior is investigated by using the asymptotic homogenization approach.

STABILIZATION OF MIXED DISPLACEMENT-PRESSURE FINITE ELEMENTS AT FINITE STRAINS USING POLYHEDRAL FORMULATIONS AND VORONOI MESHING

Bjorn Sauren[1], Emilia Oheim[1] and Sven Klinkel[1]*

[1]RWTH Aachen University

ABSTRACT

The hexahedral mixed displacement-pressure finite element of the lowest order (H1/P0) has shown to be simple and effective during both linear and nonlinear analysis of incompressible solids. While the discrete displacement field is generally considered to be sufficiently accurate, the discrete pressure field can sometimes be heavily polluted by spurious pressure modes. This results from the fact that the element does not fulfill the inf-sup condition. While postprocessing techniques, such as pressure filtering or smoothing, exist to remove the spurious pressure modes from the solution, this contribution aims on the exclusion of spurious pressure modes from the solution a priori due to the element geometry. By employing polyhedral finite element formulations on Voronoi tessellations in three dimensions, we show that the discrete kernel of the linearized mixed bilinear form only consists of the hydrostatic pressure mode. A spurious pressure mode is automatically suppressed due to the vertex-to-volume ratio in the finite element mesh. These considerations hold for any arbitrary physically admissible displacement state that can occur within a Newton-Raphson framework. Both linear and nonlinear numerical examples show that spurious pressure modes are indeed suppressed if the type of tessellation is changed from hexahedral to Voronoi.

STATISTICAL MECHANICS OF DYNAMICAL SYSTEM IDENTIFICATION

Andrei Klishin[*1], Joseph Bakarji[2], Nathan Kutz[1] and Krithika Manohar[1]*

[1]*University of Washington*
[2]*American University of Beirut*

ABSTRACT

Recovering the dynamical equations from observed noisy trajectory data constitutes the problem of system identification. Approaches such as Sparse Identification of Nonlinear Dynamics (SINDy) are usually framed as minimizing a loss function that balances the data fit with parsimonious regularization, requiring a trial-and-error selection of hyperparameters. In this work we formulate system identification as a two-level Bayesian inference problem that explicitly separates variable selection from variable values and uses statistical mechanics techniques to compute the posterior parameter distribution in closed form and avoid Monte Carlo sampling. The low-data limit of this approach provides an uncertainty quantification of the identified models. The high-data limit resembles the thermodynamic limit and leads to a sharp sparsity- and noise-induced phase transitions between correct and incorrect identification. The statistical mechanics perspective can be integrated with other SINDy variants and applied to sparse regression problems in other contexts.

TOPOLOGY OPTIMIZATION OF THERMAL-ELASTIC STRUCTURES: CO-DESIGN OF GEOMETRY AND FUNCTIONALLY GRADED MATERIAL

Stefan Knapik[*1], Shiguang Deng[1], Liwei Wang[1], Jian Cao[1], Wing Kam Liu[1] and Wei Chen[1]*

[1]Northwestern University

ABSTRACT

Recent developments in additive manufacturing have greatly enhanced our ability to fabricate functionally graded materials (FGMs), such as continuously graded alloys, providing unprecedented flexibility in structure design beyond discrete palettes of materials. FGMs hold tremendous potential for thermal-elastic applications, allowing for precise control over thermal and mechanical stress responses through tailored material properties. However, traditional topology optimization (TO) approaches cannot accommodate FGMs as they pre-assign material properties and segregate material selection as a distinct process. While multi-material TO approaches allow for voxel-level material composition design, they often fail to adequately consider crucial metallurgical factors like alloy compatibility. Similarly, existing thermal-elastic TO methods neglect or only partially consider the dependence of material properties on temperature.

We aim to address these gaps by developing more effective FGM design methodologies, integrating a density-based TO framework with automatic differentiation for improved computational efficiency and extensibility. This method enables the concurrent optimization of material distributions and geometric configurations. It utilizes a data-driven radial basis function interpolation to model material properties, facilitating continuously varying material combinations with minimal computational overhead. The inclusion of a penalization mechanism within the material interpolation scheme can deter the selection of unobserved material mixtures – a critical factor when accurate property interpolation is uncertain. A key feature of our method is the consideration of temperature-dependent material properties, a vital consideration for realistic design evaluation but largely overlooked in thermal-elastic TO approaches. This results in nonlinear thermal analyses for accurate temperature solutions, which are crucial since material properties can vary greatly with temperature. To ensure a robust design, we propose a unique stress constraint aggregation to efficiently manage spatially variable stress limits influenced by temperature and material composition.

A case study focusing on blisk design for aerospace applications demonstrates the multiple advantages of our approach. The continuous material design efficiently balances the interplay between temperature variation and mechanical stresses, achieving significant improvements over traditional discrete material design methods. It also successfully addresses the challenge of alloy compatibility by penalizing untested material combinations. Most notably, the holistic consideration of temperature-dependent material properties boosts the accuracy of our solutions, thereby enhancing design confidence. In addition to these benefits, our method contributes to sustainability by limiting the utilization of critical materials. These advancements collectively mark a significant stride in optimizing high-performance engineering structures while prioritizing performance, resilience, and environmental impacts.

ISOGEOMETRIC SHAPE SENSITIVITY ANALYSIS CONSIDERING TANGENTIAL DIVERGENCE OF NON-SMOOTH BOUNDARY IN BOUNDARY APPROACH

Keun-Hyeong Ko[*1], Hyun-Seok Kim[2] and Seonho Cho[1]*

[1]*Seoul National University*
[2]*Korea Research Institute of Ships & Ocean Engineering*

ABSTRACT

Despite the conventional finite element analysis (FEA) based boundary method for shape design sensitivity analysis (DSA) has the advantage of low computation costs, the accuracy of computed sensitivity is not satisfactory due to the inaccurate consideration of boundary geometry. To overcome this difficulty, employing an efficient adjoint method, we propose an isogeometric analysis (IGA) [1] based boundary method for shape DSA that can exactly handle the normal and curvature on a non-smooth boundary [2]. The accuracy can be improved by using the domain method, but in this case, the computation must be performed throughout the domain, which requires a much higher computational cost than the boundary method. For continuum-based shape DSA using the boundary method, the IGA provides more accurate values than the conventional FEA; The FEA-based boundary method provides erroneous results due to the inaccurate consideration of the boundary geometry such as normal vector and curvature, while the IGA-based one accurately considers the geometry of boundary. The required computational cost for the boundary method is much less than that of the domain method since the computation is performed only on the boundary.

The shape sensitivity of performance measure defined by a boundary functional on the non-smooth boundary can be precisely obtained using the curvature of boundary, the normal component of design velocity, and the tangential divergence of design velocity [3]. Especially for problems with non-smooth boundaries, the tangential divergence must be considered, but it is not possible to calculate it accurately with conventional FEA-based boundary method. Through numerical examples, the accuracy and efficiency of the IGA-based boundary method for DSA are compared with other methods such as FEA-based boundary and domain methods. It is demonstrated that the IGA-based shape design sensitivity of the boundary functional could accurately represent the tangential divergence on the boundary that the linear shape function in the FEA-based one cannot properly represent.

GROUND ENERGY AND RELATED PROPERTIES ESTIMATION IN QUANTUM CHEMISTRY WITH LINEAR DEPENDENCE ON THE NUMBER OF ATOMS

Taehee Ko[*1], Xiantao Li[2] and Chunhao Wang[2]*

[1]*Korea Institute for Advanced Study*
[2]*Pennsylvania State University*

ABSTRACT

Density-functional theory (DFT), due to its ability to predict ground state properties without explicitly solving a many-body quantum mechanical model, has revolutionized computer simulations in chemistry and material science. A faithful implementation of the theory requires self-consistent calculations, involving repeatedly diagonalizing the Hamiltonian, for which a classical algorithm typically requires a computational complexity that scales cubically with respect to the number of electrons. This limits DFT's applicability to large-scale problems with complex chemical environments and microstructures. In this talk, we present a quantum algorithm that has a linear scaling with respect to the number of atoms, offering a drastic reduction in computational cost. Our algorithm leverages the quantum singular value transformation (QSVT) (András Gilyén et al, 2019) and an unbiased amplitude amplification method (Patrick Rall and Bryce Fuller, 2023) in order to generate a quantum circuit that encodes the density-matrix, and estimate the output electron density with the Heisenberg-limited scaling. We present an efficient hybrid approach to accelerate the self-consistent field calculations by reducing the number of components of the electron density that need to be estimated by quantum computation. We provide a rigorous convergence analysis that involves the function approximation error, the statistical fluctuation, and the iteration complexity.

EFFICIENT TWO-SCALE MODELING OF NONLINEAR HYPERELASTIC STRUCTURES AND ARCHITECTED MATERIALS

Dennis Kochmann[*1], Helen Le Clezio*[1], Claire Lestringant*[2] and Konstantinos Karapiperis*[1]

[1]*ETH Zurich*
[2]*Sorbonne University*

ABSTRACT

We present a numerical framework for modeling truss-based architected materials, which accounts for both the geometric nonlinearity inherent in the large deformation of slender struts and the nonlinear constitutive behavior of hyperelastic base materials. Akin to the FE2 method in homogenization, our approach is based on a formal, two-scale expansion. We decompose the 3D description of a structure into a macroscale problem (solving for the deformation of all beam center-lines, taking into account stretching, bending, and torsion) and a series of microscale boundary value problems defined over the beam's cross-section. To bypass the expensive pre- or on-the-fly solution of the cross-sectional problem on the microscale, we use machine learning to learn a surrogate for the effective energy density of the microscale problem, which is subsequently used in the macroscale problem based on a geometrically exact, nonlinear discrete beam framework. We demonstrate the accuracy of this approach through a set of benchmarks, highlighting the nonlinear effects of the cross-sectional geometry and constitutive material, including material heterogeneity and pre-strains. We further illustrate its application to truss-based architected materials consisting of networks of slender polymeric beams.

MODELLING FOR 4D PRINTING OF PHASE TRANSFORMING CELLULAR MECHANICAL METAMATERIAL

Sosuke Kanegae[1], Hayato Nagayama[1], Saki Morimoto[1], Masayuki Okugawa[1] and Yuichiro Koizumi[1]*

[1]Osaka University

ABSTRACT

Mechanical metamaterials have undergone revolutionary development due to additive manufacturing (AM) technologies, represented by authentic materials with negative Poisson ratios. On the other hand, AM technology of 3D objects that evolve in shape over time and in response to environmental change is emerging as 4D printing technologists, as represented by Phase Transforming Cellular Materials (PXCM) for various applications. We are developing PXCMs that exhibit phase transformations in crystalline materials induced by stress or temperature change, as in shape memory and superelastic alloys. We propose a novel design for mechanical metamaterials with temperature- and stress-responsive stable structures, offering the potential to apply to large-scale constructions with shape memory and superelastic capabilities. This innovation is anticipated to provide earthquake- resilience through advanced shock absorption and seismic isolation technologies.

Our approach encompasses three pivotal aspects:
1. Multi-Axed Stress-Induced PXCM: We designed a lattice structure based on face-centered cubic atomic arrangements, capable of phase transitions under stress along four <111> directions. The lattices consist of spherical nodes connected by beams aligned in the <110> direction, akin to atomic bonds. These beams are shaped similarly to curly brackets and undergo significant deformation via buckling under a stress beyond a stress threshold, providing impact absorption. The metamaterial's behaviors were analyzed by Finite Element Method (FEM) and predicted by machine learning with neural networks. The model was validated by actual fabrication using polyurethane with Powder Bed Fusion.
2. Thermally-Induced PXCM: We fabricated PXCMs to demonstrate thermally induced phase transitions utilizing bimetallic (Fe-36Ni Invar and Mn-Cu alloys) beams. The design incorporates beams that exhibit phase changes unidirectionally under load. The FEM model was used to construct a phase diagram indicating the stabilities of phases in stress-temperature space. The model was verified by constructing a 2D PXCM, which exhibited stress- and thermally-induced phase transformations.
3. Multi-Material 3D Printing for 4D Applications: The creation of PXCMs with thermal phase transformation necessitates multi-material AM techniques. In powder-based AM technologies, such as Directed Energy Deposition (DED), Binder Jetting, and Powder Bed Fusion (PBF), important issues are separating, collecting, and recycling mixed powders. We developed a novel vibratory process for powder separation experimentally. The factors influencing the separation efficiency were analyzed through discrete element method (DEM) simulations.

This study contributes to the development of mechanical metamaterials in disaster mitigation infrastructure and extends the possibility of the functional metamaterial fabricated by AM.

PREDICTION OF THREE-DIMENSIONAL DEFECT'S INFORMATION IN COMPLEX SHAPED CFRP SPECIMENS USING GNN BASED ON STRESS DISTRIBUTION ON SURFACE FROM HOMOGENIZED FINITE ELEMENT ANALYSIS AND INFRARED MEASUREMENTS

Yuta Kojima[*1], Kenta Hirayama[1], Yoshihisa Harada[2] and Mayu Muramatsu[1]*

[1]*Keio University*
[2]*National Institute of Advanced Industrial Science and Technology*

ABSTRACT

In this study, a machine learning model which is pretrained by the distribution of sum of the principal stress on surface (DSPSS) obtained from simulations by the finite element method (FEM) is used to predict three-dimensional information of defects from DSPSS obtained from infrared stress measurements for the complex shaped carbon fiber reinforced plastic (CFRP). The complex shaped CFRP used in this study is a children's athletic prosthetic leg that has both curved and straight geometries. Generally, CFRP structures are made by laminating prepregs with different microstructures. The model prepared in this study is laminated with a combination of plain weave structure and unidirectional structure. The plain weave structure is used in the prepregs which are located near the surface. Infrared stress measurements are performed to obtain DSPSS calculated from surface temperature changes using Kelvin's theory of thermoelasticity. In experiment, the bolted joints are fully fixed, and loads are applied to the surface which is in contact with the ground. The measured surfaces are painted black to prevent surface reflection. Measurements are performed on 4 specimens without defect and 16 specimens with defect. A homogenized FEM is used to obtain DSPSS which is close to the stress distribution of the infrared stress measurement. It performs a macro-scale analysis that takes into account the mechanical properties of the microstructure of the plain weave structure and unidirectional structure. As in the infrared stress measurement, the bolted joints are fully fixed and a load is applied to the surface which is in contact with the ground. The used mesh is a four-node tetra element. Analysis is performed on a specimen without defect and a specimen with defect. The machine learning model used in this study is a graph neural network (GNN), which can be trained with nodes and edges in a three-dimensional geometry and can therefore make good predictions for objects with curved surfaces, such as the prosthetic leg. Firstly, the GNN model is pre-trained using DSPSS obtained from FEM, for which a large number of data sets can be prepared. Next, we perform transfer learning using DSPSS obtained from infrared stress measurements, for which only a small amount of data set is available, to estimate the three-dimensional information of the defects with high accuracy.

FATIGUE LIFE PREDICTION WITH ELASTO-PLASTIC DAMAGE AND HARDENING MODELING

Hüray Ilayda Kök[1] and Philipp Junker*[1]

[1]*Leibniz University Hannover*

ABSTRACT

This contribution introduces an innovative and efficient methodology for modeling fatigue induced by damage, emphasizing speed and robustness. The proposed approach utilizes a rate-dependent elasto-plastic gradient-enhanced model, offering a comprehensive solution for capturing material degradation over time. The theoretical foundation of the model is established through an extended Hamilton principle for dissipative processes, incorporating internal variables as damage, elasto-plasticity and hardening.

To mitigate mesh dependency issues, the Helmholtz free energy is enhanced by gradient terms for regularization purposes. This adjustment allows for the effective fitting of fatigue models to experimental data, primarily facilitated by the fatigue rate parameter, enabling a precise characterization of material deterioration.

Efficient resolution of the coupled system of equations is achieved through an operator split and the application of the Neighbored Element Method. This integrated approach not only enhances the accuracy of the fatigue model but also significantly improves computational efficiency. By doing so, it establishes a robust framework for comprehending and addressing the intricate challenges associated with fatigue-induced damage in engineering applications.

The methodology's strength lies in its ability to balance the intricacies of fatigue modeling with the need for computational efficiency. The operator split technique streamlines the solution process, while the Neighbor Element Method contributes to the overall effectiveness of the coupled system.

Keywords: Damage, Fatigue, Gradient-enhanced regularization, Neighbored element method, Coupled processes, Variational modeling

ABSTRACT

In this talk, we present ongoing work on the development of accurate and efficient numerical methods for fluid-structure interaction. Our approach is based on a recently developed immersed interface method for discrete surfaces, avoiding the use of body-conforming discretizations for the moving fluid-structure interface. We employ a structured discretization of the fluid equations combined with a Lagrangian discretization of the structural dynamics in a partitioned algorithm. Kinematic matching conditions are imposed as a constraint on the motion, enforced through a Lagrange multiplier force along the fluid-structure interface. This numerical approach integrates stress jump conditions generated by the surface force within the Cartesian discretization, allowing us to capture accurate fluid traction forces up to the fluid-structure interface. The basic method is extended to handle both rigid-body and flexible-body fluid-structure interaction using a simple Dirichlet-Neumann coupling scheme. Numerical tests indicate that the method avoids artificial added mass instabilities. The talk will delve into the details of the numerical methodology and its extensions, addressing irregular interface discretizations that may arise in models involving complex geometries and at contact or near-contact conditions. The methodology will also be illustrated through selected biomedical applications.

MFEM: ACCELERATING EFFICIENT SOLUTION OF PDES AT EXASCALE

*Tzanio Kolev**[1]

[1]*Lawrence Livermore National Laboratory*

ABSTRACT

Modern GPU architectures favor algorithms that expose fine-grain parallelism and maximize the ratio of floating-point operations to energy intensive data movement. One of the few viable approaches to achieve high efficiency in the area of PDE discretizations on unstructured grids is to use matrix-free/partially-assembled high-order finite element methods, since these methods can increase the accuracy and lower the computational time due to reduced data motion.

In this talk we present an overview of MFEM (https://mfem.org), a library for scalable high-order finite element methods, which powers high-performance computing applications in a wide variety of fields. We also report on the body of work in the Center for Efficient Exascale Discretizations (https://ceed.exascaleproject.org/), which was a co-design center in the US Exascale Computing Project focused on next-generation discretization software and algorithms, where MFEM plays a major role.

Our approach to efficiency is based on a "matrix-free" representation of the finite element operator, that factors a bilinear form into a series of sparse and dense components corresponding to the parallelism, mesh topology, basis, geometry, and pointwise physics in the problem. The operator decomposition exposes several layers of parallelism, enables the use of batched dgemss and tensor contractions, and only requires quadrature point values to be assembled for computing the action. This "partial assembly" formulation results both in less (nearly optimal) computation and less (optimal) data movement compared to assembling a global sparse matrix, therefore increasing performance and reducing time to solution.

We will describe recent MFEM advancements in performance optimizations for GPU architectures, high-order finite element benchmarks and miniapps, scalable unstructured adaptive mesh refinement, matrix-free preconditioning for partially assembled operators, high-order data analysis and visualization, and demonstrate their impact in several large-scale applications from the US Department of Energy.

[2]Aix-Marseille University

ABSTRACT

This study provides a comprehensive investigation of Adaptive Mesh Refinement (AMR) methods within a generic algorithmic framework. We propose a fully-automatic mesh refinement framework driven by an a posteriori error estimator facilitating an on-the-fly refinement. The adopted AMR mechanism is based on user-prescribed tolerances on errors guaranteeing simulation results meeting predefined accuracy standards.

First, we compare the adaptive multilevel Local Defect Correction (LDC) method [1] to hierarchical (conforming and non-conforming) h-adaptive refinement techniques in the context of linear elastic solid mechanics. We provide a numerical assessment of their performances for all-quadrilateral and all-hexahedral meshes within the developed AMR framework. Our results demonstrate the superior efficiency of the multilevel LDC method, highlighting its great potential in solving implicit systems in elastostatic simulations based on standard metrics of efficiency (dimension of systems to be solved, storage requirements, CPU time) [2]. Due to its versatile nature, this method is able to accommodate different solvers, material models, and meshes on different levels, eliminates the necessity for a complete remeshing of the domain, and benefits from a non-intrusive implementation.

We further extend the adopted computational framework to the nonlinear quasi-static solid mechanics context, aiming to capture the evolution of multiscale phenomena over time [3]. It centers around the multilevel LDC method, which, in addition to its attractive properties mentioned above, showcases its inherent capability to dynamically generate refined mesh hierarchies that capture the evolving phenomena over time.

In the nonlinear context, the proposed AMR framework manages fields transfer between different time steps and non-matching meshes and maintains error control over time through an efficient equilibration strategy. Moreover, it encompasses a reliable remeshing algorithm which minimizes mesh regeneration frequency over time, ensuring compliance with prescribed tolerances and optimizing computational resources. Effectiveness and robustness of the proposed algorithm are validated through diverse 2D and 3D numerical experiments involving various material behaviors and loadings.

[1]*Sandia National Laboratories*

ABSTRACT

A widely used technique for data-driven model order reduction is projecting onto an orthogonal subspace discovered using truncated singular value decomposition (SVD). In practice, applying SVD requires converting the training data into a matrix, which concatenates modes that are otherwise independent (e.g., X/Y/Z spatial coordinates, variables) and obscures interactions among the independent modes that could be leveraged for efficient and accurate dimensionality reduction. We propose a multilinear alternative, using tensor decompositions, to discover a subspace that is distinct along the independent modes and provides a much better trade-off between accuracy and dimensionality reduction than matrix SVD. Tensor decompositions are higher-order extensions of matrix factorizations and, specifically, higher-order SVD (HOSVD) is a proper generalization of matrix SVD to higher dimensions.

We present techniques of applying truncated HOSVD that allows discovering separate subspaces along the independent modes of high-dimensional data. The resulting subspaces are interpretable, with precise control of a target rank along each mode of the high-dimensional data tensor. Moreover, for a specified overall 2-norm error, HOSVD allows flexibility in partitioning the truncation error along the independent modes that can prioritize accuracy of some mode(s) over other. The individual subspaces are compact, and the effective subspace of the concatenated dimensions is related to tensor product of the individual bases.

We apply the truncated HOSVD based dimensionality reduction to a climate dataset representing the atmospheric dispersion of a volcano eruption. The dataset comprises atmosphere ensemble model predictions of a simulated volcano eruption, at various forcing strengths of the volcano and different initializations of the turbulent flow field. Dimensionality reduction is sought specifically for the combined spatial modes (latitude, longitude) and multiple variables in the dataset. We compare SVD applied to the matricized data (latitude, longitude, and variables concatenated into a single dimension) with truncated HOSVD applied to the data in its original tensor form. We demonstrate that, for the same target 2-norm truncation error, HOSVD results in better accuracy in predicting unseen (test data) snapshots. We discuss how the multilinear model can be extended for other downstream tasks, e.g. training a surrogate flow map in the combined subspace using DNNs, by retaining the tensor product structure between the individual mode subspaces.

ABSTRACT

We present a framework for laser beam shaping in L-PBF/M that uses an advection-diffusion model to compute a laser intensity profile corresponding to a desired temperature field (i.e. melt pool shape)[1]. To solve this inverse problem, we minimize the functional given by the squared difference between the predicted and the desired temperature field integrated over the domain using the adjoint-based optimization method. The melt pool dimensions produced by the computed laser intensity profile are validated using photomicrographs of experiments. However, other quantities such as temperature profiles, temperature gradients, or dynamic effects cannot be validated experimentally. To this end, the computational results are compared to high-fidelity melt pool models (using Smoothed Particle Hydrodynamics). Additionally, we will present new types of laser intensity profiles designed to achieve a wide, shallow, yet stable melt pool in conduction mode.

A MIXED FINITE ELEMENT APPROACH FOR THERMO-PORO-ELASTO-PLASTIC SIMULATION OF STIMULATED VOLUME EVOLUTION IN SUBSURFACE APPLICATIONS

Mohammad Komijani[*1]

[1]*Amirkabir University of Technology, Tehran, Iran*

ABSTRACT

A new mixed nonlocal finite element framework is developed for nonlinear thermo-poro-elasto-plastic simulation of porous media with multiphase pore fluid flow and thermal coupling. The solid-fluid interaction is accounted for using the mixture theory of Biot based on the volume fractions concept. Different sources of nonlinearities arising from the multiphase fluid flow effects, advective-diffusive heat transfer, inelastic deformation, fluid flux injection induced mechanical tractions, solid skeleton deformation permeability dependence, and temperature dependent viscosity are included in developing a robust numerical solver for the targeted coupled multi-physics problem. To address the effect of microstructure in inelastic localized deformation behaviour with dilational softening, a nonlocal plasticity model is proposed based on a characteristic length scale which rectifies the non-physical pathological mesh dependence problem encountered in conventional plasticity. The accuracy and strength of the developed model is shown with comparing the obtained numerical results of a benchmark bilateral compression test with existing published data in the literature. To show the versatility and robustness of the developed computational framework in modelling the geomechanics of real-case engineering practices, large scale thermo-hydro-mechanical (THM) subsurface stimulation processes with applications in Enhanced Oil Recovery (EOR) are effectively simulated and the targeted enhanced recovery and performances are demonstrated. The current formulation does not include phase transformation modelling capability, and therefore, the developed models may not be applicable for simulation of the engineering processes that involve phase change behaviour (e.g., steam injection).

PREDICTING DUCTILE FRACTURE DURING TORSION TESTING USING DISLOCATION DENSITY TENSOR

*Kazutake Komori**[1]

[1]*Daido University*

ABSTRACT

A model based on dislocation density tensor [1] is proposed for predicting ductile fracture during torsion testing. The effect of prestrain bestowed by bar drawing on the fracture strain is examined. First, a simple torsion testing machine, which can be incorporated into a universal testing machine, is manufactured. Since the cross-sectional shape of the specimen is uniform and circular along the length owing to bar drawing prior to torsion testing, the upper and lower chucks which clamp the specimen are contrived. Next, a method for simulating the torsion testing of a bar is proposed using a periodic boundary condition, and is proved to be effective for reducing the calculation time drastically. The fracture strain calculated using the dislocation density tensor-based model agrees with the experimental values, whereas the fracture strain calculated using the ellipsoidal void model proposed previously [2] does not agree with the experimental values. Finally, the fracture strain calculated using the previously proposed practical model based on the consideration ratio of prestrain [3] agrees with the experimental values.

ABSTRACT

The Cahn-Hilliard equation is a nonlinear parabolic equation of fourth order, which characterizes diffusion by considering the gradient in chemical potential, rather than following classical Fickian diffusion. The fourth order term in the equation necessitates the usage of C1 approximation requiring interelement continuity of the primary variables (concentration) and their derivatives. In this study, we introduce a phase field algorithm that couples the Cahn-Hilliard equation with the equation of linear elasticity, with a focus on computational aspects. We propose a staggered algorithm to solve the two equations, using the Natural Neighbor Galerkin method (also called the Natural Element Method) to generate shape functions via Voronoi diagram and Delaunay triangulation. We use C1 NEM shape functions to compute concentration and C0 NEM shape functions to compute displacements. An iterative solver with the Newton-Raphson method is employed to solve the set of equations. The elasticity effects due to microstructure evolution by employing the concept of eigenstrains and investigate the effect of eigenstrains on microstructural evolution of an inclusion in a 1×1 square domain is studied. Finally, we simulate the behavior of two inclusions, with and without applied displacements. When two inclusions are present, a variation in the equilibrium configuration can be observed between the conditions of applied external displacement and the absence of such displacement. Mixed approach for Cahn-Hilliard equation is studied and implementation is carried out in Abaqus with the help of user subroutines. The elasticity effects are studied in detail with the help of several parametric studies.

SPEEDING UP CALCULATION TIME BY SPECIFYING SEARCH RANGE IN SQUEEZE COMPACTING ANALYSIS USING DISCRETE ELEMENTS WITH PARTICLE SIZE DISTRIBUTION

Fumitaka Kondo[*1] and Yasuhiro Maeda*[1]

[1]*Daido University*

ABSTRACT

Discrete Element Method (DEM) is a numerical method used to simulate dynamic phenomena of granular materials such as sand. There is a speeding up method of calculation time using neighboring particle search in DEM with uniform particle size [1]. However, to reduce computational cost while keeping calculation accuracy, it is necessary to determine the specified search range and its update interval.

In the foundry engineering field, various CAE software are used to simulate phenomena such as mold filling, heat transfer, and solidification. However, since green molding sand is a discontinuous material, the development of mold-making simulations has been delayed. Y. Maeda et. al. [2,3] have proposed the green sand modeling called the Hard-Core/Soft-Shell model, which takes into consideration the characteristics of green sand with particle size distribution and cohesion. Further, the identification method from a real particle size distribution to the discrete element has been proposed and it indicated the usefulness of molding simulation using DEM. However, DEM using discrete elements with particle size distribution requires a huge amount of calculation time.

In this study, we try to speed up calculation time by neighboring particle search in squeeze compacting analysis using discrete elements with particle size distribution. How to determine the time step, the specifying search range and the update interval of it are investigated. From the simulation results, the appropriate conditions in the case with particle size distribution are different from those in the case with uniform particle size, and it is necessary to take into consideration the size and the ratio of a peak in the particle size distribution map. Because it is greatly influenced by particle size distribution, it is clarified it has better use a large and a small search range determined by its particle size. The calculation speed is improved for any particle size distribution within the condition for the present study.

ABSTRACT

Sand flow simulation was conducted by extending the moving particle hydrodynamics (MPH) method [1-4]. Specifically, the Mohr-Coulomb yield criterion was introduced in the Bingham model [5]. With this non-Newtonian model, the sand flow behavior was reproduced. The variation of the angle of repose when the sand collapse was well expressed by varying the internal friction angle of the Mohr-Coulomb model.

AUTOMATED MESH CONSTRUCTION FROM IMAGES FOR CARDIAC SIMULATIONS IN PATIENTS WITH CONGENITAL HEART DEFECTS

Fanwei Kong[*1] and Alison Marsden*[1]

[1]*Stanford University*

ABSTRACT

Congenital heart defects (CHDs) are characterized by abnormal cardiac anatomies that dramatically impact patient outcomes. Personalized computer heart models derived from patient image data can facilitate personalized treatment planning of CHDs and surgical/procedural decision-making. However, prior studies often require prohibitively laborious human efforts to generate models from patient images. Prior deep learning (DL) methods demonstrated potential in automating cardiac reconstruction but are mostly designed to model normal cardiac structures(1). Therefore, we aim to develop a DL algorithm to generate cardiac models automatically from CHD patient images to support cardiac mechanics simulations.

Our algorithm leverages both the CHD diagnosis (types of CHD) and image data to construct cardiac models from CT images. We use neural networks (NNs) to approximate signed distance functions (SDFs) that represent the CHD anatomical abnormalities given the input diagnosis. Our method then deforms these type-specific SDFs to match target patient images. To preserve the cardiac anatomies learned by the type-specific network, we leverage neural ordinary differential equations (NODE) to learn the diffeomorphic mapping between the learned type-specific geometries (type space) and patient-specific cardiac geometries (shape space). Namely, we learn the motion of points from the shape space to the type space based on the image data. To incorporate patient image data into the NODE, we use a convolutional NN to extract an image feature volume from which we sample the image feature vectors at points in the shape space.

We used a total of 108 CT images (67 for training, 4 for validation, and 37 for testing) that covered cases of ventricular septal defects (VSD), atrial septal defects (ASD), Tetralogy of Fallot (ToF), transposition of great arteries (TGA), double outlet right ventricle (DORV) and pulmonary atresia (PuA), respectively. Our networks were successfully trained to predict type-specific SDFs that captured the typical abnormalities given the input CHD type. When evaluated on testing images, our method constructed cardiac anatomies consistent with the input CHD diagnosis, whereas the prior segmentation approach, UNet(2), produced many topological artifacts. To construct simulation-ready meshes, we created simulation-ready meshes at the type space and used our trained DL algorithm to deform the corresponding template to match with patient images. Ongoing work includes creating meshes for a cohort of DORV patients to conduct computational fluid dynamics simulations, which can reveal detailed flow patterns for individual patients to assist surgical planning.

STUDY ON PERFORMANCE AND HYDRAULIC LOSSES OF CENTRIFUGAL PUMPS WITH IMPELLERS HAVING POROUS STRUCTURE

Takeshi Konishi[*1], Yasuyuki Hirano[1] and Yasuyuki Nishi[2]*

[1]*Tokyo Metropolitan Industrial Technology Research Institute*
[2]*Ibaraki University*

ABSTRACT

The impeller of a centrifugal pump must have a structure that can be used stably over a wide flow range and that allows operation with high pump efficiency even at low-flow-rate and high-head. In this study, a closed impeller with a porous structure with radial and annular flow channels was proposed, which is expected to be effective in suppressing vortices generated inside the channels, which hinder low-flow-rate and stability, by a design that does not narrow the blade width and narrows the flow channels. The authors undertook experiments and simulations to elucidate the performance of pumps using that impeller and to accurately predict its performance.

In the experiment, the pump performance was measured with an impeller fabricated by a 3D printer. The results showed stable operation over a wide-flow-range and characteristics that prevent the pump efficiency from decreasing even in the high-flow-range.

In the simulation, a loss analysis method using unsteady CFD results was proposed to investigate the variation of internal flow and various hydraulic losses during one rotation of the impeller. As a result, it was elucidated that the increase in total hydraulic losses of the pump with increasing flow rate is due to losses in the impeller other than friction losses due to changes in the size of the vortex in the impeller. Furthermore, it was elucidated that the variation of total head with impeller rotation is affected by losses in the volute casing other than friction losses originating from the vortex generated by the rear shroud and intermediate disk near the outlet of the radial flow channels.

Based on these results, an impeller with a porous structure is useful for centrifugal pump applications. CFD using the Navier-Stokes equations as the basic equations and SST as the turbulence model is effective for the analysis of this impeller. Furthermore, the loss analysis method using CFD results is expected to assist in the development of this type of impeller, since the losses could be evaluated quantitatively.

NONLINEAR MULTILEVEL AND DOMAIN DECOMPOSITION METHODS FOR PHASE-FIELD FRACTURE SIMULATIONS

Alena Kopanicakova[*1], Hardik Kothari*[2] and Rolf Krause*[2]

[1]*Brown University, Universita della Svizzera italiana*
[2]*Universita della Svizzera italiana*

ABSTRACT

The numerical simulation of failure mechanism in solids is computationally challenging, as crack paths with a possibly complex topology have to be resolved. Phase-field approach for fracture simplifies and overcomes these difficulties by regularizing the sharp crack interfaces by means of a diffusive damage model. The main challenge associated with phase-field fracture modeling is that it requires a solution of a strongly nonlinear coupled system of equations at each loading-step. This is computationally demanding due to the non-convexity of the coupled energy functional and a large number of degrees of freedom required to resolve the damaged zones. In this work, we propose to solve the arising nonlinear problems efficiently using nonlinear multilevel and domain decomposition methods. The proposed methods are designed to solve the arising non-linear problems in a monolithic manner by taking advantage of the underlying structure of the coupled problem. More precisely, we demonstrate how to construct a hierarchy of suitable sub-spaces, related to different levels or subdomains. In the multilevel settings, we employ level-dependent objective functions, that combine a fine-level description of the crack paths with the coarse level discretization. In the domain decomposition settings, we construct a preconditioner for inexact Newton's method by partitioning the degrees of freedom into two sets, related to the displacement and the phase-field. We will demonstrate the convergence behavior of the proposed multilevel and domain decomposition methods using standard benchmark problems. A comparison with the widely-used alternate minimization scheme will be also presented, showing a significant reduction in the number of iterations as well as in the execution time.

COMBINING SPACE-FILLING CURVES WITH HYBRID PARALLELIZATION FOR EFFICIENT IN-MEMORY LOAD BALANCING

Patrick Kopper[*1], Anna Schwarz[1], Stephen M. Copplestone[2] and Andrea Beck[1]*

[1]*University of Stuttgart*
[2]*boltzplatz - numerical plasma dynamics GmbH*

ABSTRACT

Particle-laden turbulent flows occur in a wide range of engineering application such as spray injection, wind energy and turbomachinery. The numerical domains required for these applications can often only be discretized using unstructured meshes. While facilitating grid generation, parallelization of particle tracking algorithms on these grids is challenging as particles can cross several numerical elements during a single time step with their trajectories are only weakly correlated to the fluid phase. The present talk presents a hybrid parallelization strategy developed for the high-order massively parallel Discontinuous Galerkin Spectral Element Method (DGSEM) framework FLEXI[1,2]. The challenge of non-local particle tracking is addressed using halo regions, which enrich the local domain with geometric information up to a certain physical distance from the domain boundaries. Using the MPI-3 shared memory model in combination with space-filling curves, geometric information is assigned either to processor-exclusive memory regions or made accessible on a compute node level[3]. Utilizing remote memory access and hardware offloading, the method is applied to in-memory load balancing. Here, runtime information such as field information and particle positions are dynamically redistributed before the simulation is seamlessly continued. Special care is taken to optimize re-initialization times while minimizing communication load on the interconnect. This work concludes by presenting examples of large scale computations of particle-laden turbulent flows in complex systems and giving an outlook on the next research challenges.

AUTOMATION OF HIGHER ORDER VIRTUAL ELEMENT METHODS

Joze Korelc[*1]*

[1]*University of Ljubljana*

ABSTRACT

The paper deals with the computational efficiency and simplicity of implementation of nonlinear higher-order virtual elements. When compared to the standard FEM the VEM lacks the simplicity of derivation of formulae and simplicity of computer implementation. This becomes especially problematic with an increasing number of polygon or polyhedral vertices, an increasing VEM order, and especially for the 3D problems. The paper presents an improved ADB (automatic differentiation based) formulation of VEM combined with an automatic derivation of corresponding formulae and automatic generation of computer code using AceGen automatic code generation system. When applied to nonlinear, path-dependent, coupled problems, such as finite strain plasticity, computational efficiency regarding the evaluation of the element tangent matrix and residual can also pose a problem. Already for a second-order, three-dimensional VEM, implementation of a complex nonlinear model can pose a significant problem, and mostly only low-order implementations have been reported in the literature so far. The paper employs a fast quadrature compression based on the computation of discrete Leja points by LU factorization (Sudhakar 2017) that, for a given accuracy goal, reduces the high number of integration points that emanate from the braking of an arbitrary polyhedral into a union of tetrahedrons. The discrete Leja points can be calculated for an arbitrarily shaped polyhedron thus enabling an efficient integration of consistency part of the VEM tangent matrix and residual. The use of FEM stabilization is essential for the convergence of highly nonlinear problems; however, its evaluation can also be computationally expensive. The computational cost of the stabilization matrix can be reduced by exploiting the sparsity structure of the resulting stabilization matrix at the individual VEM level.

STOCHASTIC FE-BE METHOD FOR HOMOGENIZATION ANALYSIS OF 2D DIFFUSION PROBLEMS CONSIDERING UNCERTAINTIES OF INCLUSION SHAPE

Kazuhiro Koro[*1]*

[1]*Niigata University*

ABSTRACT

The stochastic method for homogenization analysis of diffusion problems considering uncertainties of inclusion shape is developed using a microscopic stochastic BEM and a macroscopic FEM. The spatial variation of inclusion shape is modeled using Karhunen-Loeve expansion with exponential-type covariance kernels. The characteristic function on a 2-D unit cell and the homogenized diffusion tensor are calculated using the stochastic BEM. The macroscale diffusion problems are solved using the stochastic FEM with the polynomial chaos (PC) expansion. Through numerical tests, the expected value and the standard deviation of the concentration in a macroscale problems and their distribution are investigated.

THE ROLE OF HUMANS IN COMPUTATIONAL MECHANICS – VERIFICATION AND VALIDATION FOR QUALITY MANAGEMENT –

Seiichi Koshizuka[1]*

[1]*The University of Tokyo*

ABSTRACT

Verification and Validation (V&V) for quality management describes the role of humans in manufacturing industry from the technical viewpoint. A typical document of V&V for quality management is ISO9001 [1]. The documents of V&V for computer simulation have been published as [2, 3]. They include additional requirements specific for computer simulation as well as the general requirements in ISO9001. A typical procedure satisfying the requirements for computer simulation is provided in [4] and examples are shown in [5]. V&V for quality management is derived from our experiences of human activities in manufacturing industry to enhance the credibility of the products.

Competence required in the V&V for quality management is related to the education. For example, a qualification system for the specialists is recommended to be fair and transparent treatment of competence. Japan Society of Mechanical Engineers (JSME) manages a qualification system for computational mechanics for about 20 years [6]. Competence of humans involving the knowledge of computational mechanics should be kept high as well as detailed procedures and documents are required in the quality management system.

V&V for modeling and simulation [7] is another type of V&V for computational mechanics. Both V&Vs for quality management and modeling and simulation are needed.

Society5.0 is a concept of future society envisaged by the Government of Japan [8]. Utilization of digital twins is aimed for future industries where humans should be placed in the center of the society. There are two types of the humans considered in Society5.0: working people and customers. In the past, working people are expected to be accurate and efficient and the quality management system has been used for this purpose. In future, well-being of working people is more important and has to be included in the quality management system.

GOAL ORIENTED ERROR ESTIMATION FOR SPACE-TIME ADAPTIVITY IN PHASE-FIELD FRACTURE

Viktor Kosin[12], Amélie Fau[1], François Hild[1] and Thomas Wick[21]*

[1]*ENS Paris-Saclay*
[2]*Leibniz Universität Hannover*

ABSTRACT

In this talk, we introduce a phase-field fracture model in a space-time formulation and use the dual-weighted residual (DWR) method to formulate a goal oriented error estimator for adaptive refinement in space and time. Tensor-product space-time finite elements are being used with continuous elements in space and discontinuous elements in time, such that the primal problem can be solved with a time-stepping scheme. The temporal derivative of the phase-field variable is added as a regularization term in the Euler-Lagrange equations to allow for backwards time-stepping in the dual problem. The error is localized using partition of unity (PU). The convergence order of the space-time adaptivity is analyzed on numerical tests with different goal functionals.

ABSTRACT

The quantification of the numerical uncertainty of simulations through solution verification exercises is imperative to evaluate the accuracy of the results and make predictions, i.e., computations with a quantified and adequate degree of uncertainty that can be confidently used in engineering projects, even if reference data is unavailable or scarce. Accuracy assessments are particularly relevant to transient multi-material mixing flows due to i) complex multi-physics, ii) transient nature that makes computational errors behave nonlinearly and cumulatively, iii) most solution verification methods not being tested on such problems, and iv) common mathematical model assumptions and simplifications. The Euler equations (EE) are an example of a simplified mathematical model widely used in transient multi-material mixing problems featuring shock waves and high-Mach number flow (e.g., stellar astrophysics, shock-driven mixing, and high-speed combustion). It simplifies the Navier-Stokes equations (NSE) by assuming adiabatic and inviscid flow, i.e., neglecting heat conduction, viscous, and diffusivity effects. Despite the importance of the EE, the continuous enhancement of computing power and numerical methods makes assessing the envelope of such a mathematical model crucial. For example, neglecting the molecular viscosity makes the effective Reynolds number of simulations solely determined by the numerical viscosity and assumes an “infinite” Reynolds number. However, how high of a Re is high enough? What is the impact of an effective Re uniquely determined by the numerical viscosity on solution verification?

This work evaluates the impact of the EE on solution verification exercises of transient multi-material mixing flow simulations. Toward this end, we simulate four flows with the EE and NSE: i) 1D Riemann problem, ii) 2D triple point problem, iii) 3D Taylor Green Vortex, and iv) 3D Richtmyer-Meshkov multi-material flow measured at LANL. The computations are performed on several mesh/time resolutions to evaluate their dependence on this parameter and estimate the numerical uncertainty. From a validation point of view, the results show that inviscid and adiabatic assumptions strongly impact the simulations' physics, hampering comparisons between simulations and reference data. This outcome stems from the inability to bind the effective Re and consider heat conduction. Such assumptions can also impact solution verification exercises by significantly increasing the cost of converging the simulations upon grid refinement and artificially increasing the numerical uncertainty and the cost of solution verification exercises. Overall, the results indicate that modeling assumptions strongly impact not only validation exercises but also solution verification.

APPLICATION OF THE MATERIAL POINT METHOD IN METAL CUTTING SIMULATIONS UTILIZING THE JOHNSON-COOK MATERIAL LAW

Marvin Koßler[1], Sascha Maassen[1], Rainer Niekamp[1] and Jörg Schröder[1]*

[1]*University of Duisburg-Essen*

ABSTRACT

The Material Point Method provides an alternate method for simulations, differing from traditional techniques like the Finite Element Method (FEM). This method utilizes material points for body discretization, with the equations' solutions being executed on a computational background grid, see e.g. [1]. The simulation process during a single time step involves three primary steps. Initially, kinematic quantities of the material points are transferred to the grid nodes. Once gathered, the solution is determined at the grid nodes and then reassigned back to the material points, followed by updating their position, velocity, stress, and deformation state individually. For subsequent time steps, the existing grid is discarded in favor of a new one since it holds no persistent information. This approach allows the material points to move independently from the background grid, thus preventing mesh distortion in cases of huge deformations, a problem sometimes encountered in FEM simulations. This contribution presents simulations of three-dimensional metal cutting in both vertical and horizontal orientations. These simulations utilize the Johnson-Cook material law, see [2], which accounts for plastic strain rates and heat generated from plastic deformations. Additionally, the grid-shift method is employed to enhance solution smoothness as recommended in [3].

ON SOLVING CONTACT PROBLEMS USING SUBSTRUCTURING DOMAIN DECOMPOSITION METHOD

Hardik Kothari[*1], Patrick Zulian[1] and Rolf Krause[1]*

[1]*Università della Svizzera Italiana*

ABSTRACT

Contact problems refer to modeling of the interaction between two or more elastic bodies when they are in contact with each other. While solving such contact problems, we must accurately model the forces the bodies induce at the contact surfaces and compute the resultant deformation due to the interaction between bodies. These problems are common in many scientific fields, e.g., mechanical engineering, automotive engineering, robotics, and biomechanics. The formulation of the contact problems gives rise to variational inequalities, as the contact boundaries are part of the solution and are unknown apriori. Due to these reasons, it becomes essential to employ iterative solution methods to solve contact problems. At each iteration, the algorithm aims to satisfy equilibrium conditions for a given contact boundary. In many cases, the iterative schemes are computationally intensive and heavily rely on the geometric information of the problem. To address these challenges, we present a domain decomposition-based solution strategy for solving contact problems in a fully algebraic manner. In this work, we employ a dual Lagrange multiplier-based mortar Finite Element method for discretization. In addition, we also apply a Householder reflection to transform the local coordinate system such that the linear contact constraints can be transformed into point-wise constraints. Once the algebraic system is constructed, we must solve a sequential quadratic programming problem. To this aim, we employ a sub-structuring domain decomposition-based strategy that decomposes the domains in non-overlapping subdomains. Using these non-overlapping subdomains, we decouple the unknowns into the interior of the subdomains and the ones that are on the interfaces and the contact boundary. By employing this decomposition, we eliminate the interior unknowns and construct a smaller subproblem on the skeleton, which is subjected to inequality constraints. Once we have constructed a smaller constrained optimization problem, we can solve it using projection-based methods. This robust approach allows us to solve large-scale problems using a distributed computing environment.Finally, we will present some numerical results to demonstrate the performance of our method using several numerical examples. We will test our solution strategy for solving the contact problem with hyperelastic material with multiple bodies in two and three dimensions.

DISCOVERY OF CONDUCTIVE INKS AND ELECTRONIC DEVICES CO-DESIGNED WITH CLOSED-LOOP, AUTONOMOUS, REINFORCEMENT ECOSYSTEMS

Matthew Kottwitz[*1] and James Fowler*[1]

[1]*Sandia National Laboratories*

ABSTRACT

The end-to-end design and manufacturing of printed circuit boards substrates, a ubiquitous and critical technology in energy storage, communication, and defense systems, is poised to undergo a transformation following developments in additive manufacturing within the last decade. These advancements include droplet-on-demand inkjet printing of conductive inks—suspensions of metallic nanoparticles, graphene, carbon nanotubes, etc.—onto dielectric substrates. Despite extensive research, few printed commercial inks possess the conductivity and robustness desired by high-reliability design agencies. A major contributor to the limited availability of viable inks is the enormous parameter space of processing conditions and material structure, property, and performance criteria that must be balanced during development. For this reason, Sandia National Laboratories, together with university partners, has engaged in the design and implementation of an autonomous materials discovery platform to efficiently (1) synthesize Cu, Ag, and Au nanoparticles, (2) formulate those nanoparticles into inks, and (3) print those inks to form devices. At each step of the process, characterization data of the structure, properties, and performance is provided to a machine learning algorithm. Initial approaches have utilized off-the-shelf machine learning methods while development of bespoke solutions such as multifidelity reinforcement learning and scientific machine learning continues to address the challenges of relatively sparse data sets, multimodality and fidelity, and the need identify underlying process-structure-property-performance relationships.

ABSTRACT

This talk focuses on the representation of model-form uncertainties in various molecular dynamics ensembles. In prior contributions, the modeling of such uncertainties was formalized and applied to quantify the impact of, and the error generated by, pair-potential selection in the microcanonical ensemble (NVE). In this work, we extend this formulation and present a linear-subspace reduced-order model for the canonical (NVT) and isobaric (NPT) ensembles. We randomize the reduced-order basis on the tangent-space of the Stiefel manifold to provide topological relationships and capture model-form uncertainty. Using the Large-scale Atomic/Molecular Massively Parallel Simulator (LAMMPS), we assess the relevance of these stochastic reduced-order atomistic models on problems for Lennard-Jones fluid and Cu-Al segregation energy simulations.

BACKWARD DIFFERENCE FORMULAE FOR THE TRANSIENT STOKES PROBLEM: OPTIMAL ORDER VELOCITY AND PRESSURE ESTIMATES

Alessandro Contri[1], *Balázs Kovács**[2] *and André Massing*[1]

[1]*Norwegian University of Science and Technology*
[2]*Paderborn University*

ABSTRACT

In this talk we will present a new stability and error analysis of fully discrete approximation schemes for the transient Stokes equation.
The numerical method uses backward difference formulae (BDF methods) of order 1 to 6 in time and a wide class of Galerkin finite element methods including both inf-sup stable spaces and symmetric pressure stabilized formulations.

We perform a unified error analysis for the above method, and prove stability of the method and show optimal-order error estimates for both the velocity and the pressure. The main tools in our stability analysis is the G-stability theory of Dahlquist together with the multiplier technique introduced by Nevanlinna and Odeh.
We will report on various numerical experiments.

The talk is based on joint work with Alessandro Contri and André Massing (NTNU Trondheim).

A FRAMEWORK FOR UNDERSTANDING VASCULAR REMODELING: FROM GEOMETRY TO TRANSPORT DYNAMICS.

Jérôme Kowalski[*1], Lorenzo Sala[2], Dirk Drasdo[1] and Irene Vignon-Clementel[1]*

[1]Inria Saclay
[2]INRAE

ABSTRACT

A number of diseases affect perfusion and function of organs. Liver cirrhosis is a complex and widespread disease. A better understanding of the consequences of its development on the organ would allow for more effective treatment. Cirrhosis affects the liver's vascular network as it remodels around the cirrhotic nodules. Quantifying the alterations of the vascular network permits to predict the resulting hemodynamic shifts and the modified transport of chemical substances entering the organ. Contrast-enhanced dynamic imaging offers a means to evaluate organ perfusion in diseased states. However, quantitatively interpreting dynamic imaging is a non-trivial task that requires modelling the transport of species within the vascular network. Current reduced models unfortunately lack information on the network geometrical characteristics. We here present a mechanistic model of an organ vascular network, aiming at unraveling how vascular remodeling affects the organ's hemodynamic and transport features.

Based upon the concept of structured binary trees [1], the model constructs vessels iteratively from a root vessel until the terminal vessels' radius reach a threshold. Fixed area ratio and power law index for the entire tree enable to deduce the two downstream vessel radii from an upstream vessel radius at each bifurcation. The length-to-radius ratio of each vessel is also fixed. Steady hemodynamics, computed by Poiseuille law, with an imposed pressure difference at the boundaries, are the basis for transport of the injected substance. The substance is injected in the root vessel and follows blood flow in each branching vessel via advective transport. The substance collected at terminal vessels is compared to the injected profile forming the transfer function which characterizes the linear transformation induced by the tree.

This framework allows to describe simulated transport behaviors through the architecture of the vascular network. Notably, as the asymmetry of a tree increases, the substance transport displays a behavior similar to that of diffusion – otherwise absent from the model. This behavior aligns best with a Gamma distribution of the exiting times and lies halfway between the two commonly used models for transport in an organ. Furthermore, as a vascular tree remodels during disease progression, the geometric parameters of the model evolve, mirroring the remodeling process. This study lays the groundwork for characterizing and comparing liver vascular structures throughout cirrhosis development, offering valuable insights into disease progression.

EFFICIENT COMPUTATIONAL HOMOGENIZATION OF MATERIALS WITH RANDOM MICROSTRUCTURE MORPHOLOGY THROUGH ENHANCED MACHINE LEARNING TECHNIQUES

Sergey Kozinov[*1], Niklas Miska[1] and Daniel Balzani[1]*

[1]*Ruhr University Bochum*

ABSTRACT

The optimization of macroscopic material properties for specific engineering requirements by the utilization and adaption of heterogeneous microstructures gained increased interest in the last years. The challenge therein lies in accurately predicting the uncertain macroscopic behavior resulting from a variability in the microstructure's morphology. Building on the method proposed in [2], this contribution introduces an approach using machine learning to enhance the efficiency and by that, the design of artificial microstructures for computational homogenization.

In this study, we advance the concept of statistically similar representative volume elements (SSRVEs) [1] to create artificial microstructures that statistically replicate real microstructure morphologies. The original method, as detailed in [2], relied on extensive numerical simulations using the Finite Element Method (FEM) to homogenize microscopic mechanical fields, facing challenges in achieving accurate statistics for macroscopic material properties due to the associated numerical costs. Our approach overcomes these challenges by integrating machine learning into the process, which allows the evaluation of an increased number of microstructure samples.

The technique is demonstrated with an application to a dual-phase steel, characterized by a martensitic phase fraction within a ferrite matrix. Artificial microstructures with ellipsoidal inclusions are constructed, such that the morphology of the entire set varies similar to the real material. Based thereon, the machine learning model is constructed, such that the characterizing parameterization of the microstructure's morphology as input yields macroscopic material properties as output. This method shows remarkable efficiency improvements and is set to extend to more complex scenarios, such as a fully coupled FE2 calculation.

PREDICTING ELASTIC AND INELASTIC FRACTURE OF PERIODIC BEAM-BASED ARCHITECTED MATERIALS USING A MIXED-ORDER QUASICONTINUUM METHOD

Kevin Kraschewski[1] and Dennis Kochmann*[1]

[1]*ETH Zurich*

ABSTRACT

Predicting the failure mechanisms of low-density periodic architected materials has been a challenge for computational mechanics. One of the key differences between these materials and classical monolithic solids is their discrete nature of failure. Shaikeea et al. [1] found that even for brittle base materials that are linear elastic up to failure, this gives rise to significant differences in fracture behavior compared to continuous media.
Their fabricated specimen contained up to ten million, periodically arranged, unit cells (UCs), resulting in finite element (FE) simulations with up to a billion degrees of freedom. To investigate fracture in large manufacturable specimens, FE simulations are too costly, especially if the inelastic behavior of commonly used base materials in additive manufacturing is modeled.
Therefore, multiscale techniques become the method of choice. However, classical hierarchical homogenization techniques rely on the assumption of a separation of scales. When this assumption breaks down, e.g., in fracture mechanics, such techniques fail. Therefore, we present a concurrent multiscale technique, viz., a fully-nonlocal quasicontinuum (QC) multi-lattice formulation based on a conforming mesh. Our QC formulation is applied to trusses, whose struts are represented by a corotational beam model with cross sections discretized by fibers [2]. Each fiber's material response relies on an incremental variational description, allowing a thermodynamically consistent formulation. The overall setup captures significant nonlinearity and localization effects in fully-resolved regions, while efficiently approximating the remaining simulation domain through a coarse-graining technique. Coarse-graining is achieved by selecting representative UCs (RepUCs) and introducing geometric constraints based on interpolation, here exploiting finite-element interpolation.
Previous studies showed that within coarse-grained regions the strain energy of bending-dominated lattices undergoing non-uniform deformation is overpredicted when using affine interpolation. To overcome the overprediction, we introduce higher-order interpolation in coarse-grained regions, while using affine interpolation in the discrete, fully-resolved domain.
In conclusion, we present an efficient multiscale framework to investigate inelastic and linear elastic fracture of bending- and stretching-dominated periodic beam-based metamaterials. The method is equivalent to a fully-discrete calculation in certain regions, e.g., near the crack flank, where every UC is also a RepUC, but is significantly more efficient in coarse-grained regions.

THE METHOD OF BOUNDARY INTEGRAL EQUATIONS IN THE BOUNDARY VALUE PROBLEMS OF DYNAMICS OF FLUIDS AND GASES

Yurii Krashanytsia[*1]*

[1]*Kharkov Aviation Institute*

ABSTRACT

The numerical experiment has become widely applicable alongside the physical one due to multiple parameters and the non-linearity of the main problems of continuum mechanics. Significant achievements are recognized in the computational analysis, especially in numerical implementation of particular mathematical models in mechanics [1]. In gas mechanics, significant progress has been achieved in viscid gas mechanics that takes into account physical and chemical processes, which allows determining aerodynamic characteristics in transonic flight modes and creating real-time computational models. Viscid gas dynamics pays the most attention to qualitative methods of formalization of initial boundary value problems, which lead to creation of the new mathematical models raising new questions and allowing solutions for the problems of viscid gas flows at low and medium Reynolds numbers. In the aerodynamics of complex lift-generating systems, the method of boundary-integral equations and variants of its numerical implementation was used to obtain the distributed and integral aerodynamic characteristics for two- and three-dimensional loadbearing forms and to study processes that cause flow separation, creation and stability of vortex structures.

The method of boundary integral equations has obvious and proven advantages over the finite difference and finite element methods. Reducing a boundary value or initial boundary value problem to an integral equation or an adequate system of boundary integral equations allows not only to reduce the dimension of the problem, but also, due to the analytical representations of solutions, to solve problems of optimization of aerohydrodynamic characteristics [2].

Generalization and development of the boundary integral equation method onto dynamic problems of interaction between viscid gas flow and a finite span wing of an arbitrary spatial form have been presented. Existence of a vector potential of the momentum conservation law is established for the first time. Further, analytical integral representations of the solutions of general conservative forms of differential conservation laws of fluid mechanics have been obtained.

PROJECTION-BASED REDUCED-ORDER MODELS FOR COMPACT CIRCUIT MODELS

Elizabeth Krath[*1], Edgar Galvan[1] and Heidi Thornquist[1]*

[1]*Sandia National Laboratories*

ABSTRACT

This work presents the use of projection-based reduced-order models (ROMs) using Proper Orthogonal Decomposition (POD) with Galerkin projection to reduce the computational expense of compact models within Spice simulations. The work focuses specifically on modeling compact models within Xyce, Sandia's circuit simulator code.

Galerkin POD is generally applied to systems of nonlinear partial differential equations (PDE) [1]. These PDEs have many degrees of freedom, e.g., a spatial domain, that allows for Galerkin POD to significantly reduce the size of the system being solved by reducing the system from a PDE to an ordinary differential equation. Spice compact models consist of systems of differential algebraic equations that do not necessarily have a large "spatial" domain. This presents a challenge for creating Galerkin POD ROMs for Spice compact models.

Model order reduction using Galerkin POD has been used for Spice models with varying degrees of success and challenges, usually projecting along the state space [2, 3]. A "spatial" component can be recovered by chaining subcircuits together, but this inherently limits the use of ROMs for Spice models. Similar to hyper reduction for ROMs applied to PDEs, techniques such as Missing Point Estimation are needed to see a significant reduction in computational expense for Galerkin ROMs of Spice models [2].

In this work, instead of projecting along a state space or "spatial" domain, we project the residual equation of the compact model along a parameter domain. This approach, which is admittedly case-dependent, was able to (1) generalize the method for any subcircuit, (2) reduce the size of the system of DAEs of the compact model, and (3) predict accurate solutions across different parameter points in the domain.

Results for the projection-based ROMs for the compact models will be presented for three circuits: a nonlinear capacitor circuit, a nonlinear capacitor and diode circuit, and a nonlinear transmission line. Results are shown for how well the projection-based ROMs can predict solutions in the parameter domain and how much computational speedup the ROM achieves compared to the full-order model.

IMMERSED DOMAIN APPROACH FOR FLUID-STRUCTURE-CONTACT INTERACTION PROBLEMS

Maria Giuseppina Chiara Nestola[1], Patrick Zulian[12], Hardik Kothari[1] and Rolf Krause[*12]*

[1]Università della Svizzera Italiana
[2]FernUni Schweiz

ABSTRACT

We present an embedded approach for the numerical solution of contact problems be- tween multiple elastic structures immersed in a fluid flow. Our parallel approach is designed to simulate the full dynamics of a bio-prosthetic heart valve. We model the blood-valve interaction, the blood-aortic wall interaction, and the contact among leaflets during the valve closure. The solid bodies are modeled as hyperelastic and anisotropic materials, whereas the fluid is regarded as a Newtonian flow. The mathematical modeling of such material properties and the contact mechanics give rise to a large-scale nonlinear problem that is both challenging and computationally expensive to solve. We employ a localized version of the L^2-projection for handling the fluid-structure vol- umetric coupling and a variant of the mortar method for coupling the surfaces of the structures in contact.
In this contribution, we describe our approach to solving the contact problem between the immersed solids. First, we provide an algorithmic overview of the FSI algorithm, which is specifically designed to include and fully resolve the contact constraints. Second, we illustrate our parallel large-scale solution strategies for solving the arising contact sub-problem in a non-smooth optimization framework. The proposed strategy is validated and finally employed to model the dynamics of a bio-prosthetic heart valve placed in the aortic root.

OPTIMIZED FORCE MANIPULATION IN ADAPTIVE TRUSS STRUCTURES USING INSIGHTS FROM STRUCTURAL MECHANICS

Lisa-Marie Krauß[1], Mathias Maierhofer[1], Achim Menges[1] and Manfred Bischoff[1]*

[1]*University of Stuttgart*

ABSTRACT

Growing worldwide issues like resource scarcity and climate change are in large part caused by the construction sector. Therefore, rapid development of promising solutions is necessary to speed up the transformation of the construction sector. One potential strategy to tackle this challenge is investigated by the University of Stuttgart's collaborative research center CRC 1244 “Adaptive skins and structures for the built environment of tomorrow”. Control units, actuators and sensors are integrated into civil engineering structures to enable them to adapt flexibly to varying load scenarios. This can extend the service life of buildings and save a significant amount of material [1].

In the CRC a variety of topics, including design, dimensioning and operation of adaptive structures, is examined. Design studies have demonstrated that stiffness-governed structures can be transformed into strength-governed structures through the use of actuators, resulting in a significant reduction in the amount of material required [2]. Furthermore, actuators allow to manipulate the forces in the structure during operation. One possible aim is to minimize the maximum utilization ratio in the structure to avoid too high utilization ratios in individual elements. To achieve this, the actuator strokes are adjusted in response to the loads.

In this contribution, we present our approach to treat this task as an optimization problem, where the highest cross-sectional utilization ratio in a truss structure is minimized and the actuator strokes serve as design variables. We formulate the optimization problem mathematically and apply insights from structural mechanics to simplify it. The objective function is identified as a convex function. Instead of searching on the initial objective function, which is convex but non-differentiable, a further reformulation allows searching in the convex set. As a result, the linear optimization problem can be conveniently solved using the simplex method. Finally, we illustrate opportunities and limitations of force manipulation in adaptive structures using various examples.

The work described in this contribution was conducted within the Collaborative Research Center 1244 “Adaptive skins and structures for the built environment of tomorrow”, funded by the Deutsche Forschungsgemeinschaft (German Research Foundation) under project number 279064222. This support is gratefully acknowledged.

A SENSITIVITY APPROACH FOR DEEP NEURAL ARCHITECTURE ADAPTATION

C. G. Krishnanunni[*1] and Tan Bui-Thanh*[1]

[1]*The University of Texas at Austin*

ABSTRACT

This work presents a novel algorithm for progressively adapting neural network architecture along the depth. In particular, we attempt to address the following questions in a mathematically principled way: i) Where to add new capacity (layer) during the training process? ii) How to initialize the new capacity? The algorithm is based on defining the sensitivity for a neural network which is conceptually the derivative of a lost function with respect to infinitesimal changes in the neural network. Using an optimal control viewpoint, we show that the network derivative exists under certain conditions and a closed-form expression for the same is derived. Further, we show that the derived expression for the topological derivative leads to an eigenvalue problem for deep neural architecture adaptation. The algorithm we derived simply determines the most sensitive location along the depth where a new layer needs to be inserted during the training process and the associated parametric initialization for the newly added layer. We also show that our layer insertion strategy based on the topological derivative approach can be viewed as a solution to a constrained optimization problem in the infinity-Wasserstein space. Numerical investigations with feed-forward networks (fully connected network and convolutional neural network) on prototype regression and classification problems demonstrate that our proposed approach can outperform an ad-hoc baseline network and other neural architecture adaptation strategies.

ABSTRACT

The optimization of the dimensioning of constructive designs is constantly evolving. FEM, evolutionary, and other various methods are being developed, which are implemented with algorithms in computer simulations of building models. The problem with these methods is solving large differential equations, which is inconceivable without computers and large memories. The Ritter-Križaić (RK) iteration method works for both straight and oblique networks with one side, and it can even be used instead of trigonometric and FEM equations. It does this by adding the geometric properties of the networks and outside actions to the directional equations. By creating straightforward monograms of RK-FEM technology (Fig.1) with straightforward differential or subspace equations that are simple to calculate by hand or draw with Mathcad tools, the RK-FEM loop enables COD to define various types of trusses and even other supports. RK-FEM COD is therefore used to create simulation games that explain many logical phenomena in the design of external and internal actions of beam supports, which can be compared to a spider thread or an ice plate structure as an RK string and even to the moon.

EXPERIMENTAL AND NUMERICAL ANALYSIS OF BUCKLING OF THIN POLYETHYLENE STRUCTURE DURING DYNAMIC IMPACT LOADING

Martin Kroon[*1], Eskil Andreasson[2] and Viktor Petersson[2]*

[1]*Linnaeus University*
[2]*Tetra Pak*

ABSTRACT

Polyethylene is a semi-crystalline polymer that is widely used in the industry in general and in the packaging industry in particular. Dynamic, inelastic buckling of a polyethylene structure in the form of a package top is the focus of the present study.

A constitutive framework for the isotropic elasticity and inelasticity of HDPE is proposed. All state variables in the model are defined in the current state of the material, and the evolution of elastic deformations is prescribed directly. The proposed model was calibrated by use of uniaxial tensile tests. The uniaxial tests were carried out at different loading rates. Drop-testing was also performed by dropping a weight on the 3D geometry, which would then buckle. Also, a 3D numerical implementation of the constitutive model was provided (VUMAT in Abaqus), and by use of this 3D implementation, the drop-testing could be simulated.

The results show that the air trapped inside the structure/top during the droptest needs to be included in the simulation model when simulating the droptests. In order to do this, a coupled Eulerian-Lagrangian (CEL) analysis, which is a kind of fluid-structure-interaction analysis, was employed. Through this type of analysis, the correct buckling scenario could be predicted in the numerical analysis. The droptests were recorded using a high-speed camera. The position and velocity profiles from the tests could then be compared to the simulations. In general, the simulations showed very nice agreement with the experimental measurements.

TOWARDS COMPOSITE BEAM ELEMENTS FOR STEEL TRUSS IN CONCRETE COMPOSITE BEAMS

Robert Kroyer[*1], Valentino Vigneri[1] and Andreas Taras[1]*

[1]*ETH Zurich*

ABSTRACT

Steel composite construction is a discipline in civil engineering that strives for efficient structural members through a reasonable combination of a steel section with another material. The most popular steel composite structures are certainly steel-concrete composite beams consisting of a concrete slab on a downstand steel profile connected through shear studs. After decades of research, this type of structure has become a popular solution in the construction industry, especially for multi-storey buildings with large spans. Accurate and reliable structural analysis of such composite sections requires careful consideration of the material non-linearities as well as the deformability of the shear connectors coupling both components. Newmark et al. [1] approached this subject both experimentally and analytically by proposing a first kinematical model of the interlayer slip between the components. This model has been pioneering for the development and successful implementation of composite beam elements in the framework of finite element methods. In recent times, technical developments in steel-concrete composite construction have focused more on shallow steel-concrete composite beams consisting of a steel profile partially embedded in concrete. The European Norms for composite construction (EN 1994-1-1) do not exclude slim-floor beams from their scope but a more comprehensive design approach is recommended. For example, the design checks for the shear connection shall be based on experimental tests and a conceptual model unless headed stud shear connectors are used. Whilst this suggestion accounts for the resistance of the shear connection, the computation of the shear connector load effects remains pivotal. More precisely, the accurate determination of the shear connectors' forces and deformations is not straightforward in the ultimate limit state due to the material non-linearities of the components and their interaction. Composite beam elements are commonly still unavailable for shallow steel-concrete composite beams while being potentially suitable to fill this gap. The proposed contribution thus presents a numerical framework for shallow composite steel truss and concrete (CSTC) beams that was inspired by companion numerical investigations on conventional composite beams. It intends to emphasize first the role of the kinematics in the development of composite beam elements and to present the full-scale beam tests conducted with the specific type of slim-floor beams under investigation to study the kinematics and finally validate the numerical framework developed.

GRADIENT-BASED LAYOUT OPTIMIZATION FOR EFFICIENT 3D PACKING OF COMPLEX COMPONENTS

Daniel Krsikapa[*1] and Il Yong Kim*[1]

[1]*Queen's University*

ABSTRACT

There is an ever-growing need for effective integration of advanced technologies into limited spaces. This challenge is relevant across diverse industries such as aerospace, automotive, and electronics, where optimizing the layout of components within a system can enhance overall system performance, reduce cost, and maximize space utilization. Component layout optimization is a complex non-linear multimodal problem that poses substantial challenges for traditional optimization methods. To manage these complexities, design spaces are often discretized into predetermines potential component locations, leading to a significant limitation in design freedom. Moreover, many existing tools in this domain tend to focus narrowly on placing components based on a small number of application-specific parameters, such as heat transfer or mass distribution. These approaches often overlook other simpler, but critical aspects necessary for a feasible and realistic design. A layout that is mathematically optimal but overlooks even one basic requirement, such as mounting or accessibility, becomes unfeasible for practical application. In real-world scenarios, the complexity of these problems is amplified when considering multiple engineering parameters. Developing a layout that not only meets all essential requirements for feasibility and practicality but also considers more specialized, application-specific parameters, all while ensuring complete design freedom for the parts, is not merely desirable but imperative for future layout optimization tools.

This work outlines a novel gradient-based layout optimization method tailored for 3D packing of complex geometries. This approach provides full translational and rotational freedom for all components while considering parameters such as packing space, part overlap, mounting requirements, proximity relationships, accessibility constraints, and connection distances. To demonstrate the effectiveness of this approach, both academic and industry-related test cases were used. In one such industry application, the method achieved a notable 68% increase in packing density when focusing solely on packing space. When the problem statement was updated to include both mounting and cable length considerations, a 14% increase in packing density was achieved, coupled with a 19% reduction in cable length, underscoring the versatility and efficacy of the optimization method. This research holds promise for substantial advancements in the field of component layout optimization, offering practical benefits in both academic and industrial settings.

INTEGRATING OSTEOBLAST MECHANICS AND BEHAVIOURS IN A DISCRETE CELL-BASED MATHEMATICAL MODEL FOR BONE TISSUE FORMATION

Shahak Kuba[*1], Matthew Simpson[1] and Pascal Buenzli[1]*

[1]*Queensland University of Technology (QUT)*

ABSTRACT

During bone tissue growth, active bone-forming cells (osteoblasts) proliferate and embed into the extra-cellular matrix that they produce to form new bone tissue. This growth occurs in confined spaces with complex geometries, such as resorption cavities in cortical bone and trabecular resorption pits. Restricted available space in these geometries causes the progression rate of the new bone tissue interface and the density of osteoblasts to be highly regulated by local geometry, resulting in what is called geometric control of tissue growth [1]. While the effects of geometry during tissue growth are established, empirical observations also suggest cellular mechanics significantly influences the growth process [2,3]. Furthermore, particularly around cylindrical cavities such as Haversian canals in cortical bone, the deposition rate of new tissue material slows down as the growth process progresses. This slowdown can be attributed to the decrease in the population of active osteoblasts due to cell death and the embedment of osteoblasts as osteocytes into new bone tissue.

In this contribution, we present a discrete, cell-based mathematical model of osteoblast forming new bone tissue to explore how the rate and pattern of bone tissue growth depends on osteoblast cell-cell mechanical interactions and the stochastic embedment of osteoblasts as osteocytes into newly formed bone tissue. Our model effectively replicates two key phenomena seen experimentally: the smoothing of the initial geometry of resorption cavities, and the slowdown of new tissue deposition. Additionally, our discrete model provides the positions of osteocytes generated during bone formation, enabling further research into their distribution.

ABSTRACT

Storm surge finite element models are essential tools in helping to assess the extent and severity of coastal flooding associated with tropical cyclones (TCs); however, the flooding that occurs during these storms is often generated by both surge and accompanying rainfall, resulting in a so-called compound flooding event, which U.S. cities are under increasing risk of experiencing [1]. Simulating compound flooding events requires a modeling framework that extends beyond the "standard" capabilities of storm surge models, which generally account for surges in water levels driven by TC winds and pressures, but not by the accompanying (often torrential) TC rainfall. To address this shortcoming, we develop a local discontinuous Galerkin (LDG) finite element method for modified shallow water equations, which include, in addition to momentum source terms due to TC winds and pressures, a mass source term in the continuity equation to represent TC rainfall [2]. Central to our modeling approach for these terms is the estimation of the TC winds, pressures, and rainfall by use of parametric storm models, which exploit the defined structures exhibited in TC meteorological patterns. This approach allows us to construct the TC meteorological fields using (relatively) simple analytic expressions that are a function of a small number of (predicted or observed) storm parameters (e.g., the storm center, maximum sustained wind, etc.) — parameters that are made publicly available by various weather agencies, such as the National Hurricane Center (NHC), both pre and post storm events. The developed modeling framework is used to simulate compound flooding due to both storm surge and rainfall for a number of TCs making landfall in the US, where our results demonstrate that improved peak water levels are obtained compared to modeling surge alone and highlight the potential of using parametric TC rainfall models in compound flood simulations.

PARTITIONED COUPLING OF MULTIFIDELITY, MULTIPHYSICS MODELS USING OPTIMIZATION-BASED COUPLING

Elizabeth Hawkins[1], Pavel Bochev[2] and Paul Kuberry[2]*

[1]Clemson University
[2]Sandia National Laboratories

ABSTRACT

Problems involving coupling over a nonoverlapping interface abound, with common examples including virtual interfaces introduced for the purpose of domain decomposition and physical interfaces such as are found in, e.g., multimaterial solid interaction and fluid-structure interaction. Although monolithic formulations for such problems can be developed, they can be very challenging to solve once posed, due to the large size of the resulting nonlinear systems of algebraic equations. Partitioned approaches for solution of coupled problems enable the use of subdomain solvers developed by domain experts and are more amenable to a “plug-and-play” style of framework. However, with partitioned approaches, considerable attention must be given to enforcing coupling conditions.

As model reduction techniques continue to mature, it is natural that there is a desire among analysts to use cheaper, more efficient models where possible. This fits closely with the partitioned approach to solving coupled problems. It is towards this goal of solving multifidelity coupled problems involving reduced order models (ROMs) and full order models (FOMs) that we extend a partial differential equation (PDE) constrained optimization technique, developed for elliptic FOMs [1] and later extended to parabolic FOMs [2] and multiphysics [3], to ROM-ROM coupling.

The use of a ROM in one or more subdomains allows for harnessing their efficiency, but also presents a challenge with respect to reduced adjoint systems required to be solved as part of the technique. We explore the ROM-ROM coupling technique, applying it to coupled advection-diffusion equations. We present numerical studies demonstrating the accuracy of the approach along with an investigation related to selecting a reduced order basis for the adjoint systems.

MODELING THE DIRECT INK WRITE PROCESS USING A SHARP INTERFACE FINITE-ELEMENT METHOD

Alec Kucala[*1], Rekha Rao[1], Jessica Kopatz[1], David Noble[1] and Anne Grillet[1]*

[1]*Sandia National Laboratories*

ABSTRACT

Direct Ink Write (DIW) is an additive manufacturing technique that allows for the creation of complex patterns by extruding an “ink” material through a syringe onto a substrate; it is used in a variety of applications from biological systems to electronics. The printing process requires inks with complicated rheological properties, including shear thinning to be extrudable and yield stress in order to hold their shape. Modeling DIW presents many challenges for computational models, which include the highly nonlinear behavior of materials, as well as tracking of the complex material interfaces as the ink is deposited onto the substrate. We simulate the DIW process using finite-elements to solve the transient, three-dimensional Navier-Stokes equation using a non-Newtonian viscosity model to capture the effects of the complex ink rheology. To track the ink/air/substrate interfaces a sharp interface method is used, known as the conformal decomposition finite-element method (CDFEM). CDFEM is a conformal meshing algorithm that creates sharp boundaries between materials, which allows for the application of boundary conditions such as capillarity and to accurately capture discontinuities in properties such as density or viscosity between materials. In this talk, we will present the results of our simulations of the DIW process. In particular, we will investigate the ability of our computational model to predict a DIW printing failure mode when there is a mismatch between the substrate velocity and extrudate deposition rate. For a given extrudate deposition rate, a relatively fast-moving substrate can cause defects in the printed pattern, allowing discontinuities in the printed pattern where none should be present. We will compare our modeled results to our existing experimental data for both Newtonian and non-Newtonian inks.

PARAMETER AND DOMAIN-ROBUST PRECONDITIONERS FOR COUPLED MULTIPHYSICS PROBLEMS

Miroslav Kuchta[*1] and Timo Koch*[2]

[1]*Simula Research Laboratory*
[2]*University of Oslo*

ABSTRACT

Mathematical modeling of the so-called glymphatic system at the macroscale is based on multiphysics systems describing the interaction of the porous media flow and the viscous free flow. Here, interaction of the two subsystems, wide ranges of parameter regimes and importantly also the problem geometry (notably the domain's aspect ratio) present a difficulty for establishing robust and efficient solution algorithms. Focusing on the coupled Stokes-Darcy system [Layton 2002, Discacciati 2002] as a model problem we discuss in this talk monolithic and domain decomposition preconditioners which address these challenges.

STRESS-BASED TOPOLOGY OPTIMIZATION FOR ROLLER-BOX DESIGN IN ADDITIVE MANUFACTURING, INCLUDING BUILD PREPARATION

Erin Kuci[*1], Julien Leclerc[1] and Charles Chary[1]*

[1]Cenaero

ABSTRACT

The design freedom and local control over material properties provided by additive manufacturing are key advantages compared to traditional methods. Fully harnessing these benefits poses a complex challenge that questions intuitive design approaches. In response to these challenges, we developed Morfeo, an in-house software solution specifically tailored to address the complexities of AM design. Two topology optimization strategies are available in MORFEO and combined : the density method (SIMP) which parameters the design by material densities, and an XFEM Level Set method with an explicit (extended finite element) representation of the void-solid interfaces. We show here the integration of specific aspects of additive manufacturing into the design process.

Expanding our capabilities, a novel staged optimization loop, powered by the advanced in-house tool Cafeine, enhances additive manufacturing preparation. Swiftly analyzing critical manufacturing areas, it surpasses mere analysis by detecting closed cavities, evaluating roughness, sensing recoater impacts, identifying support needs, estimating volume, assessing depowdering risks, pinpointing cross-section changes, and evaluating manufacturing time. Integrating part preparation early in the design stages, we aim for a more integrated, efficient design process tailored to manufacturing requirements, fostering design innovation.

The effectiveness of the approach is vividly demonstrated in the redesign of a roller box, where a remarkable 30% reduction in mass was achieved compared to the existing concept, while still fulfilling the stress-based criterion. Moreover, this optimization strategy seamlessly integrates into our part design processes, underscoring its positive impact on both structural performance and the manufacturability of AM components.

ABSTRACT

Concrete is the most widely used construction material due to its high compressive strength, local availability of raw materials and simple production methods. However, it is a brittle material with low tensile strength resulting in occurrence of micro-cracks, which reduce the durability and stiffness of the concrete structure and may successively lead to a loss of its structural integrity.

This presentation introduces a novel approach to address concrete crack-closure utilizing capsules laden with a biogenic healing agent alongside shape memory alloy fibers. Drawing inspiration from biomineralization processes, a cutting-edge method for the fabrication of these capsules will be unveiled and thoroughly examined using various modern analytical tools like AFM, SEM, FTIR, TG. This pioneering methodology not only holds promise for enhancing the durability and performance of concrete structures but also underscores the transformative potential of biomineralization-inspired strategies in materials science and engineering. Through elucidating the synthesis and application of these innovative capsules and healing agents, this presentation endeavors to propel the advancement of sustainable, resilient construction materials into the future.

The results of in-house laboratory experiments on such concrete composites as well as the modeling and simulation of the deformation and healing processes will be presented and discussed, using the concepts of thermodynamics and phase-field approach and finite element approximation [1, 2].

AUTOMATED MODEL DISCOVERY FOR SOFT MATTER SYSTEMS

Kevin Linka[1] and Ellen Kuhl[2]*

[1]RWTH Aachen
[2]Stanford University

ABSTRACT

Sparse regression and feature extraction are the cornerstones of knowledge discovery from massive data. Their goal is to discover interpretable and predictive models that provide simple relationships among scientific variables. Statistical tools for model discovery are well established in the context of linear regression; yet, in solid mechanics, model discovery typically translates in a nonlinear regression problem that remains incompletely understood. Here we explore model discovery and sparse regression through the lens of Lp regularization using data from the human brain [1], arteries [2], and artificial meat. Lp regularization introduces two hyperparameters: the power p by which it penalizes individual terms, and a penalty parameter by which it scales the relative importance of regularization and regression [3]. Our study reveals that L0 regularization is the only member of the Lp family that explicitly allows us to fine-tune the balance between interpretability and predictability, simplicity and accuracy, and bias and variance. We demonstrate that its penalty parameter acts as a discrete switch to select the desired number of terms. While L0 regularization across all possible models translates into an expensive NP hard discrete combinatorial problem with 2^n possibilities, our results suggest that beginning any discovery by performing L0 regularization for all possible one- and two-term models provides quick and valuable insight into the nature and hierarchy of the best-in-class models. Taken together, our study reveals the importance of L0 regularization in model discovery, because it is honest, transparent, and unbiased. We anticipate that our results will generalize to alternative discovery techniques including neural networks and symbolic regression, and to other domains including biology, chemistry, or medicine. Our ability to automatically discover material models from data could have tremendous applications in generative material design and open new opportunities to manipulate matter, alter properties of existing materials, and discover new materials with user-defined properties.

MESHFREE: MINIMAL EFFORT FOR BEST QUALITY. ENSURE RELIABILITY OF INDUSTRIAL SIMULATION APPLICATIONS IN FLUID AND CONTINUUM MECHANICS.

Joerg Kuhnert[*1]*

[1]*Fraunhofer Institute for Industrial Mathematics (ITWM)*

ABSTRACT

MESHFREE (meshfree.eu) is a simulation tool that originates from Fraunhofer ITWM (Germany) and is currently developed in cooperation with Fraunhofer SCAI. It is designed to solve industrial and scientific problems in fluid and continuum mechanics. Its geometrical basis is a non-meshed point cloud which moves (in Lagrangian sense) with the velocity of the continuum. The basis of approximation is a specific moving-least-squares-approach (MLS) together with a dedicated quality optimization. Both together provide a desired order of approximation accuracy as well as numerical stability.

Due to its design, MESHFREE is especially capable to address problems with dynamic free surfaces and phase boundaries, complex geometries and kinematics, fluid-structure interaction, and complex physics such as expanding flows (evaporation/foaming) or freezing.

In order to proof quality/validity of MESHFREE simulation results, the classical way is to proof numerical convergence of the result upon refinement of the geometrical basis (using finer and finer resolution of the point cloud) and/or upon using higher orders of approximation. However, this way of quality-testimonial is often ignored in practical or industrial applications as it is both time and resource consuming. This, indeed, is a conflict.

MESHFREE can provide a practicable solution/relaxation to this conflict. On one hand, MLS allows to precisely estimate the local approximation errors and thus establish reliable quality measures of the simulation result. On the other hand, it is almost trivial to locally refine or coarsen the point cloud based on given quality targets.

In this way, MESHFREE can provide simulation results with user-requested quality. Moreover, if computational or time resources are limited, MESHFREE can provide the qualitatively best solution within the given resource-spectrum. This widely enhances the scope of industrial applicability of simulations of this method in general.

Based on two industrial examples (modelling of water wading in vehicle design, modeling of PUR-foaming processes in chemical engineering), quality-triggered adaptivity of MESHFREE simulations will be demonstrated. The numerical convergence of the method will be shown based on significant result parameters.

THE REVISITED PHASE-FIELD APPROACH TO BRITTLE FRACTURE: APPLICATION TO THE DIAMETRAL COMPRESSION AND WING-CRACK PROBLEMS

Aditya Kumar[*1], Chang Liu[1], Yangyuanchen Liu[2], John Dolbow[2] and Oscar Lopez-Pamies[3]*

[1]*Georgia Institute of Technology*
[2]*Duke University*
[3]*University of Illinois Urbana-Champaign*

ABSTRACT

In a recent contribution, Kumar et al. (2020, 2022) have introduced a comprehensive macroscopic phase-field theory for the nucleation and propagation of fracture in linear elastic brittle materials under arbitrary quasistatic loading conditions. The theory can be viewed as a natural generalization of the phase-field approximation of the variational theory of brittle fracture of Francfort and Marigo (1998) to account for the material strength at large. This is accomplished by the addition of an external driving force—which physically represents the macroscopic manifestation of the presence of inherent microscopic defects in the material—in the equation governing the evolution of the phase field. Through comparisons with experiments in materials soft and hard under various loading conditions, it has been shown that this theory may be a complete phase-field theory of fracture for brittle materials.

This talk will focus on the application of the theory to two problems involving fracture under large compressive forces: (1) Brazilian fracture (diametral compression) test and (2) Wing-crack evolution test. Such problems have proved to be challenging for the classical phase-field models, and various energy splits have been proposed in the literature to accurately describe experimental observations. We will show that the theory of Kumar et al. can intrinsically capture the compression-tension asymmetry without requiring an energy split. Computational implementation of the theory will be discussed.

From an application point of view, this talk will discuss how the theory can be used to correctly interpret the results of the Brazilian fracture test to measure tensile strength. Our analysis shows that the formulas proposed by the latest ASTM standard for the Brazilian test generally do not yield correct values for the material's tensile strength. A new protocol is proposed to deduce the tensile strength of a material from a Brazilian test. Moreover, for the wing-crack evolution test, the analysis shows that wing cracks can be obtained even when the mode II fracture toughness is equal to the mode I fracture toughness, in contrast to previous claims in the literature that mode II fracture toughness has to be much higher.

OPTIMIZED LATTICE DESIGN FOR TAILORED FORCE-DISPLACEMENT CHARACTERISTICS

Saketh Sridhara[1], Akshay Kumar[1] and Krishnan Suresh[1]*

[1]University of Wisconsin, Madison

ABSTRACT

Optimized frames are employed in various large deformation applications such as energy-absorbing lattices, load-carrying structures, and compliant mechanisms. This study focuses on the development of an optimized lattice design leveraging advanced techniques for differentiation (auto-diff) and employing the Euler-Bernoulli beam theory. The objective is to tailor the force-displacement curve of energy-absorbing lattices to meet specific application requirements.

The computational framework utilizes auto-diff to efficiently compute derivatives for gradient-based optimization, allowing for the systematic exploration of design spaces. The Updated Lagrange method with Euler-Bernoulli beam theory is employed to model the non-linear mechanical behavior of the lattice structures using frame structures, providing a solid foundation for the optimization process. This integration of auto-diff and analytical modeling enables the generation of 3D lattice designs with enhanced performance in terms of force absorption and load-carrying capacity.

To validate the optimized lattice designs, a series of experiments are conducted to compare the predicted force-displacement curves with real-world physical behavior. Experimental setups involve the fabrication of prototypes using advanced manufacturing techniques such as 3D printing. The physical tests aim to confirm the accuracy and reliability of the computational models, ensuring that the optimized lattice structures perform as intended in practical applications.

The results demonstrate the effectiveness of the proposed approach in achieving the desired force-displacement characteristics in lattice structures. The experimental validation further strengthens the reliability of the computational predictions, providing confidence in the practical applicability of the optimized lattice structures in energy-absorbing and load-carrying applications. This interdisciplinary approach contributes to advancing the state-of-the-art in structural design with optimization, offering a powerful combination of computational efficiency and experimental validation for optimized lattice structures in large deformation scenarios

COMPUTATIONAL OPTIMIZATION OF HIGHER-ORDER HOMOGENIZATION FRAMEWORK FOR LARGE-SCALE RVE MODELS

Athira Anil Kumar[1], Aewis K.W. Hii[1], Bassam El Said[1] and Stephen Hallett[1]*

[1]*University of Bristol*

ABSTRACT

This study delves into the intricate computational challenges inherent in multi-scale modeling, particularly in the context of composite materials. The complexity arises from both generic and specific computational hurdles, such as the resolution of large system matrices and the management of dense constraint equations typical in higher-order homogenization frameworks. These issues are highlighted through the application of a second-order homogenization using thick shell elements proposed by Hii and El Said[1], with a focus on large-scale, finely-discretized Representative Volume Element (RVE) models. Such models are crucial for multi-scale modeling of complex structures like sandwich panels, porous and woven composites, where RVE sizes can become comparable to macro-scale models. Two primary computational challenges are highlighted through the downscaling and upscaling procedures of the framework. The downscaling procedure confronts the dilemma of handling large constraint equations in commercial finite element software, which typically have memory limitations on the size of elements or equations they can process. Conversely, the upscaling procedure underlines the task of solving large dense matrices to derive homogenized properties, such as ABD matrices. These challenges pose significant barriers to effective modeling and analysis, particularly in complex structures requiring fine discretization and high memory.
To address these challenges, our research proposes innovative solutions. For the downscaling procedure, Broyden’s method is employed iteratively to evaluate constraint forces. This method bypasses the conventional application of displacement boundary conditions to satisfy constraint equations. The iterative nature of this solution adapts seamlessly to complex non-linear problems while optimizing memory usage. Furthermore, this method has been extended to support multi-threaded parallelization, thus leveraging additional computational resources. Conversely, for the upscaling procedure, we leverage the use of Dask libraries, known for their effectiveness in handling extensive matrix systems via chunking. An adaptive approach is employed here, utilizing a conditional algorithm to select between static condensation or forward difference methods for the computation of ABD matrices, depending on specific model and computational conditions.
This new framework has been tested in various models requiring fine discretization and substantial memory resources. These include RVEs with embedded defects, sandwich panels, and 3D woven composites. The results demonstrate the framework's capability in effectively addressing and resolving the computational intricacies inherent in multi-scale modeling of complex structures.

COMPUTATIONAL MODELING OF RATE DEPENDENT FRACTURE RESPONSE IN SOFT ELASTOMERIC MATERIALS

Paras Kumar[1], Miguel Angel Moreno-Mateos[1] and Paul Steinmann[1]*

[1]*Friedrich-Alexander-Universität Erlangen-Nürnberg*

ABSTRACT

Soft materials, owing to their low elastic moduli that are usually only a few KPa, can undergo extremely large deformations of up to several hundred percent strain prior to fracture. Such materials consequently present themselves as ideal constituent materials for a wide range of emerging cutting-edge biomedical applications such as tissue engineering and soft robotics [1]. This work deals with computational modeling of soft elastomeric materials exhibiting rate-dependent constitutive response, both in the pre-fracture as well as the fracture regimes, as revealed by an array of in-house experimental investigations conducted on representative materials of this class. A nonlinear finite viscoelasticity model based on the generalized Maxwell model is employed to capture the viscoelastic constitutive response. Further, we extend the finite-deformation elastic phase-field fracture model of [2] by introducing the dependence of fracture properties on the applied loading rate in order to capture the rate-dependent fracture response. The developed formulation is validated against experimental observations thereby providing useful insights regarding the rate-dependent fracture response of soft elastomeric materials.

Keywords: soft elastomers, viscoelasticity, phase-field fracture, constitutive modeling, experimental validation

MODELING RIBBONS/STRIPS AS A COSSERAT ROD

Roushan Kumar[*1] and Ajeet Kumar*[1]

[1]*Indian Institute of Technology Delhi*

ABSTRACT

This study presents a computational approach to obtain nonlinearly elastic constitutive relations of strip/ribbon-like structures modeled as a special Cosserat rod. Starting with the description of strips as a general Cosserat plate, the strip is first subjected to a strain field which is uniform along its length. The Helical Cauchy-Born rule is used to impose this uniform strain field which deforms the strip into a six-parameter family of helical configurations-the six parameters here correspond to the six strain measures of rod theory. Two vector variables are introduced to model the position of the deformed centerline of the strip's cross-section and to model orientation of thickness lines along the strip's width. The minimization of the strip's plate energy together with the aforementioned uniformity in strain field reduces the partial differential equations of plate theory from the entire mid-plane of the strip to just a system of nonlinear ordinary differential equations along the strip's width line for the above mentioned two vector variables. A nonlinear finite element formulation is further presented to solve the above mentioned set of ordinary differential equations. This, in turn, yields the strip's stored energy per unit length as well as the induced internal force, moment and stiffnesses of the strip for every prescribed set of six strain measures of rod theory. The proposed scheme is used to study uniform bending, twisting and shearing of a strip. For the case of uniform twisting and shearing, the strip is also seen to buckle along its width into a more complex configuration which are accurately captured by the presented scheme. We demonstrate that the presented scheme is more general and accurate than the existing schemes available in the literature.

[2]*Georgia Institute of Technology*

ABSTRACT

We present an inverse uncertainty quantification (UQ) framework for the input fields of complex fluid flows based on measurements that take the form of images. In particular, we demonstrate our framework on a turbulent supercritical carbon dioxide (sCO_2) mixing layer configuration that models an experiment designed and performed by researchers at the Georgia Institute of Technology (Lim C.H. et al. (2022) Proceedings of the ASME, Lim C.H. (2022) PhD thesis). Because of its proximity to the critical point of CO_2, the behaviour of the supercritical flow is sensitive to thermodynamic properties, namely pressure and temperature. In addition, while extensive measures have been taken to control the conditions on the boundary of the interrogation region, practical limitations inevitably introduce uncertainties in pressure and especially temperature boundary fields. As such, these fields must be accurately estimated to provide reliable predictions, and in our demonstration, we focus on estimating the temperature field at the inlet of the channel confining the mixing layer. Our approach to estimate and quantify the uncertainty of the inlet temperature field builds on the following four foundations. First, we model (i) the fluid dynamics using a large eddy simulation (Purushotham D. et al. (2022) AIAA SciTech Forum) and (ii) the planar laser Raman scattering measurements yielded by the experiment using an assortment of image synthesis methods of varying fidelity. Second, we approximate the inlet temperature in terms of a truncated Karhunen–Loève (KL) expansion, which recasts the field inversion problem into a parametric one. Third, we construct a rapidly evaluable likelihood function using (i) proper orthogonal decomposition of prescribed sets of synthesized, time-uncorrelated images and (ii) a surrogate model based on a cut high-dimensional model representation. Lastly, we approximate the posterior distributions of the KL coefficients using a Hamiltonian Monte Carlo sampling algorithm. We assess our framework using simulation-based solutions and synthesized images of the sCO_2 flow.

PREDICTION OF PULSATING TURBULENT PIPE FLOW WITH EXTENSIVE DRAG REDUCTION EFFECTS BY DEEP LEARNING WITH GENERALIZATION CAPABILITY

Sota Kumazawa[*1], Tomohiro Nimura[1], Akira Murata[1] and Kaoru Iwamoto[1]*

[1]*Tokyo University of Agriculture and Technology*

ABSTRACT

Pulsation control is one of promising turbulent controls for reducing skin friction drag. Significant drag reduction effect is achievable by carefully tuning pulsation parameters. However, it is difficult to optimize the pulsation control due to computational costs and the large number of parameters involved. Matsubara et al. (2023) constructed a deep learning model capable of predicting acceleration and deceleration [1], while the prediction accuracy of Reynolds shear stress (RSS) is low. In addition, its generalization capability across varying pulsation parameters remains unverified for flow fields exhibiting different drag reduction effects.

In this study, we have propose a deep learning model with a new input of RSS, building upon the framework established by Matsubara et al. (2023) [1]. The model structure comprises a convolutional autoencoder (CAE) and long short-term memory (LSTM). We normalize the low-dimensional modes obtained from CAE to enhance LSTM learning. Our training dataset consists of time series data from direct numerical simulations, including streamwise velocity, radial velocity, RSS, and pressure gradient.

It was found that the model fails to improve the prediction accuracy of RSS, although RSS is added for in training dataset. Further exploration revealed a weak correlation between low-dimensional modes and RSS. Next, we predict flow fields exhibiting various drag reduction effects resulting from changes in pulsation parameters. Interestingly, both the Matsubara et al. (2023) [1] model and our proposed model can predict these flow fields under identical parameters during both learning and prediction phases.

Investigation of prediction accuracy under different parameters during the prediction phase would reveal whether the model is predictable for flow fields with extensive drag reduction effects. This would provide valuable suggestions for improving its generalization capability.

HOMOGENIZED LATTICE BOLTZMANN METHODS FOR EFFICIENT FLUID-STRUCTURE INTERACTION SIMULATIONS

Adrian Kummerländer[*1] and Mathias J. Krause*[1]

[1]*Karlsruhe Institute of Technology (KIT)*

ABSTRACT

Lattice Boltzmann methods (LBM) are an established mesoscopic approach to the simulation of a diverse range of transport problems, most prominently flows described by Navier-Stokes (NSE) and reaction-advection-diffusion equations. Their algorithmic structure renders LBMs uniquely suited to massively parallel high performance computation (HPC). LBMs have successfully been used in the context of computational fluid-structure interaction (FSI), primarily by coupling external structural solvers via immersed boundary methods (IBM).

The homogenized lattice Boltzmann method (HLBM) [1] is a recent approach to modeling flows with dynamic boundaries that considers fluid and solid regions as a unified, time-dependent porous medium. The HLBM has been successfully employed for the simulation of resolved arbitrarily shaped particles [2] but remained specialized to swarms of non-deformable particles treated as discrete elements. Compared to IBM-based approaches, the HLBM offers advantages for HPC due to its local, non-interpolated nature and straightforward coupling to arbitrary structural modeling approaches.

This presentation discusses a novel approach to the simulation of arbitrary FSI problems with two-way coupled deformable boundaries using HLBM, combined with a molecular dynamics (MD) model, yielding a unified and efficient high performance FSI solver. Such a performance-focused approach is essential to enable large-scale ensemble simulations aimed at uncertainty quantification of flows derived from phase-contrast magnetic resonance imaging (PC-MRI) measurements, specifically capturing unsteady hemodynamics in moving vessels. For the present talk, benchmark results of established reference cases, including flow-induced beam bending and filament oscillation as well as an application case simulating a model of the human vocal fold will be presented. The implementation and parallel performance on heterogeneous multi-GPU clusters using the open source LBM framework OpenLB [3] will be discussed.

ABSTRACT

Accurately predicting the surface heat flux experienced by a spacecraft during atmospheric (re-)entry is crucial for determining the appropriate Thermal Protection System (TPS) material and thickness. The high speeds involved during (re-)entry lead to the formation of strong shockwaves, beyond which flow pressure, density, and temperature rapidly increase. This results in the excitation of internal energy modes and molecular dissociation, directly impacting the surface heat flux. Modeling this phenomenon is challenging due to nonequilibrium conditions, where the characteristic time scales of species collisions become comparable to the characteristic time scales of flow.

Various models, ranging from low accuracy and low computational cost (such as multi-temperature models) to high accuracy and high computational cost (such as state-to-state models), are available to simulate thermochemical nonequilibrium. Adding to this complexity, uncertainties exist in flow parameters, such as (re-)entry speed, boundary conditions, and in chemistry rate coefficients. Accounting for these uncertainties is essential to determine the uncertainty in key quantities like surface heat flux.

In this context, the necessity for a surrogate model for non-equilibrium thermochemistry is evident, as it facilitates computationally tractable forward propagation of flow parameter and rate coefficient uncertainties. The diverse range of models at different fidelities allows the development of multi-fidelity surrogate models, leveraging abundant yet less accurate low-fidelity data and sparse but highly accurate high-fidelity data to strike a balance between accuracy and computational cost.

This work proposes a multi-fidelity surrogate model that combines numerous, less accurate low-fidelity simulations with a select few accurate, yet expensive, high-fidelity ones to create a comprehensive dataset. This combined dataset is utilized to identify a low-dimensional subspace using two methods: the linear dimensionality reduction method Principal Component Analysis and the non-linear method Diffusion Maps. Probabilistic Learning on Manifolds (PLoMS) [1] is used to enrich the high-fidelity data by conditioning on corresponding low-fidelity data. The enriched dataset is then employed to train a Polynomial Chaos Expansion (PCE) with stochastic coefficients, accommodating model form uncertainty. This multi-fidelity surrogate model, combining the strengths of dimensionality reduction and PCE, allows for quicker predictions of the full flow field at new locations in the uncertain input parameter and boundary condition space with impressive accuracy but at a significantly lower computational cost compared to high-fidelity simulations. This framework paves the way for a comprehensive characterization of uncertainty in thermochemical nonequilibrium phenomena.

COMPARISON OF FULL-FIELD OBJECTIVE FORMULATIONS FOR MATERIAL MODEL CALIBRATION

Matthew Kury[*1] and Kyle Karlson*[1]

[1]*Sandia National Laboratories*

ABSTRACT

Critical safety simulations need to credibly model physical evolutions of their components in extreme conditions. Feature rich material models, such as those with anisotropic yield and hardening, provide the necessary physics to represent material response under these conditions. A significant obstacle in using feature rich material models is the substantial quantity of calibration parameters present. Using conventional experimental data, such as uniaxial load-displacement, to calibrate these models is difficult and requires many iterations of the same experiment. Full-field data acquisition systems and tools, such as digital image correlation and infrared cameras, provide a plethora of data from an individual experiment. Full-field data tools capture experimental measurements at a level of detail that conventional probe and fixture-based measurements cannot. Experiments designed around the capture of full-field data can enable richer sets of data from single experiments, potentially enabling the calibration of more elaborate material models with fewer experiments.

We investigate this assumption by comparing three full-field calibration techniques to a conventional calibration where only conventional data is used. The three full-field calibration techniques differ in that they provide different formulations of the objective that is minimized during calibration. The first objective studied is formed by spatially interpolating the experimental data to the simulation nodes and directly differencing the data to form a set of residuals. The second method transforms the spatial data to a common set of orthogonal basis functions, and then compares the data in this transformed space. We determine this set of basis function using a variation of Alpert wavelets[1]. The final method is an implementation of the virtual fields method [2]. In the presentation, we describe our implementation of each method and compare their performance on a set of synthetic data where the true solution is known.

TOPOLOGY OPTIMIZATION FOR FRACTURE RESISTANCE USING NEURAL REPARAMETERIZATION

Gawel Kus[*1] and Miguel Bessa*[1]

[1]*Brown University*

ABSTRACT

Consideration of fracture is crucial in a wide range of design problems: from simple load-bearing structures exposed to fatigue and corrosion cracks to specialized energy-dissipation designs. However, optimizing structures for fracture resistance remains one of the most complex challenges in the Topology Optimization field. The process relies on solving fracture simulations, which are expensive and challenging to combine with standard topology optimization approaches due to their non-linear nature. Furthermore, the crack trajectories are sensitive to even minor design changes, which results in a poorly behaved loss function that is difficult to optimize.

We explore addressing these challenges with neural reparameterization, where the optimization variables are represented using the latent space of a deep neural network. We investigate neural reparameterization with gradient-based and gradient-free optimizers. In the first case, we use neural reparameterization to expand the problem dimensionality, leading to overparameterization, which makes the loss landscape easier to explore by a gradient-based optimizer. In the second case, we use neural reparameterization to reduce the dimensionality of the problem to mitigate the curse of dimensionality of the gradient-free optimizer. We benchmark both methods on several examples of optimizing topology designs for fracture resistance and compare them against the conventional approach.

STRESS-STRAIN STATE OF HTSC TAPES IN SPARC CENTRAL SOLENOID

ABSTRACT

Successful test of 20 T toroidal field model coil (TFMC) in 2021[1] demonstrated feasibility of fabrication of large scale high field HTS magnets. SPARC[2] central solenoid will be another high field, high energy HTS magnet. It is based on cable-in-conduit conductor technology. The cable consists of four twisted petals of copper former, each has a groove for a stack of soldered HTS tapes. The cable is immersed in a steel jacket, providing structural support.
During magnet operation at high field magnet will experience time-dependent electromagnetic, structural and thermal loads. Superconducting tapes will experience high mechanical stresses and strains. Exceeding certain bounds leads to degradation of superconducting tapes and reduction of critical current. At the same time, allowable stresses and strains are design specific and there is very limited information about their values for a soldered multi-tape conductor.
In this study we present multi-scale models of SPARC central solenoid and TFMC coil and estimate mechanical stresses and strains experienced by HTS tapes in both cases. We report these values and review critical stress and strain available in the literature. Based on the successful completion of TFMC test we conclude that computed stress and strain values can be considered as allowable and can be used to design new high field high energy magnets such as SPARC central solenoid.

[1]Norwegian University of Science and Technology
[2]SINTEF Digital

ABSTRACT

A challenge for establishing predictive digital twins is access to data that may be confidential. Federated learning (FL) has been argued to address this issue in the context of digital twins. We show that federated hybrid models can - with the right training strategy - by design to achieve results that are of the same quality as models trained on a central data. We have combined FL with Hybrid Analysis and Modelling (HAM) to enable Structural Health Monitoring (SHM) in te context of predictive digital twins.

NUMERICAL MODEL FOR THERMAL BUCKLING ANALYSIS OF FGM THIN-WALLED STRUCTURES

Sandra Kvaternik Simonetti[*1], Domagoj Lanc[1], Goran Turkalj[1] and Damjan Banić[1]*

[1]*University of Rijeka*

ABSTRACT

A numerical approach for solving the problem of nonlinear stability of beam structures made of FG (functionally graded) materials under variable temperature is presented in this work. The approach utilizes a geometric nonlinear algorithm based on a 1D numerical model using a spatial beam finite element. The deformations are considered small and the Green-Lagrange deformation tensor is used for defining them. The finite element model is based on the Euler-Bernoulli beam theory for bending and the Vlasov theory for torsion. The UL (updated Lagrangian) incremental formulation is used in the nonlinear analysis with the principle of virtual works. The cross-sectional displacement field includes the effects of warping torsion and large rotations. The material properties assumed to vary continuously through the wall thickness based on power-law distribution. The proposed beam model enables buckling analysis for cases of uniform, linear and nonlinear temperature distribution through the thickness of the cross-sectional walls. The analysis also includes the temperature dependence of the mechanical properties of the material. Numerical results are obtained for different thin-walled sections with various configurations such as boundary conditions, geometry, FG skin-core-skin ratios, and power-law index to investigate critical buckling temperatures and post-buckling responses. The numerical algorithm is tested for accuracy and reliability by comparing the results obtained using 2D and/or 3D finite element models from established software packages. The comparison shows that the numerical results are in excellent agreement with the results obtained with shell and solid models.
The proposed algorithm is more efficient and faster than numerical models based on shell and solid finite elements, making it an advantage. This numerical model provides the possibility of describing and analysing beam structures made of composite FG materials during the process of their design. It is especially useful in assessing the response and loss of structural load-bearing stability in a thermal environment.

NEURAL NETWORK PLASTICITY MODELS WITH ABAQUS UMAT FOR ALUMINUM 7079

Chulmin Kweon[*1], Hyoungsuk Suh[2], Brian Lester[3], Sharlotte Kramer[3] and WaiChing Sun[1]*

[1]*Columbia University*
[2]*Case Western Reserve University*
[3]*Sandia National Laboratories*

ABSTRACT

This study introduces a publicly available PyTorch-ABAQUS deep-learning framework of a family of plasticity models where the yield surface is implicitly represented by a scalar-valued function. In particular, our focus is to introduce a practical framework that can be deployed for engineering analysis that employs a userdefined material subroutine (UMAT/VUMAT) for ABAQUS, which is written in FORTRAN. To accomplish this task while leveraging the back-propagation learning algorithm to speed up the neural-network training, we introduce an interface code where the weights and biases of the trained neural networks obtained via the PyTorch library can be automatically converted into a generic FORTRAN code that can be a part of the UMAT/VUMAT algorithm. To enable third-party validation, we purposely make all the data sets, source code used to train the neural-network-based constitutive models, and the trained models available in a public repository. Furthermore, the practicality of the workflow is then further tested on a dataset for anisotropic yield function to showcase the extensibility of the proposed framework. A number of representative numerical experiments are used to examine the accuracy, robustness and reproducibility of the results generated by the neural network models.

ENHANCING THE OXIDATION RESISTANCE BY ADDING IMPURITIES TO CARBON SITE IN ULTRA HIGH TEMPERATURE CERAMICS: AN AB INITIO MOLECULAR DYNAMICS STUDY

Seunghwan Kwon[*1], Jongkyung An[1], Rajkamal Anand[1], Jiwon Jung[1] and Gunjun Yun[1]*

[1]*Seoul National University*

ABSTRACT

C/C composites are suitable structural materials for aerospace engineering because of their superior mechanical properties, lightweight and excellent thermal shock resistance, but they are vulnerable to severe degradation induced by oxidation during atmospheric reentry. Such degradation will impair their physical/chemical properties. Therefore, surface coatings are required to protect them in extreme environment. Ultra high temperature ceramics (UHTC) are promising candidates for such coatings due to their good mechanical properties and chemical stability at high temperature. However, even though we can compare the oxidation resistance of different materials experimentally, we lack the fundamental understanding of the reaction mechanisms at atomic level. In this study, we did ab initio molecular dynamics (AIMD) simulation for three types of carbides UHTC, ZrC, HfC and TaC, at various temperature and oxygen coverage. Surface orientations of each materials for the simulation were selected to (100), (110) and (111). These surface planes were selected due to their dominance of those materials, observed from the experimental results gathered from x ray diffraction or transmission electron microscopy. Moreover, we replaced carbon atom on the surface of carbides UHTC to several other elements such as B, N, O, Al, Si, P, S to further enhance the anti oxidation ability than pristine surface and executed AIMD simulation. Such doping elements were selected based on the difference in ionic radius and number of valence electrons with carbon. To substitute carbon to other elements, those should possess similar size of ionic radius and valence number. From AIMD simulation results, we gathered trajectories of each atoms and calculated diffusion coefficient of surface atoms from those trajectories to quantitatively compare the oxidation resistance of materials doped with different elements. Also, from the atomic configuration shown in snapshots, we calculated charge density difference and partial density of states to reveal the nature of chemical bonding. Further, we have gained insights about the reaction mechanisms of each materials and the effect of added impurities on oxidation based on molecular dynamics simulation trajectories that fully reflect the sequential chemical reaction process. Through this study, we were able to select the optimized impurities, enhance the oxidation resistance.

ACCELERATING FLUID-STRUCTURE INTERACTION SIMULATIONS WITH MULTI-TIME-STEP COUPLING OF IMPLICIT-EXPLICIT SCALAR AUXILIARY VARIABLE TIME INTEGRATION SCHEMES

Sun-Beom Kwon[*1] and Arun Prakash*[1]

[1]*Purdue University*

ABSTRACT

Simulating fluid-structure interactions (FSI) problems, such vortex-induced vibrations, is usually associated with a high computational cost because of the presence of multiple temporal scales. Most time integration schemes, however, are constrained to use the smallest time-step necessary to resolve these scales over the entire fluid and solid domain. There are several time integration schemes available to solve the Navier-Stokes equations and coupling strategies that allow fluid and solid domains to be integrated with different time-steps with different stability and accuracy characteristics. The focus in the study, however, is on recently developed implicit-explicit (IMEX) scalar auxiliary variable (SAV) schemes that are able to achieve high-order accuracy and unconditional energy stability.

In this work, we present a novel multi-time-step (MTS) method that allows the use of small time-steps in boundary layers and large time-steps in the far field to reduce computational cost while maintaining accuracy within fluid domains. Further, we formulate up to 5th order accurate IMEX-SAV schemes for structural dynamics as well and investigate different coupling strategies for FSI. We show that the proposed MTS-IMEX-SAV method for solving the Navier-Stokes equations is unconditionally stable and involves only linear algebraic systems thereby eliminating the need for iterations due to the presence of nonlinear terms. We demonstrate the computational performance of the proposed MTS-IMEX-SAV method using several numerical examples and show the computational gains compared to existing time integration schemes.

AN IBEM-FEM MODEL OF THE CONVERSION BETWEEN SURFACE AND BODY WAVES RESULTING FROM THE INTERACTION OF PAVEMENTS WITH THE SOIL

Leonardo Antoniazzi Marques[1], David Carneiro[2], Persio Leister de Almeida Barros[1] and Josue Labaki[1]*

[1]State University of Campinas
[2]KU Leuven

ABSTRACT

This paper investigates the phenomenon of conversion of Rayleigh (surface) waves into primary and secondary body waves caused by the presence of a pavement on the soil surface. To investigate this phenomenon properly, an IBEM-FEM model is used, in which the pavement is represented via a classical finite element method (FEM) discretization, and the soil is represented via a boundary element discretization, in the context of the Indirect Boundary Element Method (IBEM). Both the pavement and the soil are modeled as linear-elastic, isotropic media, which is a reasonable model in this case, in which low magnitude, low frequency time-harmonic excitation is considered. Coupling at the interface between the pavement and the soil is achieved by establishing equilibrium and continuity conditions between the finite and the boundary element nodes of both meshes, resulting in a case in which the pavement is fully bonded to the surface of the soil. This allows for the energy exchanged between the two bodies to be represented properly as well. Because of the boundary element scheme used to represent the soil, this model can capture accurately some features of wave propagation in the soil, such as the scattering of waves due to the presence of the pavement, the conversion of surface into body waves resulting from the pavement-soil interaction, and attenuation of energy at infinity, as imposed by Sommerfeld's radiation condition. In this paper, this model was used to investigate specifically the intricated phenomenon of conversion of surface waves into body waves, especially with regards to the angle at which a wavefront of the converted body waves is injected into the soil. The results of a parametric study show how geometric and constitutive parameters of the soil and pavement affect this injection angle. Converting surface waves into body waves has shown to be one of the main mechanisms by which surface structures can be used to attenuate ground vibration. Understanding these details about this mechanism can help geotechnical engineers to design pavements that also work as ground vibration mitigation devices.

NONLINEAR CFD DATA INTERPOLATION IN PARAMETERIZED ADVECTION-DOMINATED FLOWS

Jon Labatut[*1], Angelo Iollo[2] and Tommaso Taddei[2]*

[1]*ONERA*
[2]*INRIA*

ABSTRACT

The Reduced Order Models (ROM) have been introduced as a low rank approximation of a studied dynamics to speed up its evalutaion. This low rank approximation is crucial for application related to CFD as the number of degrees of freedom limits their usage in design optimization or real time evaluation for dynamics and control. Even though some ROMs have been proven efficient on certain applications, their construction around linear subspaces reduces their usage to some specific industrial cases.

To overcome this issue we propose a general interpolation technique between snapshots of parametric simulation results. The core of this method relies on the computation and the use of spatial mappings to transport the snapshots over the manifold of solutions. This kind of approach is referred to as image registration and has been largely used in medical imaging. Today we propose to apply image registration to CFD data and compute an accurate interpolation in a non intrusive manner. The method starts with the use of markers to identify the coherent structures of the flow. From these markers, we will define the registration problem as the minimisation of an energy functional depending on the mapping we are looking for. The functional is designed to fill three objectives: align the markers, produce a bijective mapping through the regularization of its displacement field and impose on the interpolation trajectories to be compliant with the boundary conditions of the CFD domain. Finally, the solution should be computed fast enough so the interpolation method remains relevant for real time applications. For this, we constructed an appropriate compact research space for the velocity of the displacement field. This research space was built as the span of the first eigenfunctions of the Navier-Lamé operator along with the appropriate boundary conditions. The regularization of the field was ensured by the minimization of its H2 norm. Finally, by applying this pseudo temporal mapping on the solution it is possible to construct non linear latent spaces [1] or use it directly to perform a convex displacement interpolation of the snapshots [2].

NUMERICAL MODELLING OF LARGE POUCH LITHIUM-ION BATTERY

Francis Lacombe[*1], Kintak Raymond Yu[1] and Florin Ilinca[2]*

[1]National Research Council of Canada (NRC)
[2]National Research Council of Canada

ABSTRACT

The need for a reliable thermal management system for lithium-ion batteries is paramount, primarily due to the critical role it plays in maintaining an optimal operating temperature range, and mitigating aging effects. Elevated temperatures accelerate aging by increasing the rate of internal chemical reactions, leading to capacity loss and reduced battery life. To address this issue, electric vehicle (EV) battery manufacturers often employ small cylindrical cells to improve reliability and temperature uniformity, thanks to their large surface-to-volume ratio. However, this method also adds to the pack's weight, thereby affecting the vehicle's range. As a result, large pouch cells are becoming more popular in EV applications. To enhance the safety and performance of these cells, various heat dissipation techniques are employed to improve temperature uniformity and cooling. To help in the design of future large pouch cells, reliable numerical tools that can account for local temperature changes are required, moving beyond a basic single-cell model. This comprehensive method offers a more accurate simulation of real-world conditions by considering thermal variation in the electrochemical model.

A case of study in which a local thermally coupled electrochemistry model is used to simulate cell behavior and temperature variations. We investigate the design space and propose strategies to alleviate temperature non-uniformity. This approach allows us to represent and address the challenges faced in real-life applications more accurately.

APPLICATIONS OF THE PARTICLE FINITE ELEMENT METHOD FOR 3D FLUID-STRUCTURE INTERACTIONS AND MULTIPHYSICS SIMULATIONS

Martin Lacroix[*1], Simon Février[1], Eduardo Fernandez[1], Luc Papeleux[1], Romain Boman[1] and Jean-Philippe Ponthot[1]*

[1]*University of Liège*

ABSTRACT

The present work focuses on the partitioned coupling between a structural solver based on the Finite Element Method (FEM) and a fluid solver based on the Particle Finite Element Method (PFEM) (Idelsohn, Oñate and del Pin, 2004) in order to simulate thermo-mechanical Fluid-Structure (FS) interactions involving free surface flows and large deformations of the solid. The coupling is performed by transferring nodal information (such as the heat flux, the mechanical load, the nodal temperature and the nodal displacement) between the two solvers, under the form of Neumann-Dirichlet boundary conditions imposed at the fluid-structure interface. When the solid and fluid meshes are non-matching at the interface, an interpolation technique is required to transfer the nodal data from one solver to another. In particular, the Radial Basis Function (RBF) interpolation is considered for its flexibility and its efficiency (Lacroix et al. 2024).

The use of different solvers aims at combining their individual potentials for simulating complex physics (such as phase change and free-surface flows on the fluid side, or rupture and contact mechanics on the solid side) while exchanging a minimum amount of information between the two solvers to achieve the coupling (Cerquaglia et al. 2019). The presentation starts with a brief introduction to the basic principles of the PFEM and the Neumann-Dirichlet partitioned coupling, followed by a discussion regarding the mesh-interpolation technique. Notably, the interpolation step and the detection of the FS interface is challenging when the boundaries of the fluid and of the solid evolve in their topology due to large deformations, rupture of finite elements or local mesh refinement. Finally, our presentation includes some examples of applications of the FPEM in friction melt bonding, water-jet cutting or frictional contact between debris in a pipe.

TOPOLOGY OPTIMIZATION FOR THE DESIGN OF MANUFACTURABLE PIEZOELECTRIC ENERGY HARVESTERS USING DUAL-MMC METHOD

Qi Lai[1], Weisheng Zhang[1], Xu Guo[1] and Sung-Kie Youn[2]*

[1]*Dalian University of Technology*
[2]*Korea Advanced Institute of Science and Technology*

ABSTRACT

A new topology optimization scheme for the manufacturable piezoelectric energy harvesters (PEHs) are proposed. Most of the existing topology optimization schemes for the design for PEHs are difficult to cope with manufacturing constraints producing design results that pose serious challenges for the local poling of the piezoelectric materials. In this work, dual-Moving Morphable Component (dual-MMC) scheme for explicit topology optimization for the design of PEHs is presented. In dual-MMC scheme, two independent sets of MMC are employed to describe the structural topology of the PEH and polarization profile in piezoelectric material in an explicit manner. With the use of the scheme, the shape of electrodes and the opposite polarization directions in the local poling process can be effectively treated as a constraint making the realization of the PEH an easy task. Several examples for the design of cantilever-type PEH are provided to demonstrate the effectiveness of the proposed approach. Furthermore, a designed PEH is actually manufactured to demonstrate of the production process.

AN UPDATED LAGRANGIAN PARTICLE HYDRODYNAMICS (ULPH) - NON-ORDINARY STATE-BASED PERIDYNAMICS COUPLING APPROACH FOR MODELING FLUID-STRUCTURE INTERACTION PROBLEMS

Xin Lai[*1], Zhen Wang[1], Shaofan Li[2], Junsong Xiong[1], Lisheng Liu[1], Xiang Liu[1] and Jun Sun[1]*

[1]*Wuhan University of Technology*
[2]*University of California, Berkeley*

ABSTRACT

In order to solve the fluid-structure interaction problem of Newtonian fluid, a fluid-structure interaction approach is proposed based on Non-ordinary State-based Peridynamics (NOSB-PD) and Updated Lagrangian particle Hydrodynamics (ULPH), to simulate the fluid-structure interaction problem in which large geometric deformation and material failure are considered. In the coupled framework, the NOSB-PD theory is used to describe the deformation and fracture of the solid material structure. ULPH is applied to describe the flow of Newtonian fluids due to its advantages in computational accuracy. The framework effectively utilizes the advantages of NOSB-PD theory for solving discontinuous problems and ULPH theory for solving fluid problems and has good computational stability and robustness. To deal with the interface of fluid structure, a fluid-structure coupling algorithm using pressure as the transmission medium is established. The dynamic model of solid structure and the PD-ULPH fluid-structure interaction model involving large deformation are verified by several numerical validations, which are in good agreement with the analytical solution, the available experimental data and other numerical results, that demonstrates the accuracy and effectiveness of the proposed method in solving the fluid-structure interaction problem. Overall, the fluid-structure interaction model based on ULPH and NOSB-PD established in this paper provides a new idea for the numerical solution of fluid-structure interaction and a promising approach for engineering design and experimental prediction.

ADVANCING GRANULAR MATERIAL ANALYSIS: NEURAL NETWORK-DRIVEN REPRESENTATION AND COMPUTATIONAL PARTICLE MECHANICS VIA SIGNED DISTANCE FIELDS

Zhengshou Lai[*12] and Linchong Huang[12]*

[1]*Sun Yat-sen University*
[2]*State Key Laboratory*

ABSTRACT

We introduce a novel approach, the Neural Network-Encoded Signed Distance Field (NetSDF), for the representation of shapes and computational particle mechanics in granular materials. Our method utilizes a neural network to learn and depict a Signed Distance Field (SDF), which defines a mapping from a point to a signed distance. Specifically, the neural network takes point coordinates and a latent code representing a single shape as inputs, generating the signed distance from the point to the particle surface. The sign distinguishes between the interior and exterior of a particle, making the zeroth isosurface of the SDF an accurate representation of the particle surface. Upon training the NetSDF with a designated set of particle samples, it can effectively represent an entire class of particles exhibiting the characteristic morphology of the granular material. Our results demonstrate the NetSDF's proficiency in accurately representing irregular-shaped particles and generating virtual particles within the same class. Moreover, the NetSDF seamlessly integrates with the SDF-based discrete element method (Lai et al., 2022, Computational Mechanics), showcasing notable advantages in terms of memory consumption and computational efficiency.

MODELING OF AN OBLIQUE INCIDENT P-WAVE WITHIN A WATER SATURATED SOIL WITH THE WAVE BASED METHOD

Mirjam Lainer[*1] and Gerhard Müller*[1]

[1]*Technical University of Munich*

ABSTRACT

Due to irregularities at the surface of a soil, oblique incident wave fronts may cause amplifications of displacements and stresses. To model these for a water saturated soil in the 2D case, it is necessary to consider two irrotational potentials (1st and 2nd P-wave) and one solenoidal potential (S-wave). The Wave Based Method (WBM) permits to model poroelastic soil for a harmonic loading efficiently, which has already been shown for a surface loading [1]. The following contribution focusses on the modeling of an incoming 1st P-wave, which excites a poroelastic halfspace with a trapezoidal canyon.

Amongst other advantages of the WBM, this numerical method is chosen as it needs significantly less degrees of freedom than a finite element approach to model a boundary value problem. This saves computational time, especially for the approximation of an infinite poroelastic soil medium.

In this contribution, a coupling approach between the WBM and an oblique incident 1st P-wave is presented. The approach is used to model a poroelastic halfspace with an empty canyon. The system’s response is compared with a reference solution from literature. Moreover, a second coupling approach is introduced to permit the modeling of a filled canyon. In the special case of a canyon filled with the material of the surrounding soil, the simulation results are compared with the underlying analytical solution.

ON THE DESIGN OF CONFORMAL COOLING CHANNEL THROUGH TURBULENT FLOW TOPOLOGY OPTIMIZATION

Marc-Etienne Lamarche-Gagnon[*1], Vincent Raymond[1], Francis Lacombe[1] and Florin Ilinca[1]*

[1]*National Research Council Canada*

ABSTRACT

Research on improving the efficiency of heat exchangers has been a longstanding focus, impacting not only the heat exchanger industry but also extending to areas like the mold and die sector. In molding processes, the material cooling time is often the bottleneck when aiming to reduce the part cycle time. Traditional straight-line drilling often leads to suboptimal cooling, particularly in overheating-prone areas. To enhance the tooling's performance and sustainability, the use of conformal cooling channels is a promising solution, especially in processes like aluminum die casting. However, the design of conformal cooling lines in mold inserts can become particularly complex, especially when the cast part involves intricate features such as deep ribs or elongated cores. This work focuses on the application of topology optimization for conformal cooling channel design in a simplified mold geometry. Our framework employs a porosity-based conjugate heat transfer model and considers turbulent flow conditions through the use of a linear eddy viscosity model. The topology optimization algorithm aims at improving the overall cooling performance of the insert, which here translates into a balance between maximizing heat dissipation and ensuring uniform temperature across the cavity surface. The latter is achieved by penalizing the objective function with the surface temperature standard deviation. A projected-perimeter-based additive-manufacturing constraint is further employed to limit the generation of overhangs. One sub-objective of the investigation is to assess the cooling efficiency of the designed channels in comparison to a counterpart optimized for laminar flow conditions. Lastly, to validate the computations, dedicated experiments are conducted using an additively-manufactured prototype based on the optimized cooling channels design.

HYBRID KNOWLEDGE- AND DATA-DRIVEN LIVER SIMULATION ON MULTIPLE SCALES

Lena Lambers[*1], Steffen Gerhäusser[1], Luis Mandl[1] and Tim Ricken[1]*

[1]*University of Stuttgart*

ABSTRACT

The liver, a crucial organ for metabolic functions, exhibits a complex interplay between perfusion and function across multiple scales, from the entire organ to microscopic liver lobules and cellular structures. To unravel the complex hepatic function-perfusion relationship, we present a novel multicomponent, poroelastic multiphase, and multiscale function-perfusion model based on the Theory of Porous Media [1,2].

At the lobular scale, our model incorporates a homogenized tetra-phasic mixture body, representing healthy liver tissue, blood, and growing and depleting solid phases mimicking fat and tumor tissue. On the cellular scale, systems biology models express metabolism as well as metabolite production, utilization, and storage within liver cells. Bridging to the whole-body scale, interactions with organs like the kidney or lung are integrated.

To achieve seamless multiscale coupling, we employ a modular and efficient tri-scale ODE-PDE-ODE coupling approach. This framework enables simulations of critical processes such as detoxification, zonated fat accumulation, and ischemia-reperfusion injury during transplantation [2].

In a step toward clinical applicability, we enhance the model using hybrid knowledge- and data-driven approaches. Realistic liver lobule geometries are derived from histological sections, enhancing the model's accuracy. Additionally, patient-specific data provided by clinical partners enrich the simulations, allowing for individualized analyses of hepatic processes [3].

This integrated approach not only advances our understanding of the hepatic function-perfusion relationship but also provides a powerful tool for predicting and optimizing outcomes in clinical scenarios. In perspective, such a computational model can serve as a clinical decision supporting tool.

A HIERARCHICAL QUADRATURE ELEMENT METHOD FOR TWO- AND THREE-DIMENSIONAL GEOMETRICALLY NONLINEAR ANALYSES

Yingying Lan[*1] and Bo Liu*[1]

[1]*Beihang University*

ABSTRACT

High-order finite element methods have the advantages of fast convergence, insensitiveness to mesh distortion, and convenience to realize adaptive analysis. As a high-order scheme, the hierarchical quadrature element method (HQEM) has already been applied to linear finite element analysis and was found to be with high accuracy and efficiency. Under the constant stiffness assumption, the solution equation of stiffness only needs to be constructed and solved once, without any updating when the structure is deformed, which greatly simplifies the calculation. However, for many practical applications in engineering, such as in aerospace applications, it is unrealistic to assume constant stiffness and must be considered as nonlinear. Geometrically nonlinear analyses require repeated iteration and updating of the stiffness matrix. This paper carries out geometrically nonlinear analyses of two-dimensional (2D) and three-dimensional (3D) configurations using the HQEM under the total Lagrange framework. Based on the Green-Lagrange strain tensor and the second Piola-Kirchhoff stress tensor under the reference configuration, the virtual work equation is constructed and discretized in the space domain. In this work, the quadrilateral element is formulated for analyzing large deformation problems in plane stress, and hexahedral element is developed for analyzing geometrically nonlinear problems in complex spatial three-dimensional structures such as spatial beams and shells. The static analysis problem of unidirectional load increase can be solved by Newton-Raphson method, and the analysis of post-buckling characteristics can be solved by arc-length method. The results of several typical examples obtained by HQEM were firstly compared with the widely verified reference results to verify the correctness and accuracy of HQEM, and then compared with commercial software Abaqus to verify its high efficiency. Compared with low-order schemes, HQEM requires far fewer degrees of freedom when analyzing the same problem. It shows that HQEM has a promising application prospect in geometrically nonlinear analyses.

THE EFFECT OF THE DIAMETER OF THE LAUNCH CANISTER ON THE SHAPE OF THE CAVITATION OF THE VEHICLE

Zhang Lan[1]*

[1]*Harbin Engineering University*

ABSTRACT

In this paper, the effect of the change of the diameter of the launch canister on the shape of the tail cavitation bubble generated during the salvo discharge of the vehicle is studied.
The research method was a combination of experimental and simulation research, and the Monte Carlo algorithm was used to estimate the cavitation area and then analyze.
In terms of experimental research, a launch system with variable diameter of the launch canister was established, and the salvo test was completed with a high-speed camera, and the tail cavitation morphology and motion trajectory images recorded by the twin-engine vehicle in the hydrostatic launch test were first observed, and the flow field interference between the two launchers and their tail cavity morphology were analyzed during the salvo out of the water, and the influence of the diameter of the launch canister on the salvo was analyzed.
In terms of simulation research, a simulation model of the six-degree-of-freedom motion of the salvo water was established, and the underwater salvo simulation with different launcher diameters was carried out accordingly. For the cavitation morphology of the vehicle under different working conditions, the Monte Carlo algorithm is used to estimate the cavitation area, and the variation law of the cavitation of the vehicle with the diameter of the launch canister is given, and the reasons for the area change are analyzed.

A PHASE-FIELD VISCOELASTIC MODEL FOR THE DESCRIPTION OF CRACK PROPAGATION IN ELASTOMERS

Giovanni Lancioni[*1], Jacopo Ciambella[2] and Stortini Nico[1]*

[1]*Polytechnic University of Marche*
[2]*Sapienza University of Rome*

ABSTRACT

The experiments on fracture dynamics in pre-stretched elastomeric membranes proposed in [1] have shown that crack propagation speed is proportional to the amount of pre-stretching applied to the membrane. Additionally, the numerical analysis performed in [2] has shown that the evolution of crack is influenced by the viscous dissipation occurring in the material surrounding the crack tip.
In this talk, a mechanical model for the description of crack evolution in elastomers is proposed, which is able to capture the main features of fracture dynamics observed in experiments [1,2]. A variational theory for finite viscoelasticity is formulated that incorporates phase-field fracture. Besides the viscosity related to strains, a viscous force driving the fracture is included. Consequently, two distinct characteristic times appear into the formulation which influence both the advancement of the crack and the relaxation of strain in the material close to the crack tip.
The rule played by the two characteristic times on the crack evolution is investigated through analytical estimates and numerical simulations.

GENERALIZED HILL-MANDEL-CONDITION FOR DISSIPATIVE POLYCRYSTALLINE FERROIC MATERIALS

Stephan Lange[1] and Andreas Ricoeur*[1]

[1]*University of Kassel*

ABSTRACT

The class of so-called smart materials nowadays ranges from magnetostrictive and shape memory alloys to electro- or magnetoactive polymers and ferroelectrics. As components of smart structures, this class of materials is widely used in different fields of application, e.g. the automotive sector, in the field of medical engineering or in the aerospace technology. Thus, the modeling of the constitutive behavior of smart materials has been in the focus of solid mechanics for more than 30 years. Approaches are basically divided into phenomenological and micromechanical/-physical ones. The problem of many, in particular phenomenological constitutive models, is the comparatively large number of parameters, typically exceeding the number of key quantities available from experiments. Consequently, the fitting does not yield a unique set of parameters, thus allowing for a certain arbitrariness. Micromechanical models, on the other hand, are mostly restricted to switching within a crystallographically defined set of domains of a single grain or consider polycrystalline behavior with unconstrained reorientation of an arbitrary number of domains, suitable to represent changes of macroscopic polarization.

With the so-called condensed method (CM) a different approach has been introduced to model the constitutive behavior of ferroelectrics [1, 2]. The latter involves processes on different scales with a focus on transition from grain to polycrystalline level, considering mechanical and electric intergranular interactions. The aim of this talk is the derivation of a generalized Hill-Mandel-condition for dissipative polycrystalline ferroic materials. In [3] an extension of the classic Hill-condition towards linear piezoelectric materials was introduced. It could be proven that the generalized condition was fulfilled, independent of the control volume, by assuming homogeneous stress or strain and electric field or electric displacement. First, it is reviewed, if the generalized condition holds for nonlinear ferroelectric materials, too. Since this is not the case, it is proven under which conditions the generalized Hill-Mandel-theorem is fulfilled for dissipative polycrystalline ferroelectric material behavior. The findings can be generalized and applied to other ferroic materials and beyond and provide a framework for energetically consistent multiphysical scale transitions.

DAMAGE THRESHOLD AND LIFETIME PREDICTION FOR MULTIAXIAL CYCLIC LOADING

Kai Langenfeld[*1], Rodrigue Desmorat[2], Patrick Kurzeja[1] and Jörn Mosler[1]*

[1]TU Dortmund University
[2]ENS Paris-Saclay

ABSTRACT

The accurate prediction of fatigue-induced failure remains an essential task in engineering. When considering metals subject to low cycles fatigue, failure typically develops in two phases: (i) the nucleation phase and (ii) the coalescence phase. Cracks nucleate at the micro scale due to cyclic plastic deformation, which subsequently coalesce into cracks at the macro scale, cf. [1]. Nowadays, numerous models exist in order to predict the lifetime of components and structures subject to cyclic loading. For instance, critical plane approaches are an efficient tool for the prediction of the lifetime with respect to uniaxial load paths [2]. For multiaxial load cases, however, continuum damage mechanics might be more accurate to consider the interaction between different strain component. Within the respective models, the criterion for damage initiation is of utmost importance.

The probably most frequently damage initiation criterion in the spirit of continuum damage mechanics is based on the stored energy function [1]. An extended initiation criterion has been proposed, which additionally accounts for the plastic strain amplitude to distinguish between different load amplitudes on the local scale [3].

The present talk focuses on the formulation of a new damage initiation criterion suitable for multiaxial fatigue – e.g., cyclic tension and cyclic torsion. As a first step, a constitutive model suitable for ductile material degradation will be extended to account for the different mechanisms associated with multiaxial loading. Subsequently, the damage initiation criterion in [3] will be modified. To be more precise, the inclusion of additional stress/strain invariants allows to explicitly account for the degree of multiaxiality. The capabilities of the extended criterion will be demonstrated by means of fatigue experiments. It will be shown that this extension can indeed capture failure associated with multiaxial
cyclic loading.

MONOLITHIC TWO-LEVEL SCHWARZ PRECONDITIONERS FOR MICRO-MACRO HETEROGENEOUS BLOOD FLOW

Martin Lanser[*1], Axel Klawonn[1] and Natalie Kubicki[1]*

[1]*University of Cologne*

ABSTRACT

In this talk, a machine learning-enhanced multiscale approach for the simulation of blood flow is presented. In the computational framework two different scales are combined: a macroscopic scale that models blood as a non-Newtonian continuous fluid and a mesoscopic scale that captures the behavior of red blood cells within the flow. Specifically, we aim to enhance the mass and momentum balance laws of classical continuum mechanics by using a data-driven approach leveraging data from cell-resolving mesoscopic simulations. Efficient parallel finite element solvers allow for the simulation of blood flow in complex and large geometries. More precisely, monolithic overlapping two-level Schwarz domain decomposition methods with GDSW coarse spaces are used to iteratively solve the macroscopic problem in parallel. Here, the implementations from the solver package FROSch (Fast and Robust Overlapping Schwarz), which is part of Trilinos, are used. The numerical properties as well as the parallel scalability of the solver applied to the micro-heterogeneous non-Newtonian flow problems are discussed.

SPARSE SENSOR DATA-DRIVEN DIGITAL TWIN FOR PREDICTION AND ESTIMATION OF GOVERNING EQUATION OF A PIPE-CONVEYING FLUID USING UNSCENTED KALMAN FILTER

Vincent Laperle[1], Esmaeil Ghorbani[1] and Frederick Gosselin[1]*

[1]*Polytechnique Montréal*

ABSTRACT

This study presents our findings toward building a sparse sensor data-driven digital twin (DT) with various time integration approaches. Specifically, we evaluate the performance of Unscented Kalman filter (UKF) for predicting states and estimating parameters of any underlying system with sparse measured vibration data. The UKF is a two-stage iterative process that comprises a prediction phase and an update phase to identify the governing physical equation of the mechanical system. However, the predictions and estimation of the method can be compromised as the number of unknowns increases. The latter is a bottleneck for identification of complex mechanical system, such as hydroelectric turbines generating units. Furthermore, for data-driven DTs, the accuracy of estimation is correlated to the quality and sampling rate of the sensor data, which is the main concern of this study. To achieve this, we chose several well-known numerical models as case study to assess the performance of the UKF with different sampling rates in a decreasing scheme. Moreover, we change the time integration scheme and evaluate the performance of the UKF using the same sparse data. In this work, Heun's method is used as the main time integration scheme and will be compared to the Euler method, currently used in the classical UKF, as well as to a fourth-order Runge-Kutta (RK4) method. Model verification is accomplished by comparing UKF predictions and estimates with the actual analytical response of the mathematical model. The primary objective of this work is to identify and quantify the threshold between sensor sampling rate and model response accuracy using our UKF. We plan to validate the model in real time on a pipe conveying fluid system. The UKF model will be used to estimate defects and imperfections of the pipe-conveying fluid experiment, as well as estimate the operating conditions based on sensor measurements. The pipe conveying fluid system is an interesting model for digital twin developments because of its relative simplicity combined with the richness of the dynamics it exhibits: buckling and flutter instabilities, flow-added damping, limit-cycle oscillations, period doubling, chaotic motion, etc. Through this laboratory scale demonstration of a digital twin, we seek to demonstrate tools that could be adapted to full-scale hydroelectric power generating units.

VARIATIONAL PHASE-FIELD FRACTURE WITH CONTROLLED NUCLEATION

Christopher Larsen[*1]*

[1]*Worcester Polytechnic Institute*

ABSTRACT

We briefly review the Gamma-convergence of phase-field fracture to Griffith fracture, and describe how softening and nucleation occur when implementing phase-field models. An example is given of how this softening and nucleation can be completely stopped, while preserving crack growth and Gamma - convergence (crack growth can also be stopped). We then show how nucleation can locally be turned back on, based on any criterion, such as a stress threshold. Again, all modifications preserve Gamma-convergence, and they can be applied to static, quasi-static, and dynamic models. Additionally, we describe why these modifications can be expected to improve the convergence of phase-field models.

WEAK AND STRONG STABILISATION OF CUT FINITE ELEMENT METHODS

Erik Burman[1], Mats G Larson[2] and Peter Hansbo[3]*

[1]University College London
[2]Umeå University
[3]Jönköping University

ABSTRACT

Cut finite element methods are based on embedding a computational domain into a background mesh that is not required to match the boundary. This leads to so-called cut elements at the boundary. By adding stabilization terms, we can control the variation of the discrete functions close to the boundary. This allows us to prove stability, condition number estimates, and optimal order a priori error estimates. Alternatively, we may use a discrete extension operator and solve the problem in a subspace of the finite element space where the unstable degrees of freedom are eliminated to retain optimal order approximation bounds. These two approaches, the first weak and the second strong, have the same goal: stabilizing the method, but they appear very different at first glance.

In this talk, we show that the definition of stabilization terms, added to the weak statement, may be generalized in two ways: (1) The stabilized quantity may be some functional of the discrete function, for instance, finite element degrees freedom. This allows us to stabilize the unstable modes more precisely than standard approaches, which may be considered element-based. (2) The choice of elements that are connected. Typically, face neighbors or connected patches are used, but we may stabilize by connecting elements intersecting the boundary to an element within a distance proportional to the mesh parameter. We show that the generalized stabilization form fits into the standard abstract requirements, and as a consequence, we obtain stable and optimal order convergent methods for second-order elliptic problems.

We also show that for a robust design of the ghost penalty, one may let the stabilization parameter tend to infinity without introducing locking. The limit corresponds to strong enforcement of certain algebraic constraints, identical to constraints implemented in specific extension operator frameworks. This illustrates the very close connection between stabilization and extension approaches.

REDUCED ORDER MODELING WITH ERROR CONTROL FOR APPLICATIONS IN COMPUTATIONAL HOMOGENIZATION OF POLY-CRYSTALS

Rituesh Bharali[1], Fredrik Larsson[*1], Kenneth Runesson[1] and Ralf Jänicke[2]*

[1]Chalmers University of Technology
[2]Technische Universität Braunschweig

ABSTRACT

Computational homogenization for finite element analyses is a multiscale framework, where the microscale features are accounted for in the (homogenized) macroscopic problem through explicit modeling of the underlying microscale on Representative Volume Elements (RVEs). More specifically, the macroscopic response is defined through the pertinent boundary value problem of an RVE. In a so-called “finite element squared” (FE2) procedure, this introduces an RVE problem associated with each macroscopic quadrature point. Such an approach becomes prohibitively expensive when the macroscale problems represent engineering structures/components. Reduced Order Modeling (ROM) is associated with the aim to reduce the computational cost when a similar problem is solved numerous times for slightly different data. The solution to the RVE-problems, where we typically seek the effective response for large variety of different macroscopic kinematic histories, is a perfect example of a problem suitable for ROM.

In this contribution, we consider the applications of polycrystals, where each grain is modeled using (gradient enhanced) crystal plasticity. A reduced order basis is constructed, using Proper Orthogonal Decomposition (POD), in terms of the dissipative stresses associated with the inelastic slip fields. Based on linear kinematics, the corresponding displacement and slip fields associated with the basis can be computed at an offline stage. Ultimately, the online evaluation of the macroscopic stress-strain response is obtained by use of a Galerkin projection method for the adopted basis. For the reduced order model, controlling the error in terms of the effective macroscopic response is imperative. To this end, we investigate a few different error estimators of varying computational cost. The accuracy and computational efficiency of the proposed ROM, as well as the performance of the different error estimators are investigated for a few basic numerical examples.

WALL-MODELED LARGE EDDY SIMULATION OF SMOOTH-BODY SEPARATION: RESULTS OF A CFD VERIFICATION WORKSHOP

Johan Larsson[*1], Ivan Bermejo-Moreno[2] and Christoph Brehm[1]*

[1]*University of Maryland*
[2]*University of Southern California*

ABSTRACT

The talk will summarize the lessons learnt from the authors' participation in the AIAA High Fidelity CFD Verification workshops held in 2022 and 2024, with a focus on the smooth-body separation test case. The test case features a fully developed incoming turbulent boundary layer at a Reynolds number that is sufficiently large to warrant the use of a wall-model, and a smooth backward-facing ramp that causes a large separation bubble. Participants had to submit blind predictions for this case, with an emphasis on the convergence of the results during grid-refinement.

The results show how elusive grid convergence can be for this type of problem, with most solutions failing to show convergence even on grids with many hundred million elements. The issue of of converging averages and the computational demands it imposes on separated flows will also be discussed, with implications on verification. The talk will also discuss several numerical experiments aimed at elucidating which simulation parameters most strongly affect the results, including the incoming turbulent boundary layer, the spanwise domain width, details of the numerical method, and details of the computational grid. In addition, experiments with residual evaluation as a means to judge where in space errors are introduced will be discussed.

MODELLING ROCK CUTTING TRANSPORT BY A COUPLED BONDED PARTICLE MODEL AND CFD

Simon Larsson[1] and Albin Wessling*[1]

[1]*Luleå University of Technology*

ABSTRACT

To understand the fracture of rock materials and the subsequent transport of rock cuttings by fluid is of fundamental importance for efficient rock drilling. The industrial incentives are many. For instance, an estimated 50 % of the total cost per installed megawatt geothermal energy is associated with drilling and well construction [1]. Multiphysics simulations provide a means to improve knowledge and understanding of rock drilling, including rock fracture, transport of cuttings and wear on drilling equipment.

In the present study, a Multiphysics approach for modelling rock drilling and transport of cuttings by fluid is proposed. The rock material is modelled by a recently developed statistical bonded particle model (BPM) [2,3]. In the BPM, rock heterogeneities are included by using statistically distributed grain sizes and shapes as well as Weibull distributed mechanical properties. The drilling fluid is modelled by computational fluid dynamics (CFD) based on the particle finite element method. The transport of cuttings during rock drilling is modelled by coupling the BPM and CFD models. Coupling of the models is realized by a loose (or weak) two-way coupling strategy.

By the coupled BPM-CFD models, the complex dynamics inside the drill hole are predicted. The model is used to quantify drilling rate of penetration, mass of transported cuttings and fluid flow in the drill hole.

COMPETITION OF CRAZING AND SHEAR YIELDING UNDER CYCLIC MODE I LOADING USING A MOLECULAR DYNAMICS INFORMED CONTINUUM MICROMECHANICAL CRAZING MODEL

Tobias Laschuetza[*1], Joerg Rottler[2] and Thomas Seelig[1]*

[1]*Karlsruhe Institute of Technology*
[2]*University of British Columbia*

ABSTRACT

Shear yielding and crazing are the key deformation and damage mechanisms which govern the inelastic behaviour of glassy polymers. The present work studies the interaction of both mechanisms during crack growth under cyclic mode I loading. To this end and as primary aim of this work, a continuum micromechanical crazing model for cyclic loading conditions has been developed [1]. To further elucidate the crazing process on the molecular level, molecular dynamics simulations of a carefully equilibrated coarse-grained bead-spring model are used to study the fibrillation process and the response of craze fibrils under cyclic loading. This is in contrast to previous work, which focused solely on monotonic loading conditions (e.g. [2]). With insights from these simulations, the continuum model is subsequently refined, resulting in a more realistic molecular dynamics informed constitutive model for crazing. This model is then applied along the ligament of a mode I boundary value problem to investigate craze and crack propagation in glassy polymers. The deformation in the glassy bulk material is described by the well-established constitutive model by Boyce and co-workers (e.g. [3]) which accommodates shear yielding. This approach allows to effectively model and study the interplay between crazing and shear yielding under cyclic loading conditions.

DEGRADATION OF GLASS FRP IN MARINE ENVIRONMENT

Denvid Lau[*1] and Xing-Quan Wang*[1]

[1]*City University of Hong Kong*

ABSTRACT

Glass fiber reinforced polymer (FRP) has been widely utilized in marine applications due to its excellent performance in the application of seawater sea-sand concrete. Although many experimental investigations have been carried out to determine the characteristics of the glass FRP under various experiments, in-depth insight into molecular-scale processes involving interfacial interactions between fiber and matrix cannot be provided. Therefore, modeling under atomistic and mesoscale is necessary so as to understand the origin of material degradation initiated from the material interface. The multiscale modeling framework that includes both molecular dynamics simulations and coarse-grained (CG) models beyond the capacity of atomistic simulations has been put forward. In this work, the degradation mechanism of glass FRP in hygrothermal and chloride environments is indicated through the changes in material structure, decreased adhesion energy, reduced interfacial stress, and the weakened intermolecular interactions with the consideration of hydration bond. The performance of different degraded polymer matrices is also compared. The work provides fundamental information on interfacial deterioration in glass FRP, which can be further extended to the research on deterioration of other engineering composite materials and the development of new nanocomposites.

GISMO & WATERLILY ADAPTERS FOR THE PRECICE COUPLING LIBRARY

Jingya Li[1], Hugo M. Verhelst[12] and Marin Lauber[1]*

[1]Delft University of Technology
[2]Università degli Studi di Firenze

ABSTRACT

Fluid-structure interaction occurs in a wide range of fields of science and engineering, from biomedical to aerospace. It covers problems such as aortic valves and bristled wings. The potentially large-scale separation between the two sub-problems makes it difficult to derive general monolithic approaches. Partitioned approaches avoid this issue by allowing problem-specific solvers for each sub-problem and coupling them through the boundary conditions. In recent years, the preCICE library [1] has greatly improved the possible solver combination to tackle these problems.
Here, we present two new adapters for the preCICE coupling library that allow the simulation of strongly coupled, geometrically non-linear, fluid-structure interaction problems. We follow the standard Dirichlet-Neumann approach; we coupled both solvers through the interracial displacements and stresses. Using the direct mesh access of preCICE, we couple a finite-volume immersed-boundary fluid solver, WaterLily.jl [2], to an iso-geometric structural solver G+Smo. Using immersed boundary and iso-geometric analysis allows for arbitrary interface displacements within the fluid solver. Nurbs-based representation of the structure within the fluid solver allows for analytical distance function and normal vector. The iso-geometric approach for the structural problem significantly improves basis function continuity and reduced element count. This ultimately results in a fast and accurate coupling approach.
We demonstrate the capabilities of the adapters by performing 2D and 3D simulations of complex fluid-structure interaction systems. We focus on membrane and plate/shell structures with a perpendicular flap, inverted flag, and flapping filaments. We also demonstrate that the coupled solver is agnostic to the structural model (Euler-Bernoulli beam, Kirchhoff-Love shell). Finally, we discuss the GPU acceleration of the fluid solver and the effects on the resulting coupled solver.

SIMPLIFIED MAINTENANCE ACTIONS FOR INDUSTRIAL DECISION SUPPORT SYSTEMS

Alexander A. Laurence[*1] and Keiro Muro*[1]

[1]*Hitachi LTD*

ABSTRACT

Introduction: Decision support systems (DSS) used in industrial predictive maintenance encounter the challenge of distinguishing relevant from irrelevant information for user recommendations. This challenge becomes more pronounced as the number of available maintenance actions increases, leading to a dense decision network of possible actions. To reduce the number of decisions, we can remove similar decisions from being used in a DSS, leaving only distinct decisions.

Methods: We define similarity of maintenance decisions as a function of cost of taking a repair action vs the result of taking a repair action. Using a sample case in Nuclear Plant maintenance, we set Time To Repair (TTL) as the cost of taking a repair action and Remaining Useful Life (RUL) in years as the result of taking a repair action. We generated 4 datasets of random repair actions that conforms to a monotonic relationship between TTL and RUL. In this sample case, we used SCARLET (Similarity-based Clustering and Reduction of Action pLans for Effective Decision SupporT), a novel algorithm, to reduce the number of redundant maintenance actions by eliminating the most divergent actions within similar pairs. SCARLET also avoids removing action pairs that are exist on opposite sides of the threshold border. This process iterates until no redundant actions remain.

Results: When reducing actions to a manageable size (n<100), our findings revealed that SCARLET achieved between 2% to 15% error across datasets of varying sizes. In the accuracy test, we confirmed that SCARLET’s ability to classify redundant actions against domain knowledge of cost (TTR=2) and result (RUL=1.08) thresholds was high, achieving an AUC of >80% compared to other rival methods (<80%).

Discussion: SCARLET's unique approach of leveraging similarity-based clustering enables it to identify and eliminate redundant information against domain-knowledge, resulting in a more compact and representative dataset which considers of cost and result thresholds. Through the result, we see that in borderline cases where actions exist within cost and result thresholds, SCARLET is the most effective approach to take as the algorithm handles cost and result thresholding.

Conclusion: By avoiding the incorrect removal of non-redundant data, SCARLET, compared to other conventional techniques, has a more domain driven reduction approach in special borderline cases where actions exist close to cost and result threshold borders. The result of this study is important for the development of human understandable, and accurate decision-making systems by removing unnecessary decisional nodes in a dense network.

CONSTRAINED PARAMETRIC GLOBAL OPTIMIZATION OF A VIBRATION PROBLEM WITH NON-LINEAR INTERFACES

Luc Laurent[*1], Quentin Ragueneau[12], Antoine Legay[1], Thomas Larroque[2] and Romain Crambuer[2]*

[1]LMSSC, Conservatoire national des arts et métiers
[2]INGELIANCE Technologies

ABSTRACT

The design of complex structures is a challenging task, especially for structures with non-linear interfaces. In this context, the use of advanced numerical methods is required to accurately predict the behavior of the structure. However, these methods are often computationally expen sive, which makes the global optimization of such structures difficult especially when classical optimizers are used. In this work, the considered vibration mechanical problem, which remains on the design of an anti-tipping device for a gantry crane [1], is solved using Craig-Bampton and a Harmonic Balance Method [2] improved with Alternating Frequency-Time approach [3] and continuation procedures. This strategy allows to compute the response along a frequency range and for a set of design parameters which govern, here, the non-linear behavior at the inter- faces (stiffnesses and gaps at contact area). Although the approach provides accurate solutions with a significant time reduction in comparison with other approaches (time iterative solver for instance), this method remains computationally expensive and not suitable for constrained global optimization. Therefore, a constrained Bayesian optimization is used to find the optimal design of the structure. Based on Gaussian Process, this method consists in the construction of initial surrogate models for the objective and constraint functions which are iteratively infilled with new responses in order to efficiently locate the optimum. For this purpose, an acquisition function called Constrained Expected Improvement is used. The proposed strategy is applied on the gantry crane problem and it is especially analyzed for many number of initial sample points. It shows good performance to identify optimal design with a limited number of solver calls.

DAMAGE IN CONTINUUM-KINEMATICS-INSPIRED PERIDYNAMICS

Marie Laurien[*1], Ali Javili[2] and Paul Steinmann[1]*

[1]*Friedrich-Alexander-Universität Erlangen-Nürnberg*
[2]*Bilkent University*

ABSTRACT

Peridynamics (PD) is a nonlocal continuum formulation that was introduced by Silling in 2000 [1] and has become more and more established in the field of fracture and damage mechanics. The PD balance equations are governed by an integral term which computes the interactions between a continuum point and its neighboring points within a finite distance. Modeling damage therefore no longer leads to singularities as partial differential equations are replaced by integral terms. The basic version of PD, i.e., bond-based PD, is restricted to a fixed Poisson ratio, since it lacks the consideration of volume dilation. Recently, Javili et al. [2] have overcome this limitation by transferring the kinematic measures of CCM to a nonlocal setting, resulting in a geometrically exact theory, called continuum-kinematics-inspired peridynamics (CPD). There, in addition to pair-wise interactions, multi-neighbor interactions characterize the interplay of points. In this manner, it is possible to capture changes in length through one-neighbor interactions, changes in area through two-neighbor interactions and changes in volume through three-neighbor-interactions. The novelty of this work is the introduction of damage into the formulation of CPD. For each type of interaction, we introduce a separate damage variable, ranging from 0 for an intact interaction to 1 for a fully damaged interaction. The damage variables are obtained by evaluating a damage function at the current length strain, area strain and volume strain, respectively. An interaction is considered fully damaged once a critical threshold is reached. The choice of the damage function allows to model not only abrupt damage but also progressive damage. The latter is achieved by modeling a gradual decrease of the interaction forces until they are completely deactivated. Examples are linear, exponential and power law decreases of the interaction forces (see [3]). In this work, the proposed damage model is presented in detail and investigated in a series of numerical examples.

IMPACT SIMULATIONS OF CONVENTIONAL STRENGTH CONCRETE USING EXPLICIT POLYHEDRAL AGGREGATE MORPHOLOGIES

William Lawrimore[*1] and Andrew Bowman*[1]

[1]*U.S. Army Engineer Research and Development Center*

ABSTRACT

Conventional strength concrete featuring coarse aggregate undergoes complex deformation and damage mechanisms when subjected to dynamic loads. These mechanisms are difficult to capture in a simulation with a homogenous morphology or in a simulation with heterogenous morphology using only elementary geometry. Historically, embedding coarse aggregate or other types of inclusions in laboratory-scale simulations has not been possible due to the resolution of the resulting finite element (FE) meshes. Improvements in computational power coupled with more advanced meshing techniques have made simulating complex morphologies realistic at laboratory scale. This work features simulations that better capture the dynamic solid-state physics of impacts by including polyhedral aggregate shapes within the concrete mesh. These polyhedral aggregate shapes were inscribed within nonintersecting spheres which were generated with ‘ParticlePack’, a piece of software included within the FE software suite ALE3D[1] from Lawrence Livermore National Laboratory. FE meshes were built using a “shape-in” method included in ALE3D. Individual aggregate geometries were stored as ‘STL’ files and imported, or “shaped’, into a homogeneous hexahedral mesh. Impact targets were 16 inches in diameter and 4 inches thick to match physical experiments. Targets were struck with 0.5 inch diameter stainless steel ball bearings over a range of impact velocities. Residual velocities were extracted from simulation data and compared to those from physical experiments for validation. Simulations were also validated visually to compare impact cratering and damage.

PARALLEL NODE-TO-SURFACE STRATEGY FOR 3D CONTACT MECHANICS PROBLEMS WITH ADAPTIVE MESH REFINEMENT

Alexandre Epalle[12], Isabelle Ramiere[1], Guillaume Latu[1] and Frédéric Lebon[2]*

[1]CEA, DES, IRESNE, DEC, SESC
[2]Aix-Marseille Université, CNRS, Centrale Marseille, LMA

ABSTRACT

As contact mechanics problems are locally highly non-linear and non-smooth, their fast and accurate numerical simulation is computationally challenging. Efficient numerical solutions to such problems increasingly rely on high-performance computing (HPC). To optimize the number of degrees of freedom, a relevant mesh discretization is also often sought via adaptive mesh refinement (AMR) strategies. Even so, combining the parallelization of AMR methods with contact mechanics remains a challenging task, current developments on contact numerical solutions focusing either on new non-parallelized adaptive mesh refinement methods or on parallelization ones for uniformly refined meshes.

In previous work, we introduced a generic and parallel node-to-node strategy for solving 3D contact mechanics problems with AMR on hexahedral elements [1]. In this contribution, this strategy is extended to node-to-surface pairing, allowing a wider range of problems to be considered. The main challenge of this extension concerns a mesh partitioning that enables the proposed scalable contact algorithm to be applied effectively. Here, the mesh partitioning is defined via overlapping domain decompositions strategies of the contact interface discretization to guarantee the contact paired nodes to be on the same processes. The contact problem is treated with a penalization technique and is solved thanks to an iterative solver. Once the contact loop converged, the AMR strategy is locally applied and the mesh decomposition is rebalanced with the previously discussed partitioning contact constraints. For the AMR process, a non-conforming h-adaptive mesh refinement solution is considered. This method has already shown high scalability in other contexts [2]. Super-parametric elements are used to preserve the shape of hierarchically refined geometries, even for first-order finite element solutions. In order to carry out simulations, we place ourselves in the MFEM software [2] environment, an open-source finite elements method library. In MFEM, the currently implemented h-adaptive method is enriched with our own estimate-mark-refine approach based on recent works [3].

The proposed AMR-HPC strategy will be confronted with academic and industrial elastostatics test cases.

A HYBRID LEVEL-SET/DENSITY TOPOLOGY OPTIMISATION FOR MORPHING STRUCTURES WITH LATTICES AND STRESS CONSTRAINTS IN A LARGE DEFORMATION SETTING WITH MORFEO

Julien Leclerc[*1], Pierre-Alexandre Beaufort[1] and Erin Kuci[1]*

[1]*Cenaero*

ABSTRACT

Coupled to the additive manufacturing, topological optimization helps engineers to imagine efficient and innovative possibilities of design. In particular, it enhances their capacity to create morphing structures and compliant mechanisms.

In this context, this work presents a generic topology optimisation framework applied to morphing structures. This framework is implemented in our in-house finite element software Morfeo. To obtain high performance designs, the optimization relies on several design variables, enabling the introduction of lattices [1]. The topology of the unit cell at the mesoscale is assumed fixed and parametrised by dedicated design variables. It is then represented at the macroscale by an equivalent material behaviour obtained by homogenization.

The optimization problem is modelled thanks to a hybrid method using density-based and level-set XFEM approaches [2]. Thereby, the level-set method enables an accurate surface and stress representation. Moreover, the density-based approach allows holes nucleation during the optimization. Besides, the optimization involves stress constraints under a large deformation setting. Indeed, stress constraints are essential to ensure the mechanical integrity of the designed structure. Moreover, an hyperelastic material model is used to include geometrical non-linearities for more flexibility and better performances in the design.

This framework is applied on morphing wing trailing edges in 2D and other examples in 3D. Taking advantage of the flexibility of our optimization solver, the performances of the resulting structures are compared in terms of model hypotheses and material models (isotropic or lattices).

THERMAL CONDUCTIVITY CORRECTION IN W, AND EFFECTS ON DAMAGE CASCADES FROM ATOMISTIC CALCULATIONS

Younggak Shin[1] and Byeongchan Lee[1]*

[1]Kyung Hee University

ABSTRACT

Atomistic calculations have been widely used to understand the material properties at the nanometer scale, and useful thanks to the all-atom microstructures often in polycrystalline materials. However, the thermal conductivity of a metal predicted from atomistic calculations is typically around 10% of the experimental measurements as only the phonon contribution counts.

In this talk, we introduce an electron-temperature model to be used with interatomic potentials, and show atomistic calculations can still be useful in predicting the thermal conductivity of metals that play a role in fast cooling. As an example, we present irradiation damages in tungsten used as a divertor in fusion reactors, and show how the thermal conductivity correction changes the damage profile.

Our electron-temperature model is an extension to the concept of two-temperature model, and enables both ion-thermal and electron-thermal contributions to the thermal conductivity. The resulting thermal conductivity of tungsten predicted from atomistic calculations is in good agreement with experimental measurements over the wide range of ionic temperature. Here, the energy exchange between ions and electrons is mediated with electron-phonon coupling coefficients, which is made electron-temperature depending in this work. The challenges and the future outlook on electron-temperature models are discussed.

ABSTRACT

The demand for improving the precision of medical image-based blood flow simulation has grown significantly over the decades, aiming to diagnose the severity of cardiovascular diseases, predict treatment outcomes, and monitor the cardiovascular system simultaneously. The accuracy of blood flow simulations, however, heavily depends on boundary conditions. Murray’s law or measurement data are conventionally utilized as boundary conditions for the cardiovascular system. Murray's law, however, is known to be highly sensitive to the number and caliber of blood vessels and there is challenge in accurately segmenting small vessels using medical image data. In this study, we develop a physiologic model based on a supply-demand relationship between arteries and tissues and utilize the model as a boundary condition for blood flow simulations of the cerebrovascular system. The geometry of blood vessels and tissues is extracted from MR angiography and T1 MRI, and perfusion territory of each blood vessel and flow rate required for the perfusion territory is estimated using Voronoi tessellation. We validate estimated flows in major arteries against measurements via transcranial color-coded Doppler. Further, we conduct three-dimensional blood flow simulation and cerebral perfusion simulation [1] of healthy and diseased patients using this boundary condition. We compare our results against those obtained using Murray’s law. Additionally, we examine the sensitivity of the proposed boundary condition strategy to the segmented geometry. This study will present a new, robust physiological patient-specific boundary condition strategy for cerebrovascular blood flow simulations.

A NONOVERLAPPING DOMAIN DECOMPOSITION METHOD FOR EXTREME LEARNING MACHINES SOLVING ELLIPTIC PARTIAL DIFFERENTIAL EQUATIONS

Chang-Ock Lee[*1], Youngkyu Lee[2] and Byungeun Ryoo[1]*

[1]*KAIST*
[2]*Brown University*

ABSTRACT

Extreme learning machine (ELM) is a methodology to solve partial differential equations (PDEs) using a single hidden layer feed-forward neural network. It pre-sets the weight/bias coefficients in the hidden layer with random values and fixes them throughout the computation, and uses a linear least squares method for training the parameters of the output layer of the neural network. It has been known much faster than the Physics informed neural networks. However, classical ELM requires to solve a least squares system of large size to get the high level of representation for the solution so that it comes with a computational burden. In this paper, we propose a nonoverlapping domain decomposition method (DDM) for ELMs, that not only reduces the training time of ELMs, but is also suitable for parallel computation. In numerical analysis, DDMs have been widely studied to reduce the time to obtain finite element solutions for elliptic PDEs through parallel computation. Among these approaches, the nonoverlapping DDMs are attracting most attention. Motivated by this method, we introduce local neural networks which are valid only at corresponding subdomains and an auxiliary variable at the interface. Then, we construct a system on the variable and the parameters of local neural networks. A Schur complement system on interface can be derived by eliminating the parameters of the output layer. After that, the auxiliary variable is directly obtained by solving the reduced system and then the parameters for each local neural network are solved in parallel. Numerical results that verify the acceleration performance of the proposed method with respect to the number of subdomains are presented.

DEVELOPMENT OF HIGH-ORDER MULTI-SUB-STEP IMPLICIT TIME INTEGRATION METHODS

Chanju Lee[*1] and Gunwoo Noh*[1]

[1]*Korea University*

ABSTRACT

This study aims to develop a higher-order implicit multi-sub-step time integration method. The study demonstrates that the proposed s-sub-step schemes, with $2 \leq s \leq 5$, attain (s+1)th-order accuracy while simultaneously ensuring unconditional stability and dissipation control. The proposed composite s-sub-step method does not require acceleration vectors during calculation; instead, these vectors are obtained using finite difference approximation (FDA). We present the outcomes of linear and nonlinear example solutions to validate our theoretical results. These results indicate that the proposed multi-sub-step technique, in comparison to conventional methods, can yield more accurate solutions.

EXPLORATION OF CHEMICAL SPACE FOR STABLE SOLID-STATE ELECTROLYTES WITH HIGH ION CONDUCTIVITY

Chi-Hsuan Lee[1] and Chun-Wei Pao*[1]

[1]*Academia Sinica*

ABSTRACT

Lithium halides Li3MX6 (M = trivalent metals; X = Cl, Br) have emerged as promising solid electrolytes for high-capacity, all-solid-state lithium-ion batteries, acclaimed for their outstanding electrochemical stability and high ionic conductivity. Despite of their potential, the correlation between alloy compositions and resulting material properties has not been fully elucidated. This study aims to bridge this gap by proposing a design strategy for lithium halides, targeting optimized performance in material stability and ion conductivity for advanced high-voltage Li-ion batteries. We systematically investigate crystal structures, phase behavior, electronic properties, and ionic conductivities through extensive density functional theory (DFT) and ab-initio molecular dynamics simulations, incorporated by on-the-fly machine learning energy/atomic force predictions to speed up chemical space exploration. Our analysis indicates significant impacts from varying M:X ratios on structural stability. Mixed halogen anions, Cl and Br, notably alter the material's structure, while different trivalent metal substitutions lead to distorted lattices, affecting Li-ion diffusion activation energy. These findings offer a pathway for the tailored design of lithium halide electrolytes in advanced battery technologies.

NEURAL OPERATOR ACCELERATED DESIGN OF MULTIFUNCTIONAL METAMATERIALS SUBJECT TO HETEROGENEOUS FIELDS

Doksoo Lee[*1], Lu Zhang[2], Yue Yu[2] and Wei Chen[1]*

[1]*Northwestern University*
[2]*Lehigh University*

ABSTRACT

Data-driven metamaterials design has offered a compelling route to bring the multiscale architectures to their full potential. In doing so, most prior works resorted to the mapping from a parameterized unit cell geometry to the corresponding homogenized properties, such as Young's moduli and transmission spectra. Skipping raw solution fields, any surrogate obtained with this shortcut based modeling features little generality, resuability, and transparency. To this end, we present a data-driven design framework that can accommodate solutions fields heterogeneously distributed across the system, thus at odds with conventional homogenization assumptions. As a key pillar, we capitalize on implicit Fourier neural operator that serves as a field-to-field surrogate of metamaterial systems subject to heterogeneous fields. Equipped with a gradient-based solution procedure, the proposed framework is demonstrated for the inverse problem on light-by-light plasmonic metasurface, whose electric energy distribution above the array is dynamically programmable via modulation of the incident phase distribution. Within the scope of conventional design approaches, the case study presents grand challenges, primarily (1) drastically varying field distributions with heterogeneous local spikes due to plasmonic resonance and (2) the vast design space, formed jointly by quasi-freeform supercells, incident phase distributions that can be modulated, and multiple on-demand functional states subject to a tradeoff. Tackling all the challenges without simplifications, our framework serves as a design automation tool for metamaterials, beyond the scope of the shortcut based modeling.

A FINITE ELEMENT METHODOLOGY FOR FRETTING WEAR ANALYSIS FOR PRESS-FITTED SHAFTS.

Dong Hyung Lee[*1], Young Sam Ham[1] and Chan Woo Lee[1]*

[1]*Korea Railroad Research Institute*

ABSTRACT

Fretting occurs at the ends of the contact surfaces of press-fitted shafts, such as railway axles, which has a detrimental effect on the fatigue life of the railway axles. Accurately predicting the fretting wear and fretting fatigue life of press-fit shafts is important to prevent derailments and establish appropriate maintenance standards. To predict the fatigue life of press-fitted shafts, quantitative prediction of fretting wear is essential. However, much research is still ongoing because there are many influencing factors on fretting wear, such as changes in friction coefficient, the influence of wear particles, and the selection of an appropriate wear model.

In this study, finite element analysis and numerical wear analysis methods were developed for fretting wear analysis of press-fitted shafts. When a bending load was applied to the press-fitted shaft, the contact pressure and microslip were calculated using finite element analysis. Based on the finite element analysis results, a wear analysis method using the influence coefficient and the matrix inversion method was numerically implemented. Using the developed analysis method, representative wear models including Archard's model and the Dissipated Energy model were applied to predict the fretting wear profile of press-fitted shafts. The analytical results were then compared with experimental results to evaluate the effectiveness of the wear model in fretting wear simulation of press-fit shafts.

DIGITAL TWIN DEVELOPMENT AND UNCERTAINTY QUANTIFICATION FOR THE GS-EPS BIOMASS PLANT IN SOUTH KOREA

Dongjin Lee[*1], Elle Lavichant[2], Hyeonghun Kim[2], Seyeong Lee[1] and Boris Kramer[2]*

[1]*Hanyang University*
[2]*University of California, San Diego*

ABSTRACT

Biomass power plants should become a key component of Korea's domestic energy supply. Advancements in fluidized bed combustion technology used in biomass power plants increase their combustion efficiency while reducing carbon emissions. Determining the design parameters that optimize the efficiency and stability of the combustion process in the presence of significant uncertainties is costly, time-consuming and often only done suboptimally by experienced operational engineers.

In this work, we seek a robust design to improve the fluidized bed combustion efficiency. We develop a digital twin model of the GS-EPS biomass plant in South Korea that includes a reduced-order model and a GPCE-Kriging surrogate model to efficiently represent the combustion process and constraints. We then perform design under uncertainty in a Bayesian framework to find design and process parameters that decrease the combustion variability and increase the combustion efficiency. This method achieves higher combustion efficiency and robustness while requiring training data of less than a hundred combustion simulations.

STRUCTURAL ANALYSIS CONSIDERING ANISOTROPIC CHARACTERISTICS OF FDM 3D PRINTED PARTS

Geung-Hyeon Lee[1], Da-Young Jang[1], Chae-Rim Seon[2], Min-Ho Yoon[2] and Jang-Woo Han[1]*

[1]*Kumoh National Institute of Technology*
[2]*University of Seoul*

ABSTRACT

Recently, the usability of 3D printing technology is continuously increasing in various industrial fields due to its high degree of freedom of shape and applicability to various materials. Among various 3D printing process, FDM 3D printing method which extrudes and stacks semi-molten filaments has relatively good equipment durability and low product production costs, so various studies on the FDM 3D printing technology have been steadily conducted. However, One of the main disadvantages of the FDM 3D printing method is that unexpected anisotropic material properties can be occured in the manufactured part due to the nozzle path, voids and bonding strength between filaments, even though isotropic filaments is used in the manufacturing process.[1] In particular, when short/continous fiber reinforced composite materials are considered in the FDM printing process, the above mentioned anisotropic characteristics can become more evident in the manufactured part. According to the above background, the AM-Structural Coupled analysis was conducted in this study in order to consider the unexpected anisotropic characteristics in the manufactured part which caused by various 3D printing conditions such as nozzle path, and so on.

To this end, this study attempted to analyze the effect of the nozzle path on the mechanical behavior of the manufactured part through the tensile tests on ASTM D638 standard specimens with various nozzle paths. In addition, analytical anisotropic material properties dependent on the nozzle path are derived by using a reverse engineering, provied by DIGIMAT-MX, that derives mean-field homogenized material properties based on tensile test data. Finally, based on the derived anisotropic marerial properties dependent on the nozzle path, AM-Structural Coupled Analysis was performed by linking Digimat MAP/CAE and commercial FE softwares such as Abaqus and Ansys. The validity of the proposed analysis model was verified through the AM-Structural Coupled analysis of the tensile specimen manufactured by various 3D printing conditions.

In the future, this study plan to conduct a comprehensive comparison and analysis of the anisotropic properties considering porosity and bonding strength.

RECENT PROGRESS IN CONDUCTIVE CEMENTITIOUS COMPOSITES FOR EVALUATING VARIOUS DETERIORATION PHENOMENA: AN OVERVIEW

Taegeon Kil[1], Jin-Ho Bae[1], J.S. Kim[1] and H.K. Lee[*1]*

[1]KAIST

ABSTRACT

In recent years, studies have focused on the application of conductive cementitious composites, which incorporate electrically conductive fillers into the cementitious matrix, for evaluating various deterioration phenomena [1]. These composites can be utilized to evaluate the deterioration induced by various external environments (e.g., carbonation, freeze-thaw cycles, chloride ion penetration, and sulfate attack) by examining changes in the electrical properties of the composites [2]. Carbon nanotubes (CNTs) are promising electrically conductive fillers owing to their high aspect ratio and outstanding electrical conductivity. Therefore, a small amount of CNTs can establish electrically conductive pathways in conductive cementitious composites [2,3]. Researchers have developed various conductive cementitious composites incorporating CNTs and have reported that the electrical resistance in the composites increases with exposure time to deterioration [2,3]. This paper provides an overview of recent progress in conductive cementitious composites for evaluating various deterioration phenomena, including the authors' initial work on a machine learning approach to evaluating deterioration in the composites incorporating CNTs [4].

ABSTRACT

Microbial-induced calcium carbonate precipitation (MICCP) is a biochemical process that utilizes the metabolic activities of microorganisms to facilitate the precipitation of calcium carbonate (CaCO3). Recently, research has shown that MICCP has a promising potential to heal concrete cracks. In this paper, we developed a computational uncoupled damage-healing framework to predict the fracture-healing responses of a multifunctional vascular cementitious composite. The proposed framework integrates a mathematical MICCP healing model into a damage model developed using the phase-field method. For the healing model, the chemical and enzyme kinetics of the MICCP reaction pathway based on ureolytic bacteria (i.e., urease-production bacteria) strain were extensively studied. The model considers the bacterial proliferation, the catalyzed ureolysis reaction, the shift of bicarbonate equilibrium due to pH variation, and then output the predicted CaCO3 precipitation quantity during the reaction pathway. On the other hand, the damage model is based on the FEA with phase-field method, which is utilized to simulate the fracture response of a quasi-brittle material. Therefore, a three-stage computational scheme can be established: In stage 1, the fracture and crack propagation in a virgin concrete structure embedded with vascular network is simulated using the phase-field method. The damage variables at the material points of each element are computed. In stage 2, the concrete structure is unloaded. We assume the necessary chemicals and bacteria are transported to the crack sites through the vascular channels and are immediately ready for reaction. The precipitated CaCO3 estimated by the MICCP model can be converted to the healing ratio, hd, of the damaged structure. The damaged part is assumed to be completely healed when hd=1 and not healed at all when hd=0. Therefore, we can update the damage variables at the material points of each element to the phase-field damage model based on the hd value. Finally, in stage 3, the fracture and crack propagation of the healed concrete structure is then simulated again using the phase-field method. In this study, several benchmark simulations were performed to investigate the MICCP quantity with different initial conditions. Various fracture problems were also used to estimate the mechanical response of the damaged concrete structure after healing. We observe that the simulated load-displacement curve of the healed structure shows a recovery in stiffness depending on the MICCP healing ratio. The proposed framework can be applied to various fracture-healing problems of vascular cementitious materials that adopt MICCP as the healing strategy.

FINITE ELEMENT MODELING OF BRINKMAN EQUATIONS IN POROUS MEDIA

Hsueh-Chen Lee[*1] and Hyesuk Lee*[2]

[1]*Wenzao Ursuline University of Languages*
[2]*Clemson University*

ABSTRACT

This study explains the intricate dynamics of fluid movement through tiny rock pores, particularly in challenging underground reservoirs with restricted natural flow. The Brinkman equations are crucial for describing flow in porous media. Utilizing the Brinkman equations, we model fluid flow within micro-layered rock structures. To enhance stability, we introduce a mixed formulation involving velocity, pressure, and vorticity, incorporating the rate of deformation tensor. We introduce Galerkin least-square and least-squares finite element methods to address the incompatibility of finite element spaces, treating velocity, pressure, and vorticity as independent variables. Theoretical analysis delves into critical properties such as coercivity and continuity, providing error estimates. Demonstrating robustness in theoretical findings, these methods achieve optimal convergence rates in the L2 norm by incorporating stabilization terms, even with low-order basis functions. Furthermore, we extend these methods to simulate pore-scale flow in porous media, validating their efficacy. Notably, as the inlet velocity increases, there is a significant amplification in the average pressure difference compared to solutions governed by the Stokes equation.

NEURAL NETWORKS WITH LOCAL CONVERGING INPUTS (NNLCI) FOR SOLVING PDES IN VARYING AND MULTI DOMAINS WITH COMPLICATED INTERFACE CONDITIONS

Zhen Chao[1], Harris Cobb[2], Hwi Lee[2], Yingjie Liu[2] and Dexuan Xie[3]*

[1]*Western Washington University*
[2]*Georgia Institute of Technology*
[3]*University of Wisconsin, Milwaukee*

ABSTRACT

In the series of works (Haoxiang Huang, Yingjie Liu, Vigor Yang, arXiv:2109.09316 and 2204.10424), NNLCI is introduced to predict discontinuities and smooth parts of solutions of the Euler equations in 1D and 2D accurately. For example, in order to predict the solution of the 1D Euler equations at a space-time location, one can design the output of a neural network to be the solution value at the location. If one tries to design the input as the low-cost numerical solution patch in a local domain of dependence of the location (where the information comes from), can the neural network tell if the input is across a shock or in a smooth region ? The answer is no ! The new approach uses two numerical solutions of a conservation law from a converging sequence, computed from low-cost numerical schemes, and in a local domain of dependence of a space-time location as the input for a neural network to predict its high-fidelity solution at the location. Despite smeared input solutions, the output provides sharp approximations to solutions containing shocks and contact discontinuities. The method reduces the complexity by several orders of magnitude compared to a fine grid numerical simulation, has much lower cost to train, and can be used naturally in varying computational domains through training and prediction because it's a local method. NNLCI can be applied to solving the PnP model which describes the electrochemical dynamics around a protein (Zhen Chao, Harris Cobb, Hwi Lee, Yingjie Liu and Dexuan Xie.) This model involves nonlinear Poisson systems in multiple subdomains connected with complicated interface conditions. We will demonstrate how NNLCI can be used in this problem to reduce the complexity and training costs.

A SCHUR COMPLEMENT METHOD FOR THE STOKES-BIOT SYSTEM AND ROM IMPLEMENTATION

Amy De Castro[1], *Hyesuk Lee**[1] *and Margaret Wiecek*[1]

[1]*Clemson University*

ABSTRACT

We present a partitioned method for the Stoke-Biot system based on a monolithic formulation of the problem, which employs a Schur complement equation for a Lagrange multiplier. This algorithm eradicates the need for iterations between the fluid and structure subdomains and instead allows them to be decoupled and solved separately at each time step. The Lagrange multiplier, representing an approximation of the interface flux, serves as a Neumann boundary condition for each sub-problem, allowing for the fluid and structure to be solved independently at each time step. To reduce computational costs, we consider implementing a reduced order model (ROM) for one or both subdomains. The Schur complement method developed for the original Stokes-Biot system can be utilized to couple a reduced order model with either a full order model or a reduced order model on the other subdomain. We show numerical results demonstrating the method's capability to capture each type of coupling.

MOLECULAR DYNAMICS STUDY ON ELECTROELASTIC PROPERTIES OF HEXAGONAL BORON NITRIDE NANOSTRUCTURE: COMBINED EFFECT OF VACANCY STRUCTURE AND TEMPERATURE

Jaewon Lee[*1] and Seunghwa Yang*[1]

[1]*Chung-Ang University*

ABSTRACT

As the demand for wearable and implantable devices increases, low-dimensional piezoelectric materials have received considerable attention as next-generation nanomaterials. Especially, two-dimensional piezoelectric nanomaterials are promising due to their flexible, atomically thin, and transparent characteristics with a high surface-to-volume ratio compared to three-dimensional piezoelectric crystals. Hexagonal boron nitride nanosheets(BNNS) have been one of the promising piezoelectric low dimensional nanomaterials owing to their ultrahigh mechanical properties, low toxicity, and high chemical/thermal stability, suggesting great potential for energy harvesting devices in biomedical applications.

In order to utilize BNNS in such elaborate fields, it is necessary to fully understand the structure-operation environment-properties relationship. Nevertheless, it was only three to four years ago that the piezoelectric coefficient of mono-layer hexagonal boron nitride was first measured experimentally, and most of the piezoelectric properties were theoretically predicted based on the first principle calculation. Therefore, there exists a technological gap between actual application and theoretical prediction. Although several researchers have predicted the piezoelectric properties of BNNS through molecular dynamics simulation to bridge this gap, an integrated analysis of the structure-temperature-properties relations for electoelastic properties of BNNS has rarely been studied yet.

In this study, molecular dynamics simulation was conducted to investigate the effect of vacancy defect and temperature on the electroelastic properties of BNNS, each of which is representative of structural defects and service conditions in nanomaterials, respectively. Based on the direct piezoelastic Maxwell relations, the strain-stress relation and strain-electric displacement relationships of BNNS were predicted by applying linear elastic strain along the armchair direction. To describe the electroelastic behavior, the Tersoff potential and rigid ion approximation were adopted. As a result, the vacancy defects and temperature showed a non-negligible influence on the piezoelectric constant of BNNS. The vacancy defect either increases or decreases the piezoelectric constant of BNNS depending on the alignment of BN di-vacancy, while Young’s moduli were always degraded by the vacancy. Furthermore, such an abnormal increase of piezoelectric constant with di-vacancy was more clearly observed at lower temperature conditions. To analyze the mechanism of these phenomena, the atomic displacement of B and N around the defects was monitored and compared by vacancy type and temperature based on the linear piezoelectricity theory. Finally, the possibility of defect engineering by controlling the vacancy defects in BNNS with controlled service temperature conditions was discussed.

A NEW ELASTODYNAMIC HOMOGENIZATION THEORY OF FINITE-SIZE APERIODIC MEDIA AND ITS MACHINE LEARNING-BASED IMPLEMENTATION

Jeong-Ho Lee[1] and Grace Gu*[1]

[1]*University of California, Berkeley*

ABSTRACT

Architected materials, such as composites and metamaterials, have been extensively utilized across academia and industries for their tunable, superior functionalities, e.g., high stiffness with lightweight. Their design is based on engineered microstructure patterns and/or heterogeneous material distribution rather than synthesizing chemically new materials, from which they can exhibit unprecedented features in the overall behavior at the macroscale even though they are, at the microscale, composed of typical materials in nature. Homogenization theories have been widely employed to evaluate the functionality of architected materials by seeking to define the effective material properties of an equivalent homogeneous media. This approach can simplify the analysis of architected materials by making understanding the fundamental physics behind their macroscopic behavior easier. For instance, elastodynamic homogenization on architected materials with asymmetric microstructures gives a non-classical coupling property, called Willis coupling, between stress and velocity, which plays a role in understanding and predicting a more accurate representation of wave propagation. However, most of the developed homogenization theories have limitations that challenge their application for general finite-size aperiodic media. First, they assume a volume average or asymptotic expansion for the bridge between microscopic and macroscopic fields, which only works for limited circumstances, such as when microstructures are at the subwavelength scale or have a much smaller scale than the macroscale of interest, respectively. Second, they only consider a partial domain of the target medium to be homogenized since they rely on representative volume elements and assume periodic boundary conditions. That is, it is not possible in general cases to consider the exact design and geometry of the target medium. These limitations not only hinder the accurate prediction of effective material properties but also, when it comes to practical applications such as finding optimal designs for a target effective property, restrict the design space of architected materials to periodic designs. Therefore, to overcome the limitations, we formulate a new elastodynamic homogenization theory via a polarization approach using infinite-body Green’s function of a comparison homogeneous medium. As this theory builds on Green’s function, the resultant homogenization equation inherently includes integral operators that lead to high computational costs. We resolve this issue by developing a deep neural network, in which the homogenization equation is used as a physics-informed loss, and apply this developed network to an example problem for homogenization-based design optimization.

HYBRIDIZABLE DISCONTINUOUS GALERKIN METHODS FOR COUPLED SYSTEMS OF POROELASTICITY AND FREE FLOW EQUATIONS

Jeonghun Lee[*1], Aycil Cesmelioglu[2] and Sander Rhebergen[3]*

[1]*Baylor University*
[2]*Oakland University*
[3]*University of Waterloo*

ABSTRACT

In this work we develop and analyze hybridizable discontinuous Galerkin (HDG) methods for problems such that the Stokes and Navier-Stokes equations and the Biot consolidation equations are coupled with interface. In our HDG methods the compressibilities of fluid and poroelastic matrix, and the fluid mass in poroelastic domain are strongly conservative.

EFFICIENT ESTIMATION OF HIGHWAY BRIDGE SEISMIC RESPONSE USING PROBABILISTIC LEARNING ON MANIFOLDS (PLOM)

Jeonghyun Lee[1], Kuanshi Zhong[2], Sanjay Govindjee[3] and Gregory Deierlein[1]*

[1]*Stanford University*
[2]*University of Cincinnati*
[3]*University of California, Berkeley*

ABSTRACT

Seismic risk analysis of distributed bridge networks is a crucial component of evaluating the disruption to transportation systems and the resultant travel time increase following earthquakes. The core idea behind such analyses is to assess the behavior of individual bridges at each discrete location and propagate the results throughout an entire portfolio to gain a holistic understanding of the regional impacts. The key limits in this process are obtaining high-resolution estimates of individual bridge responses through nonlinear analysis (quality) and the inherent need to repeat this procedure given a large inventory (quantity). We propose a surrogate modeling approach to efficiently assess the earthquake response of bridges while attaining both goals using Probabilistic Learning on Mainfolds (PLoM). PLoM is particularly suited to the problem given its multidimensional nature where we need to consider both the variability in the bridge design parameters and the site-specific characteristics.

Our approach predicts both the ultimate capacity of a bridge as well as the dynamic response of the bridge leading up to collapse. For both applications, the surrogate model is developed on a training set of bridges sampled from a large design space that are subjected to a grid of ground motions. The surrogate model's performance is tested on an archetype bridge at 16 real-world locations. We also provide a streamlined approach to tune the two PLoM modeling parameters (i.e., diffusion-maps kernel size and number of diffusion-map components) applicable to various sites and bridge designs, thereby reducing the burden on the end-user. The final model allows users to evaluate various damage characteristics (e.g., rebar fracture) of bridges at multiple sites and intensity levels. Such models will not only enable high-resolution regional studies, but also the evaluation of performance under preventative scenarios (e.g., which types of retrofits are most beneficial, which set of bridges should be prioritized?). Lastly, comparisons of the proposed surrogate model's computational efficiency to conventional approaches along with further enhancements to its efficiency are discussed.

APPLICATION OF BOUNDARY INTEGRAL QUADRATURE METHOD TO A CIRCULAR TORSION BAR WITH AN EDGE CRACK

Jia-Wei Lee[1], Yu-Sheng Hiesh[1] and Jeng-Tzong Chen[2]*

[1]*Tamkang University*
[2]*National Taiwan Ocean University*

ABSTRACT

Regarding the torsion problem of elastic cylindrical bar with an edge crack, the boundary integral quadrature method (BIQM) in conjunction with the dual formula is employed to solve the stress function. Comparing with the conventional dual boundary element method (BEM), the present method is free of mesh generation. To achieve this benefit, the adaptive exact solution, parametric representation and Gaussian quadrature play important roles. By introducing the adaptive exact solution, the singular integral in the sense of the Cauchy principal value can be skillfully determined. For the collocation point located on the ordinary boundary, we adopt the original adaptive exact solution. For the collocation point located on the crack, the adaptive exact solution is rederived by using the harmonic basis of elliptical coordinates. To realize the effect upon the elastic cylinder due to the crack, the torsional rigidity and the stress intensity factor (SIF) are considered to calculate. To conveniently determine the torsional rigidity, the domain integral formula is transformed into the form of the boundary integral. The computation of the SIF is dependent on the unknown boundary density near the crack tip. Therefore, the extra computation of the two shear stress fields is free. It is interesting that the self-regularized approach can be also employed to obtain the correct unknown boundary density without using the dual formula in the present method. To check the validity of above two manners, the conventional dual BEM is also adopted to examine those results. Finally, two elastic cylindrical bars containing different edge cracks are considered. One is a radial edge crack and the other is a slant edge crack.

MULTISCALE APPROACH TO EVALUATE FRACTURE TOUGHNESS OF POLYMER NANOCOMPOSITES BY CONSIDERING COHESIVE FAILURE MODE

Jihun Lee[1], Haolin Wang[1], Jae Hun Kim[1] and Hyunseong Shin[1]*

[1]*Inha University*

ABSTRACT

The covalent grafting between the nanofillers and the polymer matrix is regarded as a useful design factor to tailor the mechanical properties. Polymer nanocomposites including covalent grafting form a strong interphase due to strong interfacial interactions between nanofillers and polymer matrix. Furthermore, these strong interfacial interactions can lead to cohesive failure mode in the debonding mechanisms [1]. However, since the conventional multiscale fracture toughness model [2, 3] did not account for the cohesive failure mode, it is necessary to develop a theoretical model evaluating the fracture toughness of polymer nanocomposites by considering the cohesive failure mode. In this paper, we develop a multiscale fracture toughness model reflecting the cohesive failure mode in the debonding mechanisms. The multiscale strategy was modified by incorporating the microscopic damage mechanisms (cohesive failure mode in the debonding mechanisms and plastic yielding of nanovoids), which occur near the macroscopic crack tip. The influence of microscopic energy dissipation on the strain energy release rate of nanocomposites according to grafting ratios was quantitatively evaluated using the developed multiscale model. In addition, to investigate the effect of grafting ratios on surface roughness, the assessment of surface roughness related to fracture resistance was performed. This assessment was calculated via remaining atoms on the nanofiller surface using traction–separation behavior in molecular dynamics simulations. When collecting the results of surface roughness with those of fracture toughness obtained from the proposed multiscale fracture toughness model, it implies that excessive amount of covalent grafting may not contribute to the fracture toughness improvement of polymer nanocomposites. In conclusion, the proposed multiscale model is expected that the proposed multiscale model can be used as a design guideline for improving the fracture toughness of polymer nanocomposites.

A STUDY ON MULTI-FIDELITY SURROGATE FOR MULTIPLE LOW-FIDELITY INFORMATION

Mingyu Lee[*1], Juyoung Lee[1] and Ikjin Lee[1]*

[1]*Korea Advanced Institute of Science and Technology (KAIST)*

ABSTRACT

Over the past few decades, surrogate models (also known as metamodels) have been widely employed in optimization based on costly computer simulations to enhance computational efficiency. However, even with advancements in computing performances, obtaining sufficient data remains challenging when simulation times are prohibitively high. To alleviate these difficulties, various techniques such as screening, mapping, decomposition, and auxiliary information have been developed. Particularly, leveraging low-fidelity data as auxiliary information is considered a promising approach. Multi-fidelity (MF) surrogate models, which combine high-fidelity samples with low-fidelity samples, have proven effective in addressing this issue across various real-world problems [1]. Nevertheless, in practical scenarios, the quality of low-fidelity data may not always be good [2], and dealing with diverse types of low-fidelity data from multiple sources adds complexity [3].

As a solution to these challenges, this study proposes a MF methodology for utilizing low-fidelity information from multiple sources. The proposed approach addresses the creation of MF surrogate models from the perspective of low-fidelity data and is developed based on cross-validation error. Additionally, the proposed method uses the well-known Kriging-based MF surrogate. Numerical test results demonstrate the superior performances of the proposed approach compared to the existing methods.

BLAST ANALYSIS OF HIGH-PERFORMANCE FIBER-REINFORCED CEMENT COMPOSITE PANELS

MinJoo Lee[*1]*

[1]*KAIST*

ABSTRACT

This paper numerically investigates the performance of RC and high performance fiber-reinforced cement composite (HPFRCC) panels suffered from near field TNT explosion using MM-ALE method. HPFRCC, which is one of advanced construction materials, is promising for application to protective structures [1]. A Karagoziam & Case (K&C) model [2], which is one of plastic-based concrete material models, can describe accurately the response of concrete structures subjected to blast and impact loadings. However, since automatically determined parameters are based on plain concrete, these are not appropriate for HPFRCC. The K&C model is calibrated based on the quasi-static and dynamic experimental data of HPFRCC. The modified K&C model is implemented into LS-DYNA [3] program to perform numerical simulations of the HPFRCC panels. The accuracy and reliability of the numerical simulations using MM-ALE method were verified through comparison with the LBE method and test results. The HPFRCC panel has superior blast resistance performance than normal concrete from simulations and experiments. Additionally, parametric studies are conducted to investigate the differences between the explosive characteristics and failure shape of the specimens according to the modelling shapes of TNT explosive and scaled distance.

ABSTRACT

Air as a refrigerant in compressors provides an environmentally sustainable option that significantly lowers the global warming potential associated with traditional refrigerants. However, it directly leads to challenges in maintaining the compressor system's reliability and efficiency. Moreover, the necessity to operate the compressor's rotor system at high speeds for air refrigeration increases the risk of surge phenomena, directly threatening the compressor's integrity and operational safety. The study employs a data-driven approach, using machine learning to detect surge events in advance. However, replicating transient phenomena such as surge events in a testbed is not only difficult due to the complexity of artificially creating these conditions, but it also poses significant risks to both humans and mechanical systems, thereby complicating the process of data acquisition. To address the issue of data scarcity, this study generated synthetic data distributions that share similar characteristics with real data, utilizing machine learning techniques. Specifically, the research focused on ensuring that the datasets, inherently time-series in nature, were developed while preserving the patterns and dynamic characteristics inherent to their temporal progression. The methodologies proposed offer solutions to the challenges posed by air refrigerants and are applicable to other engineering fields facing data limitations.

ABSTRACT

This study introduces a thermo-hydraulic-mechanical (THM) model for fracture propagation using a phase-field approach. We developed a computational framework incorporating rigorous and efficient iterative coupling, high-fidelity physics-preserving finite element methods, and adaptive mesh refinement. In our governing system, we focus on four solution variables: displacements, phase-field, pressure, and temperature. These variables are determined through a vector-valued mechanics problem, a phase-field variational inequality, and scalar-valued pressure and temperature problems, respectively. The resulting overall problem forms a coupled variational inequality system. Our solution algorithm builds upon the well-known fixed-stress algorithm, solving displacements-phase-field, pressures, and temperatures sequentially. The displacements-phase-field component is addressed in a quasi-monolithic fashion. To ensure local mass conservation, we utilize enriched Galerkin finite elements for the pressure equation, and similarly for the temperature equation. Local mesh adaptivity enables the use of small phase-field length-scale parameters, ensuring numerical accuracy while maintaining reasonable computational costs. We validate our new model and algorithmic developments through numerical tests.

STUDY ON ACTION-BASED PINN TO PREDICT THE BEHAVIOR OF THE SYSTEM HAVING PHASE TRANSITION

Semin Lee[1] and Hayoung Chung*[1]

[1]*Ulsan National Institute of Science and Technology*

ABSTRACT

Liquid crystals can be controlled by external stimuli, exhibiting both crystalline and fluidity. Due to these distinctive mechanical properties, liquid crystals have garnered lots of interest. With this interest, several numerical models describing the behavior of the liquid crystal have been presented. The Landau-de Gennes free energy model is one of the most representative models to be used for describing the phase of the liquid crystal. Several approaches to simulate the relaxed state of the liquid crystal have been successfully proposed by searching the minimum point of the Landau-de Gennes free energy. However, the multi-well potential of this free energy is a critical obstacle to finding the minimum point by solving the Euler-Lagrange equation of Landau-de Gennes free energy. Consequently, the simulations to predict the equilibrium state of the liquid crystal system based on the Landau-de Gennes free energy model perform gradient-based minimization. Since gradient-based minimization requires iterative computation, these simulations encounter the challenge of acquiring high-fidelity results.

To ease the issue, we leverage the reusability of the neural network through transfer learning. Transfer learning needs much less training time by updating only a few deep layers of the pre-trained neural network. Among the neural networks, we applied this advantage to the PINN (Physics-informed neural network) to analyze the liquid crystal system. The PINNis an emerging neural network embedding the physical information of the system in the form of partial differential equations. The PINN has drawn a lot of attention in various physical domains with showing successful solving several physical problems[1]. In this study, we propose a modified version of PINN, the Action-based PINN, minimizing the action functional to predict the equilibrium state of the liquid crystal system. By the gradient-based minimum point searching, the Action-based PINN successfully predicts the ground state of the system having phase transition.

The accuracy and effects of the proposed network in this study are demonstrated by comparing the prediction results of the Action-based PINN with those of standard PINN in several numerical examples. Additionally, our study delves into the advantages of the Action-Based PINN, especially its enhanced reusability, offering a significant improvement over traditional numerical methods.

ABSTRACT

Keywords: Physics-informed neural networks, Deep energy method, Saddle point problem, Adversarial networks, Dielectric elastomers

Multiphysics systems, where two or more physical phenomena are coupled, play a crucial role in various fields including biophysics, geophysics, and aerospace engineering. These complex systems are modeled using multiple partial differential equations (PDEs) with coupling terms, posing substantial challenges in mathematical formulation, numerical analysis, algorithm design, and software engineering. Addressing these challenges, recent machine learning advancements, specifically physics-informed neural networks (PINN), have enabled more unified and flexible solutions to a broad range of PDE problems [1]. The deep energy method (DEM), a variant of PINN, utilizes neural networks to efficiently tackle PDEs by minimizing associated functionals [2]. However, its application has been mainly limited to scenarios with simpler variational principles. In contrast, multiphysics systems often present intricate saddle point problems involving multiple field variables.
To effectively address this complexity, we propose an adversarial deep energy method (adversarial DEM) that employs multiple neural networks in an adversarial relation. Adversarial DEM is particularly tailored to tackle the minimax variational principle through saddle point optimization algorithms, largely expanding the applicable range of the existing DEM. Our method has been applied to electromechanical coupling in dielectric elastomers, serving as a concrete example of a multiphysics system with the minimax variational principle. The results from benchmarking problems in dielectric elastomers showcase the strength in handling diverse material models and accurately capturing intricate nonlinear phenomena like buckling in electromechanical coupling. In summary, our method addresses the existing limitations of conventional approaches in modeling multiphysics systems, paving way for the application of machine learning in complex system simulations.

A NEW ADAPTIVE KRIGING-BASED OPTIMIZATION (AKBO) FRAMEWORK COMBINING A TRUNCATED CONSTRAINT FUNCTION (TCF) METHOD AND A NEAR CONSTRAINT BOUNDARY SEARCH (NCBS) ALGORITHM

Ungki Lee[*1]*

[1]*Korea University Sejong Campus*

ABSTRACT

Adaptive Kriging-based optimization (AKBO) efficiently performs optimization by employing adaptive sampling methods that sequentially update Kriging model [1]. To solve constrained optimization problems, existing adaptive sampling methods add samples based on probability of feasibility (PoF) representing the probability that all constraints are satisfied [2]. However, these methods have the limitation that samples are added inefficiently when the PoF is inaccurate. Therefore, this study proposes a new AKBO framework that is robust to instability of PoF in adaptive sampling. To this end, a near constraint boundary region that is expected to be close to the constraint boundary is defined based on a probability measure. Then, a near constraint boundary search (NCBS) algorithm, which explores the sample point that minimizes the objective function within the near constraint boundary region, is developed for global search, whereas a near optimum search (NOS) algorithm, which searches for better solutions that may exist near the current optimum candidate, is developed for local search. To alleviate the distortions of the Kriging model that may occur due to the highly nonlinear response, a truncated constraint function (TCF) method that limits the extremely violated constraint values used in the design of experiment (DoE) of the Kriging model is also proposed. This study verifies the performance of the proposed AKBO framework through the shared autonomous electric vehicle (SAEV) system design optimization problem. Comparison of optimum designs derived from various optimization methods shows that the proposed AKBO framework derives the feasible global optimum with high accuracy and efficiency.

TEMPORAL HOMOGENIZATION METHOD FOR VISCOELASTIC–VISCOPLASTIC MATERIALS SUBJECTED TO CYCLIC LOADING

Wonjoo Lee[1] and Hyunseong Shin*[1]

[1]*Inha University*

ABSTRACT

In this study, a formulation for temporal homogenization was developed for application to the viscoelastic-viscoplastic model. Two types of temporal homogenizations were explored: non-updated temporal homogenization and updated temporal homogenization. The non-updated temporal homogenization employs a constitutive equation with higher-order differential forms in the viscoelastic-viscoplastic model. On the other hand, the updated temporal homogenization involves separating the local initial boundary problem by applying a constitutive equation with higher-order differential forms in the viscoelastic-viscoplastic model. The solutions obtained (i.e., local displacement, strain, and stress fields) for the local initial boundary problem are also utilized for the global initial boundary value problem. Volterra equations or Laplace transforms are not required to solve the local initial boundary problem. The novelty of this study lies in the efficient formulation of temporal homogenization for viscoelastic-viscoplastic materials. Notably, this is the first attempt to develop an updated temporal homogenization formulation for viscoelastic-viscoplastic materials without relying on Volterra integrals to solve the local initial boundary problem.
In conclusion, the initial boundary value problems are divided into macro-, micro-chronological terms. To validate this approach, two examples were considered: (i) uniaxial cyclic loading on a one-dimensional bar, (ii) multiaxial cyclic loading on a three-dimensional bar. By comparing the accuracies of non-updated and updated temporal homogenization formulations, it becomes evident that the updated temporal homogenization formulation yields more accurate results. The first advantage is that stress updates are not used in solving the local initial boundary value problem. The second advantage, as demonstrated by the verification examples, is that the local initial boundary value problem subjected to local cyclic loading on the viscoelastic-viscoplastic model was resolved with high accuracy.

DATA ASSIMILATION THROUGH SEMI-GAUSSIAN BAYESIAN UPDATE

Yoonsang Lee[*1]

[1]*Dartmouth College*

ABSTRACT

This study proposes a semi-Gaussian Bayesian update framework for optimal control and data assimilation. In particular, the study focuses on an ensemble-based approach for such goals. The framework will provide insights into the meaning of inflation and sampling error correction (or localization) commonly used in the ensemble-based Bayesian update methods, such as ensemble transform or adjustment Kalman filters. The study further provides a strategy for designing a new sampling error correction for error correction instead of the distance-based ad hoc approach.

VERIFICATION METHODS FOR OBLIQUE SHOCK REFLECTIONS

Allyson Leffler[1], Jasper Thrussell[1], Steven Anderson[1] and Jim Ferguson[1]*

[1]*Los Alamos National Laboratory*

ABSTRACT

Oblique shock reflections occur in a variety of instances where a supersonic flow is concavely deflected by a contact surface. One such instance of this flow phenomenon is when a planar shock impinges on a wedge. These shock reflections can vary drastically in complexity depending on the initial Mach number of the planar shock, the number of facets on the wedge, and their corresponding angles. As multiple wedges are stacked on top of one another, the interactions between the reflected shocks become increasingly complex and difficult to analyze. This type of wedge configuration is commonly found in a variety of engineering applications and shock experiments and can be thought of as the discretization of a curved geometry. Due to the widespread use of computational fluid dynamics, understanding the level of confidence associated with numerical simulations of this flow phenomenon is necessary.

Ideally, analytical solutions could be used to draw conclusions about how well a simulation produces an expected behavior, but for this type of flow phenomenon, limited analytical solutions exist. Thus, it is necessary to explore and develop novel verification techniques. We present various assessments of numerical simulations of a planar shock impinging on both single faceted and double faceted wedges. This study proposes and demonstrates the utility of using method of characteristics to obtain semi-analytical solutions for various oblique shock reflections. These solutions can then be used as a verification tool to draw quantitative comparisons and establish confidence in the simulations.

MODELING IMMERSED GRANULAR FLOWS

Vincent Legat[*1], Nathan Coppin[1], Michel Henry[1], Simon Yans[1] and Jonathan Lambrechts[1]*

[1]UCLouvain

ABSTRACT

An unresolved Computational Fluid Dynamic-Discrete Element Method (CFD-DEM) model for the simulation of flows mixing fluid and grains is presented. The grains trajectories are solved at a fine scale using a discrete element method. It provides the velocities and the trajectories of the grains with an accuracy that is needed to describe microscopic phenomena like clogging in pipe happening in these flows. Solved at a coarse scale using the finite element method, the fluid motion is deduced from a mean continuous representation of the fluid phase giving computational performance and keeping variables evolutions that are of interest for a lot of simulation processes.

The collapse dynamics and runout of columns of elongated grains are numerically are investigated in dry and immersed conditions. The elongated grains are modelled as rigid aggregates of disks. The column aspect ratio is systematically varied from 0.125 to 16 in order to span short and tall columns. To analyse the effect of the initial grain orientation, columns with an initial grain orientation that is either random or aligned with a given direction are both considered. Collapse dynamics, both in dry and immersed cases, exhibit a power law dependency for the runout as a function of the column aspect ratio. The effect of the fluid mainly results in a decrease of the runout distance. Interestingly, the collapse dynamics and runout are not significantly affected by the initial orientation of the grains, except maybe in the extreme case where the grains are all horizontally oriented, which geometrically prevents the collapse.

STRUCTURAL REINFORCEMENT AND VIBRATION REDUCTION WITH ELASTIC AND VISCOELASTIC MATERIALS USING TOPOLOGY OPTIMIZATION

Antoine Legay[*1] and Sylvain Burri*[1]

[1]*Conservatoire National des Arts et Métiers*

ABSTRACT

This work addresses mechanical design problems such as structural reinforcement adding elastic material or vibration reduction using viscoelastic layers.
The aim is thus to attach on a pre-existing given structure a design domain in order to improve the behavior of this elastic structure, according to an objective function.
This can be useful when one wants to use, for example, additive manufacturing to reinforce a pre-existing structure or to maximize structural damping using viscoelastic layers.
Two objective functions are tested in both linear statics and dynamics: a compliance based objective function and a displacement based one.
The topology optimization formulation based on the Solid Isotropic Material with Penalization (SIMP) method is then used to minimize the objective function. It is solved by the Modified Optimality Criteria (MOC) algorithm.
In the dynamic case, written in the frequency domain, the two proposed objective functions include the viscoelastic material model (a Zener fractional derivative one) used to fill the design domain.
The displacement criteria is developed using a general formula able to take into account as many as degree of freedom as necessary.
Finally, some applications based on beams and CubeSat-like structures are shown in this article.
The proposed examples show that in both statics and dynamics, the optimization of a restrained design domain attached to an existing structure can improve its behavior: stiffness improvement or vibration reduction.

A POSTERIORI ERROR ESTIMATORS AND MODEL REDUCTION FOR MULTISCALE PROBLEMS

Frederic Legoll[*1], Ludovic Chamoin[2], Arthur Lebee[3] and Jean Ruel[3]*

[1]*École des ponts ParisTech, Inria*
[2]*ENS Paris-Saclay*
[3]*École des ponts ParisTech*

ABSTRACT

This talk is devoted to the numerical simulation of multiscale problems. The multiscale nature may stem from the presence of a heterogeneous microstructure, as for instance in composite materials. It may also stem from the geometry of the domain. A typical example is the case of elongated structures, such as plates, where the thickness of the structure is much smaller in one direction than in the others.

Dedicated numerical methods have been proposed in the literature for each of these cases. For composite materials, a possibility is to resort to the Multiscale Finite Element Method (MsFEM), a Finite Element type approach where the basis functions used to generate the approximation space are precomputed and are specifically adapted to the problem at hand. For plates, finite element methods typically distinguish the in-plane directions from the thickness direction. PGD-type approaches are also a method of choice, again to handle differently the various directions.

In this context, we will describe efficient tools enabling to certify the numerical simulations, with respect to both discretization and model errors.

This talk is based on joint works with L. Chamoin, A. Lebee and J. Ruel.

UNCERTAINTY QUANTIFICATION IN 3D PHYSICS-BASED SIMULATIONS WITH A NEURAL OPERATOR SURROGATE MODEL

Fanny Lehmann[*12], Filippo Gatti[1], Michaël Bertin[2] and Didier Clouteau[1]*

[1]Université Paris-Saclay

ABSTRACT

Wave propagation simulations are the core of numerous applications, and they have reached a high level of fidelity thanks to continuous improvements in numerical modelling and computational resources. Physics-based simulations rely on parameters describing the properties of the propagation domain. When simulating wave propagation in the Earth's crust, those properties are subject to large epistemic uncertainties due to the difficulty of conducting geophysical measurements. However, the computational costs of high-fidelity simulations in three-dimensional (3D) heterogeneous domains prevent uncertainty quantification (UQ) via a Monte Carlo-like approach. This work demonstrates using a physics-based deep learning surrogate model to quantify uncertainties in elastic wave propagation.

The surrogate model is based on a Multiple Input Fourier Neural Operator (MIFNO), our extension of the popular Fourier Neural Operator. Fourier Neural Operators rely on the Fast Fourier Transform to learn the frequency representation of Partial Differential Equations (PDEs). Our MIFNO predicts the solution of the 3D elastic wave equation from the properties of the propagation domain and the initial condition. Its main specificities are:
- a factorized architecture that limits the number of parameters and improves the scalability
- a depth-to-time conversion to predict 3D time-dependent variables without a 4D surrogate
- an implementation depending on the input representation (structured grids and vectors)

Training data are obtained from 30,000 High-Performance Computing (HPC) simulations. Each simulation represents the propagation of elastic waves from a random source inside a random 3D heterogeneous domain. Heterogeneities describe the epistemic uncertainties on the properties of the Earth's crust in different regions.

We show that the MIFNO achieves state-of-the-art accuracy when the source is fixed and maintains this accuracy for sources with varying locations and characteristics. It is the first surrogate model with the flexibility of a physics-based solver. Although the high-frequency accuracy is limited by the well-known spectral bias, the MIFNO can still be used for uncertainty analyses on low- and medium-frequency quantities of interest.

For UQ analyses, we focus on the propagation of seismic waves in a region with considerable industrial interests. We sample 500 propagation domains from the distribution of geological heterogeneities and fine-tune the MIFNO on these samples. Based on the current knowledge, all domains are equally likely but earthquakes would have dramatically different consequences in each domain. Thanks to the MIFNO, we predict the ground motion intensity probability distributions that were unachievable with conventional methods.

CONSENSUS-BASED CONSTRUCTION OF HIGH-DIMENSIONAL FREE ENERGY SURFACE

Huan Lei[*1] and Liyao Lyu*[1]

[1]*Michigan State University*

ABSTRACT

One essential problem in quantifying the collective behaviors of molecular systems lies in the accurate construction of free energy surfaces (FESs). The main challenges arise from the prevalence of energy barriers and the high dimensionality. Existing approaches are often based on sophisticated enhanced sampling methods to establish efficient exploration of the full-phase space. On the other hand, the collection of optimal sample points for the numerical approximation of FESs remains largely under-explored, where the discretization error could become dominant for systems with a large number of collective variables (CVs). We propose a consensus sampling-based approach by reformulating the construction as a minimax problem which simultaneously optimizes the function representation and the training set. In particular, the maximization step establishes a stochastic interacting particle system to achieve the adaptive sampling of the max-residue regime by modulating the exploitation of the Laplace approximation of the current loss function and the exploration of the uncharted phase space; the minimization step updates the FES approximation with the new training set. By iteratively solving the minimax problem, the present method essentially achieves an adversarial learning of the FESs with unified tasks for both phase space exploration and posterior error enhanced sampling. We demonstrate the method by constructing the FESs of molecular systems with a number of CVs up to 30.

AERODYNAMICS ANALYSIS OF DRAGONFLY FLAPPING WINGS BASED ON FORCE ELEMENT THEORY

Jie-Chao Lei[1], Min-Hong He[2], Chien-Cheng Chang[2] and Chin-Chou Chu[2]*

[1]*Kunming University of Science and Technology*
[2]*National Taiwan University*

ABSTRACT

In bionics, the flight patterns and aerodynamics of birds and insects have always been the research topics for humans to discuss aerial flight. Compared with other birds and insects, dragonflies have higher mobility and can hover, make sharp turns, reverse, and have a 360-degree flight.The flight speed of dragonflies is very fast, especially, some species can reach a speed of about 50 kilometers per hour. Therefore, several studies have directed efforts toward the aerodynamics of dragonfly flapping wings, numerically or experimentally. However, for the problem of unsteady flow formed by birds and insects flapping their wings, the commonly used surface pressure integration method to calculate the overall force cannot fully explain the force mechanism between the flow field and the force exerted on the body. To date, there have been many researches discussing the flight mode of dragonflies, but no matter whether it is numerical simulation, bionic mechanism design, or exploring the real dragonfly, it is lacking to clearly describe how the vorticity has the lift-drag effect on flight. In the present work, by applying the Force Element Theory, the vorticity was linked with the force and the flow field obtained by applying the CFD, and the sources of force in dragonfly in-phase stroking and counter stroking, as well as the changes of each force element term in a period were discussed.The main findings include: (i) In-phase stroking flight is the way the dragonfly takes off and climbs, in which the downstroke provides a lot of positive lift and drag, and the upstroke provides negative lift resistance. (ii) Counter stroking flight is the flight mode of the dragonfly when it is in stable and level flight, in which the positive and negative lift and drag of the fore and hind wings cancel each other out, so that the lift and drag curve is maintained at a low value, and the dragonfly can fly smoothly. (iii) No matter under any flight conditions, the average lift and drag of counter stroking flight is smaller than that in-phase stroking flight, and it can maintain enough lift to support body weight, indicating that counter stroking flight can keep the dragonflies stable.

MULTISCALE THEORY AND SIMULATION METHOD OF THE ANISOTROPIC DAMAGE BEHAVIOR OF DOUBLE NETWORK HYDROGELS

Jincheng Lei[*1] and Zishun Liu*[1]

[1]*State Key Laboratory for Strength and Vibration of Mechanical Structures, Xi'an Jiaotong University*

ABSTRACT

Double network (DN) hydrogels are a type of hydrogels composed of two interpenetrated polymer networks and water. It shows great potential to be applied in biomedicine and soft electronics areas etc., because of the superior flexibility and biocompatibility. In DN hydrogels, the first polymer network is crosslinked by shorter polymer chains and the second one is crosslinked by longer polymer chains. During the deformation of DN hydrogels, the polymer chains in the first polymer network are first straightened to fracture in succession, forming the microdefects, while the second polymer network with longer chains supports the bulk structure and reduces the stress concentration effectively. Thus, the toughening mechanism of DN hydrogels compared to single network hydrogels is to damage the first polymer network. Although current damage theories can capture the stress softening phenomenon of DN hydrogels, they encounter difficulties in describing and predicting the necking phenomenon of DN hydrogels, just because the multiscale mechanism of the damage behavior of DN hydrogels is still ambiguous. In this work, we conduct a multiscale investigation on the bottom-up damage mechanism, damage theory and simulation methods of DN hydrogels. We construct the random structural models of DN hydrogel in microscale using molecular dynamics methods at first. Then, the mesoscale topological network models are extracted from the microscale models with specific length and fracture criterion of every polymer chains. By developing a network mechanics method, we simulate the fracture of polymer chains and the damage of the mesoscale network models, and provide the damage behavior for developing macroscale anisotropic damage theories. The anisotropic damage theories are then numerically implemented by finite element methods. Our damage theories and simulation methods can reproduce the stress softening and necking phenomena effectively. This work provides insights on the multiscale damage mechanism of DN hydrogels and powerful simulation tool for mechanics design of DN hydrogels.

RIPPLOCATIONS IN GRAPHITE LAYERED COMPOSITES

Xiaowen Lei[*1], Mengying Li[1] and Toshiyuki Fujii[1]*

[1]Tokyo Institute of Technology

ABSTRACT

Layered structures involve the consolidation of single-layer materials through adhesive processing to solidify them into a layered form that meets specific structural requirements such as low weight, high strength-to-weight ratio, high stiffness-to-weight ratio, and fatigue resistance. The introduction of graphene nanosheets into a matrix to form layered composites can significantly improve the mechanical properties of the material. Therefore, graphite layered composites have great potential for various applications. However, at present, the theoretical calculation models for layered composites often overlook the commonly occurring interlayer deformation phenomenon and fail to effectively reflect the interlayer mechanical properties. We combine the mechanics and geometry to elucidate the deformation mechanisms of graphite layered composites.

In this study, molecular dynamics (MD) methods are used to describe the mechanical response and microevolution processes of graphite layered composite under tensile and compressive loading, revealing the microscopic evolution mechanisms that contribute to the differences in mechanical response under these two types of loading (1). At the same time, the effect of the number of graphene layers on the Young's modulus of the composite material is studied by observing the atomic structural changes under fracture conditions. During the compression simulation, kink and ripplocation deformation are observed, which are commonly generated in layered solids, but the deformation mechanisms are not clear. Due to the complex curved surfaces that occur during the compression simulation, the mean curvature and Gauss curvature based on the differential geometry methods are used to describe the non-uniform deformations (2). We calculate the external deformation of layered materials, and elucidate the reinforcement mechanism of graphene addition to the matrix and the deformation mechanism (3). The results show that ripplocation is a fully reversible elastic deformation, and it is found that ripplocation boundaries of the same sign integrate when compressed under certain conditions. Compared to existing studies, we are the first to use differential geometry methods to calculate the in-plane deformation of composites. This provides theoretical guidance for the design of high-strength, high-toughness graphite layered composites.

ANALYZING TIME-LAPSE MICROSCOPY DATA TO QUANTIFY AND UNDERSTAND THE BEHAVIOR OF MECHANOBIOLOGICAL SYSTEMS

Emma Lejeune[*1]*

[1]*Boston University*

ABSTRACT

From the beating heart to tissue assembly and repair, it is well accepted that mechanics plays an important role in the behavior of biological systems. Mechanical forces are not only fundamentally important to biological materials (e.g., the mechanics of growth), but are also fundamental drivers of cellular behavior change. However, it is often difficult to determine mechanical state both in vitro and in vivo, and it is often difficult to determine how mechanical perturbations (e.g., changes to boundary conditions) will change the mechanical state throughout the domain. Mathematical and computational modeling are important tools to bridge this gap, and image-based data is often the glue that connects mechanical theory to experimental data. In this talk, we will describe our preliminary and ongoing work in curating and disseminating microscopy data and software tools for data analysis and modeling. Specifically, we will focus on an ongoing project with collaborators in developing computational tools and mechanics based understanding of an in vitro three dimensional tissue model of wound healing. In brief, we envision a methodological framework with three essential components: (1) open access datasets of time-lapse movies of cells and tissue, (2) open source software to extract interpretable quantities of interest from these time-lapse movies, and (3) combined mechanistic and statistical models of biological behavior informed by these data. We are presently working on creating these datasets, software, and models in partnership with experimental collaborators, and releasing them to the community under permissive licenses. Looking forward, we anticipate that these large open access curated datasets combined with open source tools to extract information from them will enable significant advances in our understanding of, and ability to control, living systems. Through this talk, we hope to foster further discussion and collaborations at the interface of biomechanics, image analysis, and open science.

THE HEMODYNAMIC IMPACT OF INTRACRANIAL ARTERIAL STENOSIS AND THE CLINICAL IMPLICATIONS

Xinyi Leng[*1]*

[1]*The Chinese University of Hong Kong*

ABSTRACT

Intracranial arterial stenosis (ICAS) is a major cause of ischemic stroke around the world. It can cause an ischemic stroke by different mechanisms, e.g., the lesion (plaque) occluding the orifice of a branching artery to cause a single small infarction in the relevant territory, significant narrowing of the vessel lumen to cause hypoperfusion and possibly multiple infarcts in borderzone regions, and an unstable plaque to rupture and cause embolization of distal arteries and possibly multiple infarcts in the distal territory (cortical regions).

Presence of ICAS can impact focal and global hemodynamics. For instance, it is associated with elevated flow velocity and wall shear stress across the lesion and decreased pressure distal to the lesion, which can be affected by the morphology of adjacent arteries and the ICAS lesion. The hemodynamic impact of ICAS has important clinical implications, e.g., affecting the stroke mechanisms and risks in patients with ICAS. Those with significantly reduced pressure distally may have hypoperfusion, and those with significantly elevated wall shear stress may have increased plaque vulnerability and risk of plaque rupture and distal embolization. These both are associated with a higher risk of stroke relapse in patients with a first stroke due to ICAS, despite medical treatment recommended by clinical guidelines.

Therefore, studying the hemodynamic impact of ICAS has important value for stroke risk stratification in ICAS patients, based on which we can identify “high-risk” patients and design more effective treatment for stroke prevention.

ARBITRARY ORDER VIRTUAL ELEMENT METHODS FOR HIGH-ORDER PHASE-FIELD MODELING OF DYNAMIC FRACTURE

Yu Leng[1], Lampros Svolos[2], Ismael Boureima[1], Gianmarco Manzini[1], JeeYeon Plohr[1] and Hashem Mourad[1]*

[1]*Los Alamos National Laboratory*
[2]*University of Vermont*

ABSTRACT

Accurate modeling of fracture nucleation and propagation in brittle and ductile materials subjected to dynamic load is important in predicting material damage and failure under extreme conditions. The exact solution of the high-order phase-field fracture model has higher regularity. Thus numerical solutions of the model can embrace improved convergence and better accuracy. Virtual element methods are generalization of classical finite element methods and allow polytopal meshes. In this work, we develop a virtual element framework for the high-order phase-field model of dynamic fracture. We use H^1-conforming virtual elements and generalized-α method for the elastodynamic equation, and adopt H^2-conforming virtual elements for the high-order phase-field equation. We verify our virtual element framework using classical quasi-static benchmark problems and show numerical examples for dynamic fracture propagation.

EFFECTS OF OFFSHORE WIND ENERGY ON THE OCEAN CIRCULATION

Miguel Guzmán Hernández[1] *and Stefano Leonardi**[1]

[1]*The University of Texas at Dallas*

ABSTRACT

A one-way ocean-atmosphere coupling was developed to study the effects of offshore wind turbines on the surrounding oceanic regions. This was achieved by coupling the results of our in-house wind farm simulator UTD-Wind with FVCOM (unstructured Finite Volume Community Ocean Model). In the present study, Large Eddy Simulations were carried out to model the atmospheric boundary layer and wind turbines. The immersed boundary method was used to simulate the floating platform, tower, and nacelle, whereas the turbine blades were modeled using a rotating actuator disk model. The angular speed of the turbine was determined by the balance of aerodynamic and generator torque. The LES velocity fields were used as input by FVCOM to compute a space-time varying wind shear that served as forcing for the ocean model.

Numerical results show that wind turbines produce a low velocity wake region that impact the wind shear forcing acting on the sea surface current. Due to the wind shear gradient, upwelling is generated to counteract the lower velocity region underneath the turbine wakes. For conservation of mass, downwelling was produced in the adjacent regions of the turbine wakes, generating large vortices normal to the turbine rotor and across the depth of the domain. These results show the complex hydrodynamics occurring below offshore wind turbines. Potentially, these vortices could enhance the exchange of nutrients from the richer bottom of the ocean to the upper sea surface level. As a consequence, this could promote the growth of oceanic wildlife in the regions where the wind turbines are located.

This research contributes towards the wind energy field by utilizing numerical simulations to study the complex hydrodynamics occurring in the surroundings of offshore wind farms. It will be a large motivator to further study the presented research topic and explore how offshore wind turbines can positively impact the surrounding ecosystems. This topic can demonstrate the added benefits of developing offshore wind energy, not only because of its reduced carbon footprint, but additionally because of its positive environmental impact. In the long term, it could potentially contribute to making offshore wind a more dependable source of energy.

[2]*Universidade Estadual Paulista "Júlio De Mesquita Filho"*

ABSTRACT

Magneto Rheological Elastomers (MRE) are composite intelligent materials, which can substantially change their viscoelastic properties due to their high magneto-sensitivity in response to different regimes of external magnetic field. Under the influence of a magnetic field, both storage shear and loss factor of MREs increase, this field-induced phenomenon is often referred to as the magnetorheological effect. The practical application of MR materials demonstrates great potential for several areas, as indicates the increasing number of patents registered in the last decade. This research is included in a line aimed to develop MRE devices for structural vibrations' control, exploring the magnetorheological effect and its capacity to promote gains in viscoelastic properties, thus enabling changes of relevant magnitudes in structural systems, such as the natural frequency and damping ratio. This adaptive behavior can be studied by the analysis of qualitative numerical simulations, this study proposes to investigate the effectiveness of MRE devices on wind induced aeroelastic oscillations (galloping equation), the results are obtained by the Multiple Scale Method and numerical integrations, showing a trajectory suppression on the phase-plane of limit cycles to focal points, as well as a three-fold change in the critical speed and alterations on the shape of the Hopf’s bifurcation diagram.

GO-MELT: GPU-OPTIMIZED MULTILEVEL EXECUTION OF LPBF THERMAL SIMULATIONS

Joseph Leonor[*1], Mohammad Elahi[1] and Gregory Wagner[1]*

[1]*Northwestern University*

ABSTRACT

Computationally modeling the melt pool in a part-scale LPBF model is expensive despite the fact that the laser only covers a small area within the entire domain. Hence, we developed GO-MELT, a multilevel approach inspired by VMS, to address this problem. To calculate the solution for a part-scale model, we couple three overlapping levels. In Level 1, we compute the coarse-scale temperature solution over the full domain. In Level 2, the meso-scale temperature solution that spans the melt pool region is solved. In Level 3, the fine-scale thermal solution in the immediate region around the laser is calculated. Subgrid scales are computed from both Levels 2 and 3. Overlapping meshes can track a moving laser for the full duration of the simulation without remeshing. As a result, GO-MELT can efficiently implement GPU acceleration using Google's JAX library with JIT compilation to significantly speed up the simulation. We conducted five case studies using GO-MELT to demonstrate proper convergence behavior, to show how fewer DOFs are required to reach the same accuracy as a uniform mesh, and to quantify execution time per timestep added per DOF in each level. Using GO-MELT, a simulated production run of a 10 mm cube required around 9.36 hours to complete 20.5 million time steps, averaging 1.64 ms per time step. For the same spatial resolution used in the melt pool region, GO-MELT is 678 times faster than a GPU-accelerated uniform mesh solver. We also demonstrate efficient simulation of a more complicated part geometry, including phase- and temperature-dependent properties that capture the effects of powder melting and fusion. Finally, we show that the fine-scale solution can be replaced by an alternative model, such as a data-driven surrogate model, giving the opportunity to further bridge simulation scales and improve both the speed and efficiency of part-scale LPBF simulations.

EFFICIENT SEMANTIC SLAM: LEVERAGING DEEP LEARNING FOR ENHANCED SLAM IN DRONE FORESTRY SURVEILLANCE UNDER CANOPY

Pierre Leroy[*1], Emmanuelle Abisset-Chavanne[1], Marco Montemurro[1] and Regis Pommier[1]*

[1]*I2M*

ABSTRACT

This paper introduces an efficient approach for generating a real-time Simultaneous Localization and Mapping (SLAM) system using a stereoscopic camera mounted on a drone in an outdoor environment. Specifically, the study focuses on mono-species maritime pine forests, with an average spacing of four meters between tree rows. The primary objective is to generate a semantic map that accurately identifies the tree rows, enabling the automated estimation of an optimal trajectory that maximizes the distance between the rows to minimize the risk of collision. Standard Visual SLAM (VSLAM) algorithms, particularly those based on graph theory, are sensitive to lighting conditions because they identify, characterize, and re-associate landmarks across successive images. To operate effectively, VSLAM algorithms calculate a significant number of landmarks, enhancing robustness against occlusions and assignment errors.

In this presentation, we describe a rapid, efficient, and semantically-driven SLAM approach, leveraging object segmentation via deep learning. We have developed a robust and efficient image segmentation method that identifies nearby trees in each image. For these stationary objects, Kalman filter-based tracking techniques are employed to re-identify each tree throughout the video stream. A unique geometric feature, the centroid of each tree, is extracted and integrated into our graph-based SLAM algorithm. In this graph, each tree represents a single node, and the edges connecting different drone positions to a tree node represent depth estimations from the stereoscopic camera. Our method ensures a controlled graph size, maintaining compatibility with real-time operational scenarios.

To validate the effectiveness of the proposed method, it has been applied to real-world data collected from forest environments. This approach not only demonstrates the potential for more efficient and accurate environmental mapping but also represents a significant step forward in the application of AI and deep learning techniques in the field of robotic navigation and environmental monitoring.

PROBABILISTIC CALIBRATION OF EXPENSIVE MODELS USING EFFICIENTLY TRAINED SURROGATES

Patrick Leser[*1] and Joshua Fody*[1]

[1]*NASA*

ABSTRACT

Calibration of computational models in the presence of uncertainty is often cast as a Bayesian inference problem and solved via sampling methods, e.g., Markov chain Monte Carlo. When the computational model is expensive, this task becomes intractable due to the large number of samples required to accurately estimate the posterior distribution of the calibration parameters. A popular solution to this problem is to use machine learning to develop a faster-to-evaluate, lower-fidelity substitute for the original model to serve as a surrogate while solving the inference problem. Although considered an offline cost, generating training data to construct this surrogate model can still be an expensive task in practice.

An active learning algorithm is presented that focuses training on improving surrogate accuracy specifically in and around the bulk of the posterior distribution, as this is where the model is exercised during calibration. Candidate samples are drawn from families of distributions related to an approximation of the posterior. The sample maximizing predictive variance is then selected for evaluation by the original computational model, yielding a label for the training point. Iterating this approach increases efficiency relative to space filling designs (e.g., Latin hypercube sampling) by avoiding low probability points. Practical considerations are discussed, including the benefits of using a sequential Monte Carlo sampling approach, convergence heuristics, and the importance of both exploration and exploitation given that the true posterior is unknown a priori.

DATA-DRIVEN SURROGATE MODELLING OF RESIDUAL STRESSES IN LASER POWDER-BED FUSION

Lucas Lestandi[*1], JC Wong[2], GuoYing Dong[3] and Mark Jhon[2]*

[1]*Ecole Centrale de Nantes*
[2]*A*STAR, Institute of High Performance Computing*
[3]*University of Colorado, Denver*

ABSTRACT

In order to enable the industrialization of additive manufacturing, it is necessary to develop process simulation models that can rapidly predict part quality. Although multi-physics simulations have shown success at predicting residual stress, distortion, microstructure and mechanical properties of additively manufactured parts, they are generally too computationally expensive to be directly used in applications, such as optimization, controls, or digital twinning. In this talk we present a critical evaluation of how data-driven surrogate models can be used to model the residual stress of parts fabricated by Laser Powder-Bed Fusion. Three different models using varying levels of sophistication are compared: a multilayer perceptron (MLP), a convolutional neural network (CNN) based on the U-Net architecture, and an interpolation-based method based on mapping geometries onto a reference. All three methods were found to be sufficient for part design, providing mechanical predictions for a CPU time below 0.2 s, representing a runtime speed-up of at least 3900 × . Neural network-based models are significantly more expensive to train compared to using interpolation. However, the generality of models based on the U-Net architecture is attractive for applications in optimization.

OPTIMAL PATH PLANNING FOR LPBF AS AN EQUALITY GENERALIZED TRAVELING SALESPERSON PROBLEM

Adrian Lew[*1], Gradey Wang[1] and Eric Darve[1]*

[1]*Stanford University*

ABSTRACT

Planning a laser path in Laser Powder Bed Fusion (LPBF) printers may benefit from being optimized to improve certain conditions for a print, such as minimizing a measure for the induced temperature gradients with the hope it is correlated with residual stresses, or increasing the overall time each part of a print remains hot to partially temper it. The simplest version of this problem discretizes the laser path as a sequence of tiles and aims to determine the order in which the tiles are to be heated by the laser.

In this talk we show that the problem of determining an optimal tile ordering can be reduced to an Equality Generalized Traveling Salesperson Problem (E-GTSP), a reduction that opens the problem to be solved through commonly used heuristics. We then demonstrate the performance of this identification towards solving some simple LPBF path planning problems.

A STABLE HYPERELASTIC MODEL FOR FOAMED RUBBER OVER A LARGE RANGE OF POROSITY

Matt Lewis[1]*

[1]*Los Alamos National Laboratory*

ABSTRACT

A hyperelastic model for foamed rubber is presented. The model is a modification of the CHIPFoam (Compressible, Hyperelastic, Isotropic, Porosity-based Foam model) model. The strain energy is in terms of the first isochoric invariant, $\bar{I}_1$, of the Cauchy-Green tensors and the relative volume, J. The model includes a function that couples deviatoric and volumetric deformation. The onset of this coupling function may be delayed based on the porosity of the foam or on the morphology of the porosity. The relative volume is multiplicatively decomposed into a part derived from isochoric deformation of the rubber and a part resulting from compressibility of the rubber.

In addition to this delayed action of the pore compression function, the volumetric buckling function in CHIPFoam was modified. This modification leads to a more stable and more easily converged response.

The model may be applied for foams with initial porosities that range from less than one percent to porosities of greater than 99 percent. The model includes a simple elastic damage model for an elementary form of cyclic softening. It does not include any other dissipative deformation mechanisms. It is therefore only appropriate for materials with very little hysteresis or for monotonic loading only.

The model basis and examples of model fits to a variety of foams will be presented. Additionally, some thoughts on the inclusion of viscous deformation effects will be discussed.

MESH ADAPTATION FOR FREE SURFACE FLOW SIMULATIONS USING THE PARTICLE FINITE ELEMENT METHOD

Thomas Leyssens[*1], Jonathan Lambrechts[1] and Jean Francois Remacle[1]*

[1]*Université Catholique de Louvain*

ABSTRACT

The Particle Finite Element Method (PFEM) [1] is a strong approach for simulating free surface flows, fluid-structure interactions (FSI), and other applications featuring highly deformable domain geometries. A hybrid method that seamlessly integrates Eulerian-based solvers and particle methods, PFEM takes advantage of both approaches. In essence, PFEM represents the fluid using a set of particles, which are triangulated at each time step to construct a mesh. The conservation equations are then solved on this mesh through the finite element method, yielding the material velocity for each particle. Subsequently, using this velocity information, the particle positions are updated, resulting in a dynamically deformed domain that is triangulated again in the following time step.

Central to the PFEM's effectiveness is the need to detect domain boundaries, a key aspect that also presents one of its primary challenges. Given that the particles are triangulated again in each time step, the shape of the fluid domain requires continuous redefinition. This necessitates the use of an indicator function to discern the fluid's shape, akin to the challenge of detecting the shape of a point cloud. By combining the alpha-shape algorithm, initially proposed by Edelsbrunner [2], with a mesh adaptation step based on Delaunay refinement algorithms [3], we enhance the overall method. This approach demonstrates consistency, particularly in terms of addressing the significant challenge of volume conservation inherent in Lagrangian methods.

Our study will present comprehensive results in both 2D and 3D for free surface flows, showcasing advancements and demonstrating the efficacy of our method. Additionally, we will explore aspects of coupling with other discretisation methods, such as discrete element methods and solid mechanics finite elements, particularly in the simulation of FSI problems.

ANALYSIS OF THERMOMECHANICAL DELAMINATION MECHANISMS IN SEGMENTED HIGH-TEMPERATURE PROTECTIVE COATINGS AND DESIGN MAPS FOR THE DURABLE COATINGS

Biao Li[1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

Protective coatings play a crucial role in preserving high-temperature engineering components from environmental degradation. The durability of these coatings is crucial for maintaining the structural integrity of the components. Introducing a segmented microstructure was recognized as an effective strategy for enhancing the strain tolerance of coatings by mitigating the in-plane stiffness of the coatings, thereby alleviating interface stresses and delamination driving forces. While previous studies on delamination mechanisms in high-temperature protective coatings have predominantly focused on either pure mechanical loading or pure thermal loading conditions (i.e., residual stress) due to their ease of implementation, the combined influence of both loads remains relatively unexplored. This work systematically studies delamination problems in segmented multilayered high-temperature coatings subjected to thermomechanical loadings using computational fracture mechanics. A representative unit cell model is introduced, which is used to analyze coatings over a broad range of material properties, geometries, and loads. The findings suggest that, for a given coatings system, the mechanical load carried by the top-coat layer is the only force driving delamination along the top-coat/bond-coat interface. A mathematical model is established using combined multiple regression analyses and the design of experimental method to evaluate the delamination driving forces and rank the importance of various influential factors. Design maps are constructed to facilitate the development of durable coatings.

REACTIVE DIFFUSION OF LITHIUM IN SILICON – NEW INSIGHT FROM ATOMISTIC SIMULATIONS

Bin Li[*1] and Jun Xu*[2]

[1]*Iowa State University*
[2]*University of Delaware*

ABSTRACT

Atomistic simulations are performed to investigate the insertion of lithium (Li) in crystalline silicon (c-Si) by using a modified embedded atom method potential. The mechanism for the formation of the amorphous a-LixSi was analyzed by conducting novel structural analysis. Diffusion pathways of Li in c-Si and the energy barrier are also analyzed and calculated. The results show that Li atoms diffuse preferably along the 112 directions on the {111} planes, and the energy barrier is too high for thermally activated diffusion around room temperature. The formation mechanism for the amorphous/crystalline interface (ACI) is also analyzed. The diffusivity of Li in Si is calculated based on the simulation results. Our results show that the diffusivity of Li in the a-LixSi is about 50~100 times faster than in the c-Si. Our results also show that the composition of Li in the a-LixSi is non-uniform during lithiation, and the distribution of Li is analyzed. The simulation results are compared with the available experimental results.

STABILIZED FORMULATION FOR PHASE-FIELD FRACTURE IN NEARLY INCOMPRESSIBLE HYPERELASTICITY

Bin Li[1], Ida Ang[2] and Nikolaos Bouklas[2]*

[1]*Guangdong Technion-Israel Institute of Technology*
[2]*Cornell University*

ABSTRACT

This work presents a stabilized formulation for phase-field fracture of hyperelastic materials near the limit of incompressibility. At this limit, traditional mixed displacement and pressure formulations must satisfy the inf-sup condition for solution stability. The mixed formulation coupled with the damage field can lead to an inhibition of crack opening as volumetric changes are severely penalized effectively creating a pressure-bubble. To overcome this bottleneck, we utilize a mixed formulation with a perturbed Lagrangian formulation which enforces the incompressibility constraint in the undamaged material and reduces the pressure effect in the damaged material. A mesh-dependent stabilization technique based on the residuals of the Euler–Lagrange equations multiplied with a differential operator acting on the weight space is used, allowing for linear interpolation of all field variables of the elastic subproblem. This formulation was validated with three examples at finite deformations: a plane-stress pure-shear test, a two-dimensional geometry in plane-stress, and a three-dimensional notched sample. In the last example, we incorporate a hybrid formulation with an additive strain energy decomposition to account for different behaviors in tension and compression. The results show close agreement with analytical solutions for crack tip opening displacements and performs well at the limit of incompressibility.

NUMERICAL SIMULATION OF MATERIAL STRENGTH OF CMCS BASED ON CT DATA RECONSTRUCTION

Guoqing Chen[1], Leijiang Yao[1] and Bin Li[1]*

[1]Northwestern Polytechnical University

ABSTRACT

Ceramic-Matrix-Composites are an important material candidate for thermal structures in aero engines. To investigate the strength failure of CMC materials occurring at ordinary temperature service, this paper establishes a detailed geometric model of the material by obtaining the material structure and defect distribution characteristics through CT technology and establishes a strength prediction model of ceramic matrix composites at ordinary temperature by writing different material subroutines for the failure modes of different kinds of materials.

First, we carried out the geometric analysis model and FEM model construction for 2D-C/SiC composites containing defects. Using μX-CT technique, we conducted CT scans on four specimens of 2D-C/SiC composites at different locations and sizes, respectively. Based on the CT slice data obtained from the scans, the volume fraction and location distribution of defects were obtained by reconstructing and analyzing the material defects. Meanwhile, by analyzing the CT slice data, we obtained the geometric parameters of fiber bundles in 2D-C/SiC composites, characterized the geometry of fiber bundles more accurately, and placed the hole-type defects completed by the analysis into them, and finally obtained the single-layer finite element analysis model of 2D-C/SiC composites and the structural FEM of 2D-C/SiC composites.

Next, numerical simulations of the strength of 2D-C/SiC composites were performed. Based on FEM, the fiber bundles consisting of fibers and matrix are equated to a homogeneous material by the known use of the equivalent homogenization method. By writing the VUMAT subroutine, we defined the fiber bundle failure criterion and the matrix failure criterion respectively, and simulated the static tensile process of the material. In the simulation, we found that during the static stretching of the material, the damage of the material occurs first below the location of the coating cracks, and the cracks gradually expand downward with the increasing tensile load. After the failure of the first layer, the crack expansion path changed clearly from directly below the coating crack defect to the maximum bending position of the woven structure, which is more in line with the crack expansion law of CMC material in the static tensioning process. Through the numerical simulation analysis of the static tensile strength of the material at room temperature, the tensile strength of the material at room temperature was determined, and the reliability of the finite element model was also verified by combining the test results. This supports the effective data for ceramic matrix composites in material design and engineering applications.

RELIABILITY ANALYSIS OF CABLE-STAYED BRIDGE SYSTEM BASED ON DIRECT PROBABILITY INTEGRAL METHOD

Bingzhu Li[*1], Zhenhao Zhang[1] and Mengmeng Tao[1]*

[1]Changsha University of Science and Technology

ABSTRACT

The system reliability analysis of cable-stayed bridges is an important part of structural safety analysis, and this paper proposes a method to analyze the overall dynamic reliability of prestressed concrete cable-stayed bridges based on the direct probability integral method. Firstly, the limit state equations of the main girder bending strength failure, wind-induced vibration failure and the main tower strength damage failure in the downward direction and the transverse direction buckling failure as well as the strength damage failure of the tie ropes of the cable-stayed bridge are established. Then the reliability analysis of the whole bridge cables is carried out, and the most dangerous three pairs of cables are selected to form a series-parallel system with the failure modes of the main girders and towers of the cable-stayed bridge, and the joint probability density integral equations of the extreme value mapping of multiple performance functions are established. Finally, the equations are solved using the direct probability integration method containing Heaviside function (DPIM-H) to obtain the overall dynamic reliability index of the cable-stayed bridge, and the Monte Carlo method is used to verify the reasonableness of the results. Taking the prestressed concrete cable-stayed bridge as an example, the system degree is analyzed by DPIM-H as well as the reasonableness of the results is verified by Monte Carlo.

PORE-SCALE STUDY OF MULTIPHASE FLOW PATTERNS IN LAYERED POROUS MEDIA WITH FRACTURES

Bo Li[*1], Hao Yu[1] and HengAn Wu[1]*

[1]*University of Science and Technology of China*

ABSTRACT

The presence of fractures increases the difficulty of multiphase flow mechanism analysis, and it remains unclear how fractures affect multiphase flow displacement in the layered rock matrix. Herein, a pore-scale imbibition model considering the layered matrix-fracture system is established using the phase-field method, where oil is displaced by a range of fluids with various properties. Two typical flow modes are carefully analyzed, depending on the locations of the fracture and the interfaces between different layers of the matrix: fracture is parallel to the interface (mode I) and it penetrates through the interface (mode II), which are dominated by the co-current imbibition and counter-current imbibition mechanisms, respectively. Interestingly, the surface tension is found to be negatively correlated with the ultimate oil recovery rate for mode I and plays an opposite effect on that of mode II. For flow mode I, the conditions of lower injection rate, higher viscosity ratio, higher grain diameter ratio, and injection of the invading fluid from the larger pore throat size (positive direction flow) can improve oil recovery. For flow mode II, the fracture bifurcation angle has little effect on the positive direction flow, while it can significantly regulate the phase distribution in the negative direction flow. Based on the scaling analysis of relating pore-filling events to displacement modes and the equilibrium relationship between capillary and viscous forces, two theoretical models are derived to predict the imbibition patterns, and the variation of the flow regime under various parameters in the typical layered matrix-fracture models is systematically concluded.

IMAGE-BASED MESOSCOPIC SIMULATIONS OF ALLOYS

Bingbing Chen[1] and Chenfeng Li[1]*

[1]Swansea University

ABSTRACT

Polycrystalline materials consist of aggregates of grains with varying lattice orientations and sizes separated by grain boundaries. The random morphological and crystallographic microstructure characteristics are responsible for the anisotropic behavior of polycrystalline microstructures and determine their macroscopic properties and performance. The mechanical properties of alloys, including stress and strain response and elastoplastic anisotropy, are significantly affected by morphological and crystallographic (grain orientation, etc.) features.

The present studies of the microstructure effect on mechanical properties and performance have certain limitations. Research methodologies are mainly limited to representative volume elements (RVEs)-based experimental observations. In practice, the microstructure characterizations exhibit a large degree of randomness during deformation processing, and microstructure randomness reveals polycrystalline materials' probabilistic properties and performance. Consequently, the vast size and number of the microstructure RVE necessary to build the process–structure–properties–performance (PSPP) linkages are computationally prohibitive and challenging to investigate. Meanwhile, the simplified polycrystalline microstructures, such as single crystals, bicrystals, Voronoi, and ellipsoid polycrystals, fail to capture all the statistical microstructure characterizations of the heterogeneous grains. Aa a result, the datasets between microstructural characteristics and mechanical properties and performance are unlikely to be built without sufficient data.

In this work, we propose a patch-based texture synthesis reconstruction algorithm to accurately capture the statistical microstructure characterizations of the heterogeneous grains. Then, the established computational plasticity FEM model combined with explicit characterization algorithms was used to perform quantitative analysis on Inconel 718 superalloy to fully understand the macroscopic properties and performance responses (ultimate tensile strength, Von Mises stress, ductile failure initialization and propagation) in terms of morphological, crystallographic, and boundary characteristics. Finally, the patch-based texture synthesis coupled with explicit characterization algorithms was developed to determine the ductile failure sets using the microstructural parameters, such as grain orientation and boundary characters.

LOAD-AREA RELATION OF RANDOM ROUGH SURFACES FOR LARGE CONTACT FRACTION

Chengya Li[*1], Yue Ding[1], Xuan-ming Liang[1] and Gangfeng Wang[1]*

[1]Xi'an Jiaotong University

ABSTRACT

Establishing the accurate load-area relation is pivotal for comprehending complex phenomena such as friction, wear, and thermal and electrical conduction, particularly for large contact fraction. Unfortunately, prevailing contact models often fall short in capturing behaviors across the entire contact regime due to the oversight of intricate asperity interactions, especially in high load level. In this investigation, we address the challenge by incorporating asperity interactions in both elastic and elastic-plastic contact. The actual random distribution of contacting spots with various sizes is simplified as a hexagonal distribution of identical spots sharing the same quantity and total area. Leveraging the perfect symmetry, a representative asperity is then simulated by finite element method and asperity interaction is incorporated through the periodic boundary condition. The load-area relation is calculated up to almost complete contact. It is interesting to find that surface morphology and material properties predominantly affect the initial linear relation at small contact fraction, and the interactions among asperities are closely related to contact fraction and lead to a larger load than that neglecting asperity interactions. By comparing with the theoretical prediction of an incremental equivalent contact model at initial contact, the load-area relation is extended for general rough surfaces. Direct simulations on typical rough surfaces verify the accuracy of the advanced load-area relation within a large range of contact fraction. This developed model provides an efficient method to predict the overall contact response of rough surfaces, significantly reducing the computational burden. The advancement serves as a robust foundation for in-depth analyses in tribology, laying the groundwork for a nuanced understanding of friction, wear, and sealing behaviors.

BI-MATERIAL TOPOLOGY OPTIMIZATION FOR VIBRO-ACOUSTIC PROBLEMS BASED ON NON-NEGATIVE INTENSITY

Dan Li[*1] and Haibo Chen*[1]

[1]*University of Science and Technology of China*

ABSTRACT

In this work, the non-negative intensity (NNI) method is applied to a large-scale vibro-acoustic interaction system using the fast multipole boundary element method (FMBEM), and a bi-material topology optimization method is constructed to minimize the integration of non-negative intensity on predefined surfaces. The NNI provides a field on the surface of the radiating structure, consisting of positive-only contributions to the radiated sound power, which avoids the near-field cancellation effects that otherwise occur with the sound intensity field [1]. To intuitively characterize the contribution degree of structural surface to far-field radiation and provide a theoretical basis for acoustic radiation analysis and design of large-scale vibro-acoustic interaction systems, the FMBEM is adapted to the NNI by calculating the eigenvalue solution of the symmetric acoustic impedance matrix using a two-stage solution method. The fast multipole algorithm is adapted to accelerate the calculation of matrix vector products of adjoint problems. The topology optimization of a large-scale submerged cylindrical shell model is realized using FMBEM [2]. The vibro-acoustic interaction system is first solved using a FEM–FMBEM model, and the resulting surface fields are then used in the FMBEM calculation of the NNI. The integration of the NNI on the predefined surface is selected as the objective function to design the radiation mode of the structural surface. A structural material interpolation model is established using the solid isotropic material with the penalization method, and the topological sensitivity formulation is derived based on the adjoint variable method. Numerical results confirm the effectiveness of the proposed optimization method in minimizing the integration of the non-negative intensity.

Keywords: FEM-FMBEM coupling analysis; topology optimization; non-negative intensity

Funding Statement: This study was financially supported by the National Natural Science Foundation of China (NSFC) under Grant No. 12172350.

MULTI-PHYSICS FRACTURE ANALYSIS OF COMPOSITE LAMINATES BASED ON EXTENDED LAYERWISE METHOD

Dinghe Li[*1]

[1]*Civil Aviation University of China*

ABSTRACT

An extended layerwise method (XLWM) is presented for the composite laminates with multiple delaminations and transverse cracks. The discontinuity of displacements and temperature induced by multiple delaminations is simulated by strong discontinuous function while the discontinuity of strain between dissimilar layers is modeled by a weak discontinuous function. Transverse cracks are modeled using classical Extended Finite Element Method (XFEM). And then, based on the XLWM, some mixed variational principle is employed or presented to derive the Euler equations and the discrete forms for the multi-physics fracture analysis of composite laminates. A fully coupled time integration method is developed based on the Newmark integration algorithm and Crank-Nicolson scheme, the multi-physics fields are solved simultaneously. The thermo-mechanical, thermo-chemo, thermo-chemo-mechanical, piezoelectric-mechanical, thermo-piezoelectric-mechanical and thermo-mechanical-curing-seepage coupling analysis are carried out numerically for the damaged composite laminates. Many numerical examples are studied to demonstrate the capabilities of static response, stress intensity factor and energy release rate for the composite plates, stiffened plates and sandwich plates.

CREEP LIFE MODELLING OF NICKEL-BASED SINGLE CRYSTAL SUPERALLOY DD6 WITH MCRALY COATING

Dongxu Li[1], Chaoji Wang[2], Shengwei Pan[2] and Xueling Fan[1]*

[1]*Xi'an Key Laboratory of Extreme Environmental and Protection Technology, Xi'an Jiaotong University*
[2]*AECC Guiyang Engine Design Research Institute*

ABSTRACT

Single-crystal superalloy is a crucial structural material widely employed in aerospace, energy, and petrochemical industries. High-temperature creep resistance is a critical indicator for evaluating alloys. In this study, a method for predicting the creep behavior of MCrAlY-coated DD6 single crystal alloy was proposed, and the influences of oxide layer thickness and inner wall temperature on the creep strain rate were investigated. The model was validated experimentally. The results indicate that the MCrAlY coating has a minimal impact on the high-temperature creep lifetime of [001]-oriented DD6 single-crystal superalloy. Pre-exposure treatment thickens the initial oxide layer of the coating, effectively extending the creep lifetime of the coated alloy, particularly at higher temperatures and stress levels. This underscores the effectiveness of pre-exposure treatment in increasing the creep lifetime of the MCrAlY-coated DD6 single-crystal superalloy system. The influence of inner wall temperature on creep lifetime follows a parabolic pattern. Excessively low inner wall temperatures reduce creep lifetime due to significant thermal mismatch stresses, while excessively high inner wall temperatures decrease creep lifetime because of changes in material properties at those temperatures.

TYPE Ⅰ TO TYPE Ⅱ TRANSITION IN SWEPT-FORWARD FIN SHOCK INTERACTIONS

Guangli Li[1], Jing Yang[1] and Kai Cui[1]*

[1]*Chinese Academy of Sciences*

ABSTRACT

The transition from Type I to Type II in the swept-forward fin shock interaction is important, as it represents a shift from low to high heat flux interaction types. However, the mechanism for this transition remains unclear. In this study, theoretical and numerical analyses is employed to explore the transition mechanism. A theoretical model is developed to obtain the analytical solution for the transition condition, considering only the interaction of the incident shock and the bow shock of the fin on the symmetry plane. The theoretical solution is compared with numerical results at a freestream Mach number of 6.36. The results suggest that the transition occurs advanced, with three distinct transition mechanisms observed. At small wedge angles, the downstream flow pattern has an influence on the transition. In the downstream flow, the transmitted shock reflects on the wall as a Mach reflection. If the height of the Mach stem approaches the detachment distance of the fin shock, the transition occurs. At larger wedge angles, the transition occurs when the Mach number behind any one of the two transmitted shocks is less than 1. The other transition is observed at a wedge angle of 30°, which occurs accompanied by the disappearance of the supersonic jet.

SHAPE OPTIMIZATION FOR LITHIUM-ION BATTERY WITH POROUS ELECTRODES

Hanyu Li[1], Jorge-Luis Barrera[1] and Thomas Roy[1]*

[1]*Lawrence Livermore National Laboratory*

ABSTRACT

In this presentation, we introduce a gradient-based shape optimization framework to design porous electrodes for maximum energy storage. Lithium-ion batteries are becoming increasingly important energy storage devices. Highly tortuous electrode materials can provide significant surface area per volume, which is required for large energy density. However, such a tortuosity can also deteriorate electrochemical transport, leading to poor material utilization in planar electrodes. Consequently, architecting electrodes that account for both transport and chemical activity is a promising alternative.

We consider a model with two materials: porous electrode and pure electrolyte. Density-based topology optimization has previously been used to design batteries for both half-cell and full-cell models to maximize energy storage. Despite the capability of producing complex interdigitated structures, an appropriate penalization scheme for intermediate materials is required for the optimizer to provide near binary designs. Setting up such a penalization is often time-consuming due to the large number of design-dependent variables that affect the forward model differently. Alternatively, the shape optimization approach used in this work produces binary designs naturally by morphing conformal meshes, circumventing inaccuracies associated with fuzzy interfaces. Shape sensitivities are computed via the adjoint method and leveraging automatic differentiation. The optimization problem is solved using a nonlinear programming technique.

In this presentation, we perform shape optimization on a half-cell model to maximize its energy storage when a fixed charging current is applied. We study multiple arrangements of physical parameters and compare their performance against a monolithic electrode. Both 2D and 3D results are presented.

STUDY OF TIMOSHENKO BEAM-BASES CRANKSHAFT MODEL WITH NON-LINEAR BREATHING CRACKS

Hongliang Li[1]*

[1]*Harbin Engineering University*

ABSTRACT

With the development of the marine industry, marine diesel engines have the characteristics of complex structure and worse operating environment and frequently changing operating conditions, which put forward higher requirements on the index of shaft vibration. In the actual operation of a diesel engine, the crankshaft will generate three forms of vibration: bending, axial and torsion. These three forms of vibration are coupled with each other. Therefore, it is studied of the three-dimensional coupled vibration problems of the crankshaft system in this paper.

Firstly, the single crank is simplified as a five-segment straight beam structure. Based on the continuum vibration theory, the three-dimensional space field transfer matrix of the straight beam is derived. It is established for the point transfer matrices of coordinate transformation by using the conditions of displacement continuity and force equilibrium. The three-dimensional coupled vibration dynamic equation of the crankshaft system is constructed by using the multiplication of the transfer matrices. By taking modalities as generalized coordinates, there are simple representation for kinetic energy and potential energy of the vibration system. Lagrange equation is used to establish the differential equation of forced vibration of Simple crank system. The response of three-dimensional coupled forced vibration can be solved. A Timoshenko beam-based modelling method is proposed in this study, which considered the cross-section shape effect of the beam and non-linear breathing cracks are inserted as a spring potential energy term of the Lagrange equation.

Secondly, the finite element model of the crankshaft system was built by ANSYS WORKBENCH. The free vibration and forced vibration of the crankshaft system are calculated. The coupling vibration characteristics of the crankshaft system with non-linear breathing cracks under the burst force are analyzed. The results verified the correctness of the theoretical method in this paper.

DATA-DRIVEN MODELLING AND OPTIMIZATION METHOD FOR EFFICIENT MODELING OF COMPLEX STIFFENED CURVED SHELLS

Hongqing Li[*1]

[1]*Dalian University of Technology*

ABSTRACT

A data-driven modelling and optimization method is proposed to automatically model and optimize stiffeners on the complex stiffened curved shells. Firstly, a novel mesh-mapping method is developed for the data-driven modelling of complex stiffened curved shells based on radial basis function surrogate model. Secondly, an active learning-driven control point optimization method is proposed, which can improve the efficiency of modeling. Furthermore, a data-driven optimization approach, based on the deep neural network method, is employed to minimize the weight of the complex stiffened curved shells. Finally, two engineering examples are presented to verify the effectiveness of the proposed method, which reduces the modeling time by 84.9% and 66.3%, respectively, compared to using all control points in mesh-mapping. In conclusion, the proposed method has substantial potential in efficient modeling and improving engineering’s optimization efficiency.

INVESTIGATION OF MESOSCALE FRACKING IN HETEROGENEOUS QUASI-BRITTLE MATERIALS USING A HYDROMECHANICAL COHESIVE PHASE-FIELD MODEL

Hui Li[*1] and Zhenjun Yang[1]*

[1]*Wuhan University*

ABSTRACT

This study develops a mesoscale hydraulic fracturing modelling method combining a hydromechanical cohesive phase-field model with random field (RF) models and random aggregate models for simulating complicated 2D/3D mesoscale hydraulic damage and fracture in quasi-brittle materials. In this method, a Weibull RF generation algorithm is used to implicitly represent the material's fracture properties such as tensile strength and fracture energy, and its meso-structures such as aggregate, mortar, and interfaces are explicitly built using a random aggregate generating and packing algorithm and an aggregate scaling algorithm. The hydromechanical cohesive phase-field model is used to automatically model fluid-driven crack initiation and propagation in mesoscale models without remeshing. Monte Carlo simulations and parameter studies are then carried out to investigated the effects of mesoscale properties on fracking. A concrete cube under hydraulic pressures was analysed as an example. It is found that the predicted crack paths and fluid pressure curves both are stochastically affected by random fracture properties. A higher variance of tensile strength leads to a lower mean and larger standard deviation of peak pressures. Due to weaker fracture properties of aggregate-mortar interfaces than mortar, 3D hydrocrack tends to propagate along interfaces, leading to tortuous and non-planar crack paths after fracking.

CONFINEMENT EFFECTS ON THE THERMODYNAMICS AND FLUID FLOW IN POROUS MEDIA

Jiaoyan Li[*1]*

[1]*University at Buffalo*

ABSTRACT

Unconventional shale recovery requires fundamental understandings of confinement effects on fluids flow behavior. Natural shales have complex pore network and chemical compositions, which prevent systematic study to understand the confinement effects. In this talk, we will present results from molecular simulations and provide insights into pressure-driven hydrocarbon fluid flow confined under amorphous silica pores. Coarse grained molecular simulations are performed to elucidate how confinements including the confinement size, shape, surface wettability, influence the thermodynamics and fluid transport in pores of single nanometer size. The force parameters of the adopted coarse grained molecular model are calibrated from the thermodynamic equation of state. Our numerical results demonstrated the importance of fluid-pore interaction, pore size, and pore morphology effects in mediating the pressure-volume-temperature (PVT) properties of hydrocarbons. Also, we found that the saturation pressure predicted from the van der Waals-type adsorption isothermal loop could be elevated or suppressed relative to the bulk phase. Based on the flow simulation results, a detailed analysis regarding the impact of each of these factors will be presented.

APPLICATION OF SOLID SHELL MATERIAL POINT METHOD IN EXTREME DEFORMATION OF THIN STRUCTURES

Jiasheng Li[*1] and Xiong Zhang*[1]

[1]*Tsinghua University*

ABSTRACT

Shell structures play a significant role in large-span situations. For safety and security, large deformation and destruction of shell structures has attracted great attention. With the large span of shell structures and inhomogeneous in material distribution, experiments of equal proportion are ordinarily expensive, while the corresponding results of the same experiment conditions may vary from each other. Therefore, the development of efficient and powerful algorithms to simulate complicated responses of shell structures remains an active field of research.

The standard material point method (MPM) has been applied to simulate shell structures. Several locking phenomena induced by the linear shape function will result in an overestimation of stress state and an underestimation of deformation when adopting a coarse background grid in the standard MPM. And thus, the discretization size of background grid should be small enough for shell simulations with the standard MPM, usually smaller than 1/5 of the shell thickness, which would lead to prohibitive computational cost.

A novel solid-shell material point method (SSMPM) is proposed in this work by introducing shell particles and locking treatments. The SSMPM adopts the shell particles to define the geometry of shell structures. A shell particle consists of a hexahedral particle domain, eight corners and Gauss quadrature points. Its deformation is obtained by solving the momentum equations on the background grid. For each shell particle, the assumed natural strain (ANS) method is adopted to eliminate shear locking and trapezoidal locking, and the enhanced assumed strain (EAS) method is employed to eliminate thickness locking. With the accurate description of bending modes, a single layer of shell particles and a coarse background grid are sufficient for shell structure simulations, which dramatically increase the computational efficiency. A local multi-mesh contact method is presented for contact situations. The advantages of MPM particles to simulate fragmentation and shell particles to simulate bending deformation are combined for extreme deformation of thin structures.

DEVELOPING AND ANALYZING A NOVEL UNCONDITIONALLY STABLE EXPLICIT FINITE ELEMENT METHOD FOR THE ELECTROMAGNETIC ROTATION CLOAK MODEL

Yunqing Huang[1], Jichun Li[2] and Bin He[3]*

[1]Xiangtan University
[2]University of Nevada Las Vegas
[3]Lanzhou Jiaotong University

ABSTRACT

One potential application of metamaterials is for designing invisibility cloaks. In this talk, I'll talk about a rotation cloak model. Here we carry out the mathematical analysis of this model for the first time. Through a careful analysis, we reformulate a new system of governing partial differential equations by reducing one unknown variable from the originally developed modeling equations in our previpous work [1]. Then a novel unconditionally stable explicit finite element scheme is proposed and its stability and optimal error estimate are proved. Numerical simulations are presented to demonstrate that the new scheme for the reduced modeling equations can effectively reproduce the rotation cloaking phenomenon. The talk is based on [2].

RESEARCH ON THE DYNAMIC RESPONSE OF OIL STORAGE TANK PLATFORM STRUCTURE UNDER THE EARTHQUAKE ACTION IN ICE REGIONS

Liang Li[*1]*

[1]*Harbin Institute of Technology*

ABSTRACT

In recent years, with the rapid development of China's economy, the importance of marine resources has become increasingly prominent. Oil storage tank platform structures play a fundamental role in the development of offshore oil and gas resources. These structures often face complex and harsh environments in ice-prone regions, including the threat of seismic excitation and seasonal sea ice. To ensure the safe operation of offshore platform structures, it is necessary to conduct research on the dynamic response of oil storage tank platforms in ice zones under seismic excitation. In addressing this issue, this study developed a non-freezing model ice that is representative of the Bohai Sea ice environment. Subsequently, underwater vibration table tests were conducted on the oil storage tank platform structure using the model ice in a model ice pool. A numerical model was also established to simulate the dynamic response of the oil storage tank platform structure under seismic excitation. The seismic response analysis of the oil storage tank platform structure in ice zones was conducted by combining the numerical model and experimental data.

SELECTIN AND INTEGRIN COOPERATIVELY REGULATE ROLLING ADHESION OF LEUKOCYTE UNDER SHEAR FLOW

Long Li[1] and Jizeng Wang*[1]

[1]*Lanzhou University*

ABSTRACT

Cell interacting with its extracellular matrix involves complex structures formation consisting of a multitude of proteins and often takes place in a hydrodynamic environment, e.g., leukocyte locomotion inside blood vessel in the process of inflammation. Despite the omnipresence of rolling adhesion of cell mediated by multiple type of proteins under hydrodynamic impact, the mechanisms underlying how the mechanics of multiple proteins cooperatively may govern the dynamics of cell rolling is not yet fully resolved. Here we present a mechanical model on rolling adhesion of cell mediated two distinct adhesive proteins in shear flow, corresponding to selectin- and integrin- jointly regulating leukocyte adhesion. Considering two pairs' binding/unbinding events as Markov processes and describing kinetics of leukocyte by the approach of continuum mechanics approach give rise to the mechanical description of rolling adhesion process. Through examining the dynamics of leukocyte rolling as a function of relative fraction of selectin and integrin pairs, we show that, during recruitment, the elongation of intermittent weak selectin bonds consuming the kinetic energy of rolling leukocyte decelerates the rolling speed and enables the integrin pairs to form strong bonds, therefore achieving the arrestment of leukocyte (firm adhesion). The coexistence of selectins and integrins may also be required for effective phase transition from firm adhesion to rolling adhesion, due to dynamic competition in pairs' formation and elongation.

[1]*Dalian University*
[2]*Chinese Academy of Sciences*
[3]*China University of Mining and Technology-Beijing*
[4]*University of Chinese Academy of Sciences*

ABSTRACT

The inner wetting characteristics in the catalyst particles have a significant impact on the activity and selectivity of catalysts[1]. Due to the complexity of the internal geometry structure of particles and the limitations of experimental conditions, the wetting condition inside particles remains unknown and assumed. Therefore, the paper numerically explored the wetting state and mechanism for hydrogen-oil flow in a catalyst particle by phase field lattice Boltzmann method (pf-LBM) developed by our team[2]. First, we randomly constructed irregular pore structures and reproduced the cross-sectional morphology of the catalyst particles. Combining the uniform distribution and Gaussian distribution, using the Voronoi edge topology to take the midpoint, doing spline interpolation to satisfy the random channel, and then verifying through tortuosity. There were 36 interpolation schemes dealing with the complex inner wall boundary condition. And the wettability condition was set at the inclinded planes which hydrogen, oil and inner wall contacted. After validating the pf-LBM, we simulated the oil wetting process in the porous media with different catalyst shape under different conditions. According to the numerical results, this work mainly focused on the effect of the catalyst geometry construct, fluid physical properties and operation conditions on the wetting area and efficiency. We studied the laws how the porosity, average pore diameter, tortuosity, catalyst shape, hydrogen/ oil physical properties, hydrogen/ oil ratio and driving force decided the oil distribution. A correlation about the inner wetting efficiency for the catalyst particles was presented. Thus the results are helpful to quantitatively master the inner wetting state and optimize catalyst geometry.

Key words: inner wetting efficiency; phase-field lattice Boltzmann method; geometric construct; porous media; two phase flow

WRINKLED AND WRINKLE-FREE MEMBRANES

Heng Gao[1], Qinglin Duan[1] and Ming Li[1]*

[1]Dalian University of Technology

ABSTRACT

Membranes are easy to buckle and wrinkle due to their extreme flexibilities, leading to the performance degradation and hampering the engineering applications. Here we propose a wrinkle-free approach through optimizing the shape and distribution of interior irregular holes in the membrane. A theoretical model with Marguerre function and complex analysis is performed to accurately estimate the stress distribution and wrinkling capability of the non-uniform membrane. The non-gradient particle swarm optimization (PSO) algorithm is implemented to determine the optimized holes to achieve wrinkle-free performance with ignorable area loss, the computational efficiency has been significantly enhanced through the superposition method. Both post-buckling analyses and physical experiments are carried out to verify wrinkle-free performance of membranes with optimized holes. In addition, an easy-to-implement empirical method is provided to guide the design of wrinkle-free membranes with arbitrary aspect ratio.

MULTI-PHYSICS HIGH-FIDELITY NUMERICAL SIMULATION METHODS FOR METAL ADDITIVE MANUFACTURING PROCESSES

Ming-Jian Li[1] and Yanping Lian*[1]

[1]*Beijing Institute of Technology*

ABSTRACT

Metal additive manufacturing processes involve multi-physics interaction problems, including heat transfer, fluid dynamics, and solid mechanics. Such complexities challenge conventional numerical methods. This study introduces two novel numerical methods specifically designed to address the multi-physics problems in metal additive manufacturing processes. The first method, called the local multi-mesh finite volume method, efficiently handles heat transfer and melt pool dynamics. It utilizes a dual-mesh system to solve macroscopic temperature across the entire domain and mesoscopic heat and fluid dynamics within the melt pool vicinity. By employing a refinement-by-superposition paradigm, this method enables efficient simulations at the powder scale. The second method, known as the multi-physics material point method, effectively addresses thermo-fluid-solid interactions. It discretizes the material domain using a structured grid and a group of particles for heat transfer, fluid dynamics, and thermal stress solution under both Eulerian and Lagrangian frameworks. This method incorporates a semi-implicit local iteration for phase-changing heat transfer, a modified Chorin's projection method for Darcy's damping, and a staggered derivation scheme for Marangoni forces.

Numerical cases were conducted to validate these methods, and the results were compared with analytical, numerical, and experimental benchmarks. Notably, the local multi-mesh finite volume method demonstrated significantly improved computational efficiency, outperforming the traditional finite volume method by factors of 16 to 50. Furthermore, the multi-physics material point method achieved faster convergence in managing phase transitions, requiring 75% fewer iterations than the traditional bisection and Newton methods. The two methods present promising solutions for addressing the challenges of multi-physics phenomena in metal additive manufacturing.

A PYTHON TOOLBOX FOR BAYESIAN LEARNING OF PORT-HAMILTONIAN SYSTEMS

Peilun Li[1], Kaiyuan Tan[1] and Thomas Beckers[1]*

[1]*Vanderbilt University*

ABSTRACT

Machine learning has emerged as a powerful tool for modeling and control of dynamical systems across various scientific and engineering domains. Dynamical systems, characterized by their evolution over time, can exhibit intricate behaviors that are challenging to capture using first principal methods alone. Hence, utilizing data driven approaches to model complex dynamical systems can offer high accuracy and emerges as a generalizable method. However, for creating robust modeling and safe control of dynamical systems, machine learning approaches has often been hindered by their inherent limitation: a lack of consideration for the underlying physical laws and constraints that govern the behavior of any real-world dynamical system. As a result, the models often lack trustworthiness and generalizability.

In contrast, physics-informed machine learning leverages the inherent knowledge and understanding of the physical world to inform the learning process of machine learning algorithms. By explicitly integrating physical laws, domain expertise, and prior knowledge into the learning framework, physics-informed learning empowers control systems to leverage the flexibility and adaptability of machine learning while remaining grounded in a solid understanding of the underlying dynamics.

In the talk, we will introduce PyGpPhs – an easy-to-use toolbox for physics-informed learning of electromechanical systems. The toolbox is built on our recently introduced Gaussian Process Port-Hamiltonian systems (GP-PHS) which is a physics-constrained, nonparametric Bayesian learning approach with uncertainty quantification. In contrast to many other physics-informed techniques that impose physics by penalty, the proposed data-driven model is physically correct by design. The Bayesian nature of GP-PHS uses collected data to form a distribution over all possible Port-Hamiltonian systems instead of a single point estimate. Thus, the GP-PHS model i) generalizes well, ii) is highly interpretable and iii) the inherent uncertainty quantification enables future safe model-based control approaches. To further demonstrate theory and usages of the toolbox, we will present the learning of the dynamics of a non-harmonic oscillator in detail. The toolbox is easy to use and demonstrate high accuracy in modeling.

PHASE FIELD FRACTURE MODEL AND TOPOLOGY OPTIMIZATION FOR ADDITIVE MANUFACTURING

Qing Li[1], Chi Wu[1], Cuiyi Li[2], Jianguang Fang[2] and Grant Steven[1]*

[1]*University of Sydney*
[2]*University of Technology, Sydney*

ABSTRACT

Phase field models have been extensively studied in the analysis of brittle and ductile fracture. However, few have been explored to simulate additively manufactured materials and validated by experimental data so far. This study develops a phase field framework for modelling complex mechanical behaviours of 3D printed metallic and ceramic materials [1]. To consider the 3D printing induced microstructural orientation, transversely isotropic Hill48 and modified Mohr-Coulomb constitutive models are incorporated here to depict the plastic and fracture behaviours, respectively. The numerical results divulge that, by considering the stress state-dependent crack initiation, the proposed phase field model can better simulate the force-displacement responses [1]. Remarkably, the complex fracture sequences, including crack initiation, propagation, and final rupture, can be properly simulated by the proposed phase field model. Importantly, it is necessary to apply a transversely isotropic fracture model to characterise the orientation-dependent fracture behaviour.
Further, the phase-field damage model established is incorporated into the topology optimization framework to consider crack initiation and propagation in a path-dependent fashion [2,3]. The topological design enables to enhance fracture resistance of structures made of additive manufacturing components. A path-dependent shape derivative is developed in a step-wise manner during the nonlinear fracture analysis, which enables to drive the topology optimization properly [3]. To measure the fracture resistance of structure, a p-norm function is formulated to aggregate the phase-field variables into a single constraint. The numerical examples demonstrated that the proposed phase field based topology optimization method can significantly improve the fracture resistance of additively manufactured structures [2]. The proposed method is anticipated to provide an effective approach for sophisticated path-dependent topological design of structures reducing severe stress concentration and high risks of fracture failure.

RECENT PROGRESS IN REACTIVE DIFFUSION MODELLING FOR FLEXIBLE BIOELECTRONIC SYSTEMS

Rui Li[*1]*

[1]*Dalian University of Technology*

ABSTRACT

Flexible bioelectronics is a class of technology that involves components which physically disappear, in whole or in part, at prescribed rates and at programmed times. Enabled devices include medical monitors that fully resorb when implanted into the human body (“bio-resorbable”) to avoid long-term adverse effects, or environmental monitors that dissolve when exposed to water (“eco-resorbable”) to eliminate the need for collection and recovery. Theoretical modeling of the behaviors of the constituent materials represents important design tools for flexible bioelectronic systems. In this talk, a class of reactive diffusion models for the analyses and designs of flexible bioelectronic systems are reported, by which the key quantities such as the distribution of water concentration, thickness change, and lifetime predictions are obtained analytically. These models are well validated by the experiments and provide effective approaches to innovative designs of related devices.

DEVELOPMENT OF VARIATIONAL BAYESIAN LEARNING NEURAL NETWORK FOR SOLUTIONS OF INVERSE PROBLEMS: FROM FORENSIC ANALYSIS OF TRAFFIC ACCIDENTS TO THERMAL DISTORTION CONTROL IN 3D PRINTING

Shaofan Li[*1]

[1]*University of California, Berkeley*

ABSTRACT

We have developed a class of variational Bayesian learning neural networks-based machine learning algorithms, including a mixed Bayesian variational finite element method, to solve various inverse problems, such as reconstruction of car crash accidents, thermal distortion control in 3D printing, and general structural forensic analysis on fracture and crack propagation. In this work, powerful variational Bayesian learning-based computation algorithms have been developed to “inversely” identify the deformation maps in the sense of continuum mechanics as well as the loading conditions while the only information given is the deformed material shape or geometry.

We developed several novel techniques, such as (1) Variational Bayesian Learning formulation coupled with a Feed-forward architecture, and (2) a mixed Galerkin variational Bayesian learning finite element method and its inverse solution for deformation mappings in any dimension. We have then applied these computational algorithms to several important real engineering applications. We have demonstrated that the developed machine-learning algorithm can practically identify the deformation field of a real crashed car and recover its initial pre-crash state based on residual damaged geometric configuration, and the Bayesian regularization network can provide a powerful geometric deviation control (BRN-GDC) algorithm that has the capability to control the thermal distortion in 3D printing that is parameter- and location-dependent.

In this talk, we present an overview of the theory and computational algorithms of Variational Bayesian learning neural network methods and their applications.

THERMOELASTIC DAMPING OF FGM MICRO BEAMS BASED ON THE HIGHER-ORDER SHEAR DEFORMATION THEORY

Shirong Li[1] and Zeqing Wan*[1]

[1]*Yangzhou University*

ABSTRACT

Thermoelastic damping (TED) in free vibration of a simply supported functionally graded material (FGM) micro beam with rectangular cross section is investigated based on the classical thermoelasticity. Material properties of the FGM micro beam are assumed to be continuously vary along the beam thickness. Governing equations for the structural vibration coupled with the temperature field are formulated by using Levinson higher-order shear deformation beam theory. Heat conduction equation coupled with the bulk strain is derived on the basis of Fourier model. For small amplitude transverse vibration, we assume that heat conduction effect is dominant in the thickness direction so that the heat conduction equation is simplified as a quasi-one-dimensional differential equation with variable coefficients which are functions of the coordinate in the beam thickness direction due to the transverse inhomogeneity of the materials. A layer-wise homogenization approach is employed to approximately solve the heat conduction equation with variable coefficients, where the FGM beam is divided into numerous uniform layers where the thermal and mechanical properties in each layer are considered to be constant and evaluated at the mid-surface of the divided layer. Consequently, the heat conduction equation possessing variable coefficients is discretized into a series of differential equations with constant coefficients in each layer. Analytical solutions for these equations with the adiabat boundary conditions at the beam top and bottom surfaces and the continuation conditions at the interfaces are obtained in terms of the kinematic quantities. Afterwards, the TED in the FGM Levinson beam is determined by the complex frequency approach in terms of the isothermal frequency of the homogenous Euler-Bernoulli beam by using mathematical similarity between the eigenvalue problems for the two types of beams. Considering an FGM beam with the material properties varying as power functions from full silver (Ag) at the top surface to full silicon (Si) at the bottom one, numerical results are presented to quantitively analyze the effects of the material gradient, the geometry and the shear deformation on the TED and the frequency shift of the micro beams in detail. The numerical results show that the TED evaluated by the Levinson beam theory (LBT) is smaller than that by the Euler-Bernoulli beam theory (EBBT) and the difference becomes significant along with the increase in the value of the thickness-to-length ratio. Therefore, for a thick or moderately thick micro beam the LBT can provide a more accurate prediction for the TED than the EBBT.

A DATA-DRIVEN MULTISCALE SURROGATE MODEL FOR CFD–DEM SIMULATIONS

Shuo Li[1] and Mikio Sakai*[1]

[1]*The University of Tokyo*

ABSTRACT

Gas–solid flows are commonly investigated in industries. The CFD–DEM method is an established method for simulating the gas–solid interactions. However, the CFD–DEM simulation of industrial gas–solid flows often requires substantial computational resources. To address this issue, in this study, a novel data-driven multiscale surrogate model, referred to as a reduced-order model coupled with a signed distance function-based graph network (ROM–SGN), is proposed to accelerate the simulation of gas-solid flows. Validation studies are conducted in a fluidized bed. Macroscopic properties such as particle distribution, pressure drop, and bubble distribution are compared between the CFD–DEM and ROM–SGN simulations. The results demonstrate that the ROM–SGN accurately simulates the gas–solid dynamics and significantly reduces calculation time by several orders of magnitude compared to CFD–DEM simulation. This work will contribute significantly to the advancement of simulation and modeling for industrial multiphase flows.

Keywords: CFD–DEM; Surrogate model; ROM–SGN; data-driven coupling.

A SIMPLE MODEL FOR SIMULATING VESICLE EXPANDING AND SHRINKAGE

Shuwang Li[*1], Steve Wise[2] and Xiaoxia Tang[1]*

[1]*Illinois Institute of Technology*
[2]*University of Tennessee*

ABSTRACT

In this talk, we present a diffuse interface model for vesicle expanding (growth) or shrinkage induced by an osmotic pressure. The model consists of an Allen-Cahn equation describing the evolution of the phase field and a Cahn-Hilliard equation describing the evolution of the concentration field. We establish control conditions for expanding or shrinking vesicles using the concept of common tangent construction in materials science, allowing the exchange of materials between the interior and exterior domains. Numerical experiments reveal that the model can capture the main feature of dynamics: formation of circle-like (expanding) and finger-like (shrinking) vesicles.

CURVATURE-CONTROLLED BAND ALIGNMENT TRANSITION IN 1D VAN DER WAALS HETEROSTRUCTURES

*Wenbin Li**[1]

[1]*Westlake University*

ABSTRACT

One-dimensional (1D) van der Waals (vdW) heterostructures of coaxial inorganic nanotubes, such as carbon nanotubes and transition metal dichalcogenide (TMDC) nanotubes, have recently emerged as a new area of endeavor in materials science. A key prerequisite for designing the properties of 1D vdW heterostructures is to understand the band alignment of the coaxial nanotubes in these novel heterostructures. In this talk, I will present our recent first-principles study of the effect of curvature on the electronic structure and band alignment in 1D vdW heterostructures of TMDC nanotubes. We find that, as the diameter of an individual TMDC nanotube decreases, the combined effect of curvature-induced flexoelectricity and circumferential tensile strain causes a rapid lowering of its conduction band minimum, while the valence band maximum exhibits an initial lowering before rising. As individual TMDC nanotubes form coaxial heterostructures, the concerted effect of diameter-dependent band-edge levels and intertube coupling via flexovoltage can lead to a Type II to Type I transition in intertube band alignment in several 1D TMDC heterostructure systems, including large-diameter MoSe2@WS2, MoTe2@MoSe2, and MoTe2@WS2 heterostructures. The results lay down a foundation for the rational design of 1D vdW heterostructures.

BIOMIMETIC CELLULAR MATERIAL UNIT CELL REPRESENTATION AND ON-DEMAND DESIGN BASED ON A TRANSPARENT NEURAL NETWORK AND A NEURAL OPERATOR

Xiang Li[1], Ziming Yan[2], Zhanli Liu[2] and Zhuo Zhuang[2]*

[1]*Hainan Normal University*
[2]*Tsinghua University*

ABSTRACT

Cancellous bone is a natural cellular material that is able to proactively change its microstructure to adapt to the surrounding loading conditions. This adaptability gives the bone anisotropic mechanical properties and the ability to absorb energy. Inspired by the topological and mechanical properties of cancellous bone, this research proposes a framework to represent and design biomimetic cellular materials based on a transparent neural network and a neural operator. In this research, a transparent neural network is used to compute the Gaussian random field and generate the topology of the spinodoid, a biomimetic cellular material. Furthermore, a novel homogenization method accelerated by neural operators is presented to efficiently compute the anisotropic elastic matrices of the spinodoid unit cells, combining improved computational speed with precision. Finally, a data-driven workflow is introduced to inversely determine the topological parameters of the spinodoid unit cell based on the given anisotropic elastic matrix. Numerical examples show that the proposed framework is capable of efficiently and correctly designing spinodoid unit cells with given design goals and can be extended to the design applications of other biomimetic cellular materials.

FRONT TRACKING AND APPLICATION TO PARTACHUTE SIMULATION

*Xiaolin Li**[1]

[1]*Stony Brook University*

ABSTRACT

We introduce an integrated computational method for the simulation of the parachute system using the front tracking methodology. A dual-stress spring-mass model based on the front tracking method is used to study the dynamics of fabric surfaces in air. The numerical algorithms for this complex physics system includes fabric model and its coupling with the fluid solvers, both incompressible and compressible. The fabric porosity is modeled by the ghost cell method. The collisions, including fabric-fabric, fabric-rigid, rigid-rigid and string collisions with fabric and rigid are implemented. This presentation will introduce on the algorithms and simulation of the
supersonic parachute simulation. We will also present other applications, including fluid interface instabilities, phase transition and particle tracking with the front tracking software library.

ANALYSIS ON NONLINEAR WHEEL-HOLDING CONTACT ON NOSE LANDING GEAR DYNAMICS CHARACTERISTICS DURING NEW TOWING-OUT MODE OF AIRCRAFT

Xiaoyun Li[*1], Yijun Chai[1], Xiongwei Yang[1] and Yueming Li[1]*

[1]Xi'an Jiaotong University

ABSTRACT

The safety and efficiency of airports are compromised due to civil aircraft commonly using their own engines for taxiing in the current era. A new generation of towing-out mode has been introduced, which utilizes the external power supplied by a towbarless tractor. A complex constraint relationship exists between the nose landing gear's wheel and the wheel-holding mechanism of the tractor during this towing process. The nose landing gear, a crucial component for ground taxiing, possesses dynamic characteristics that directly influence the safety of high-speed taxiing and the service life of the structure. Given the constraint relationship of wheel-holding contact force, it is imperative that a study be conducted on the vibration characteristics of the nose landing gear, which is subjected to both heavy load and towing load. A specific type of civil aircraft front landing gear is selected as the research subject, and a mathematical model is derived to describe the constrain between the nose landing gear's wheel and the wheel-holding mechanism. This derivation is based on the wheel-holding contact geometric relationship and the Winkler contact model. The static and dynamic characteristics of the nose landing gear under heavy load are investigated. Considerations are given to the wheel-holding contact interaction during towbarless towing, the nonlinear axial force of the shock absorber, and the buffering effect of the tractor tire. The influence of wheel-holding contact stiffness and nonlinearity on the vibration characteristics of the structure is also examined. A nonlinear relationship between the radial force and radial deformation of the wheel is revealed by the results, with the degree of nonlinearity inversely proportional to the radius of the clamping rod. As the wheel-holding contact stiffness increases, frequency veering and mode conversion are gradually experienced by the first and second modes of the nose landing gear under full-load towing conditions. The occurrence of frequency steering is observed when a specific nonlinear function relationship is exhibited between the clamping contact force and the stiffness of the tractor tire. Moreover, the nonlinearity of wheel-holding contact stiffness exerts a more pronounced impact on the first-order natural frequency of nose landing gear. The findings of this study can serve as a valuable reference for optimizing the nose landing gear under the new towing-out mode and designing the wheel-holding mechanism.

INFER EXPLICIT NUMERICAL SCHEMES FROM IMPLICIT DATA WITH APPLICATIONS TO DEFECT DYNAMICS

Xingjie Li[*1], Fei Lu[2], Molei Tao[3] and Xiaofeng Felix Ye[4]*

[1]*University of North Carolina at Charlotte*
[2]*Johns Hopkins University*
[3]*Georgia Institute of Technology*
[4]*State University of New York at Albany*

ABSTRACT

Efficient simulation of SDEs is essential in many applications, particularly for ergodic systems that demand efficient simulation of both short-time dynamics and large-time statistics. However, locally Lipschitz SDEs often require special treatments such as implicit schemes with small time-steps to accurately simulate the ergodic measure. We introduce a framework to construct inference-based schemes adaptive to large time-steps (ISALT) from data, achieving a reduction in time by several orders of magnitudes. The key is the statistical learning of an approximation to the infinite-dimensional discrete-time flow map.

We use the classical numerical schemes to derive informed basis functions, leading to a parameter inference problem. We introduce a scalable algorithm to estimate the parameters by least squares, and we prove the convergence of the estimators as data size increases. The numerical tests confirm that ISALT can tolerate time-step magnitudes larger than plain numerical schemes.

NUMERICAL SIMULATION METHOD FOR FATIGUE CRACK PROPAGATION IN CLADDED C(T) TEST SPECIMEN

Yanlong Li[*1] and Toshio Nagashima*[1]

[1]*Sophia University*

ABSTRACT

To improve the corrosion resistance and rust prevention properties of nuclear reactor pressure vessel (RPV) in nuclear power plants, stainless steel is welded on the inner surface of vessel as cladding. In such cladded structure, due to the dissimilar material interface, fatigue crack propagation behavior is complex and further researches are required.

In this study, a numerical simulation method based on extended finite element method (XFEM) for fatigue crack propagation in cladded structure is proposed. This method employs 8-node hexahedral continuum elements enriched with only Heaviside step function, which can model planar crack independently of finite elements. For the crack across dissimilar material interface in cladded structure, first, the stress intensity factors along the crack front are evaluated by domain integral method, and then crack front shapes are updated by using Paris' law and then smoothed by the cubic Bezier curves in each region. The crack propagation analysis is performed by repeating this series of processes mentioned above.

In this presentation, fatigue crack propagation analyses for cladded C(T) test specimens are performed. The obtained relationships between crack length and load cycle as well as transition of propagating crack front shapes are compared with those of experiment and validated. It was shown that the proposed method appropriately simulated the fatigue crack growth behaviours in cladded C(T) test specimens.

NUMERICAL SIMULATION OF THE COMPRESSIBLE STABLE RAYLEIGH-TAYLOR-KELVIN-HELMHOLTZ INSTABILITY WITH DISCRETE BOLTZMANN METHOD

Yaofeng Li[1] and Chuandong Lin*[12]

[1]*Sun Yat-sen University*

[2]*Key Laboratory for Thermal Science and Power Engineering of Ministry of Education, Tsinghua University*

ABSTRACT

The Rayleigh-Taylor (RT) and Kelvin-Helmholtz (KH) instabilities are typical fluid instability phenomena that often occur in conjunction. The coupled RTKH system can be categorized as stable or unstable, depending on whether the heavier fluid lies beneath or above the lighter one. In stable RTKH systems, the evolution of physical fields is often accompanied by complex phenomena such as nonlinearity, multiscale effects, and nonequilibrium behavior. These complexities pose challenges for traditional methods. As a mesoscopic method, the discrete Boltzmann method (DBM) is capable of describing both hydrodynamic and thermodynamic behaviors and has recently been applied to study the RTKH instability[1-2]. In this study, we utilize the DBM to investigate the competition mechanism between the suppression and promotion of interface evolution, where stable RT inhibits interface evolution, while KH promotes it. This work aims to enhance our understanding of the nonequilibrium evolution of compressible stable RTKH instability and contribute to the theoretical framework of fluid instability.

ANALYZING THE LONG TERM BIOMECHANICAL RESPONSE OF ORTHOKERATOLOGY BY CONSIDERING THE ANISOTROPIC VISCOELASTIC BEHAVIOR OF THE CORNEA

Yifeng Li[*1], Zhuoran Yang[1], Ziming Yan[1], Huibin Shi[1] and Zhanli Liu[1]*

[1]Tsinghua University

ABSTRACT

Orthokeratology, an effective myopia correction and control technique widely adopted among adolescents, is increasingly gaining scientific attention. Most existing research focused on analyzing patient corneal morphology data to discern deformation patterns but often fell short in understanding the underlying biomechanical mechanisms. This limitation resulted in the fitting of orthokeratology lenses heavily relying on clinicians' judgment, posing a significant challenge for accurately predicting orthokeratology outcomes, i.e., corneal deformation. This study aims to reveal the mechanisms of orthokeratology by establishing a biomechanical model, facilitating the prediction of corneal deformation. We began by collecting extensive corneal morphological data from clinical myopia patients, based on which we constructed a geometrically personalized finite element model. This model considers the anisotropic, visco-hyperelastic mechanical properties of the cornea. It was validated by simulating the long-term response in central corneal thickness over an 8-day orthokeratology period and comparing these results with experimental data. Furthermore, the study explored the effects of corneal anisotropic characteristics and posterior surface boundary conditions on the shaping process. Corneal shear dominated by indentation was revealed as the key deformation mechanism in orthokeratology. Using this model, we analyzed the effects of lens-wearing time and cycle duration of orthokeratology lenses on myopia correction and proposed appropriate lens-wearing strategies for various degrees of myopia. The biomechanical model established in this research successfully captured the long-term viscoelastic response of central corneal thickness, laying a solid foundation for the quantitative prediction of orthokeratology outcomes.

HIGH-THROUGHPUT SCREENING AND PREDICTION OF HIGH MODULUS OF RESILIENCE POLYMERS USING EXPLAINABLE MACHINE LEARNING

Ying Li[1]*

[1]*University of Wisconsin-Madison*

ABSTRACT

The ability to store and release elastic strain energy, as well as mechanical strength, are crucial factors in both natural and man-made mechanical systems. The modulus of resilience (R) indicates a material's capacity to absorb and release elastic strain energy, with the yield strength (σy) and Young's modulus (E) as R = σy2/(2E) for linear elastic solids. To improve the R in linear elastic solids, a high σy and low E combination in materials is sought after. However, achieving this combination is a significant challenge as both properties typically increase together. To address this challenge, we propose a computational method to quickly identify polymers with a high modulus of resilience using machine learning (ML) and validate the predictions through high-fidelity molecular dynamics (MD) simulations. Our approach commences by training single-task ML models, multitask ML models, and Evidential Deep Learning models to forecast the mechanical properties of polymers based on experimentally reported values. Utilizing explainable ML models, we were able to determine the critical substructures that significantly impact the mechanical properties of polymers, such as E and σy. This information can be utilized to create and develop new polymers with improved mechanical characteristics. Our single-task and multitask ML models can predict the properties of 12 854 real polymers and 8 million hypothetical polyimides and uncover 10 new real polymers and 10 hypothetical polyimides with exceptional modulus of resilience. The improved modulus of resilience of these novel polymers was validated through MD simulations. Our method efficiently speeds up the discovery of high-performing polymers using ML predictions and MD validation and can be applied to other polymer material discovery challenges, such as polymer membranes, dielectric polymers, and more.

CHARACTERIZING CYCLIC INELASTIC BEHAVIOR OF ANGLE MEMBERS: A MODIFIED HYSTERETIC MODEL

Yiwen Li[*12] and Songye Zhu*[1]

[1]*The Hong Kong Polytechnic University*
[2]*Tongji University*

ABSTRACT

Predicated on the Dicleli physical model [1], a modified hysteretic model tailored for displacement-controlled cyclic loading is devised. Comparative analysis through a finite element model indicates that the interrelation between normalized axial and lateral displacements solely depends on slenderness, ensuring the physical interpretation of the equation's parameters. Additionally, the study also explores the way local buckling alters cross-section shape and macroscopic component behavior. The new model reduces this impact with effective width. Given that the residual lateral displacement of each loading cycle may transform a straight rod into a bow-shaped rod, aggravating second-order effects and triggering early buckling. The improved model integrates geometric nonlinearity by updating the tangent modulus after each cycle, except initial imperfection, which is already included in the derivation of physical model. Since subsequent simulations demonstrate that low cycle fatigue damage and fracture propagation minimally affect the component's hysteresis curve, these factors are excluded from the model. The modified hysteretic model, validated by experimental tests and finite element simulations, effectively captures the key numerical values of the hysteresis curve, enabling a smooth transition from regular to random loading. This study offers a promising methodology for representing the cyclic inelastic behavior of angle members in various structures.

AI-ENABLED RAPID IMAGE-BASED HEMODYNAMIC MODELING AND SIMULATION

Pan Du[1], Delin An[1], Yongqi Li[1], Chaoli Wang[1] and Jianxun Wang[1]*

[1]University of Notre Dame

ABSTRACT

Cardiovascular disease (CVD) has persisted as a leading global cause of mortality for decades. While image-assisted computational fluid dynamics (CFD) simulation has proven invaluable in offering comprehensive hemodynamic insights for non-invasive diagnosis and clinical treatment planning for CVD, the conventional approach faces significant challenges hindering its widespread application. Firstly, the manual extraction of geometries from medical images is time-consuming, inconsistent among different operators, and may introduce human artifacts during geometry reconstruction. Secondly, the meshing, case setup, and execution of CFD simulation under realistic settings (e.g., high spatial and temporal resolution, fluid-solid interaction (FSI), Wind-Kessel boundary conditions) can be time-demanding, limiting its applicability in clinical scenarios requiring timely feedback or iterative model queries for device implant design. Thirdly, uncertainties in boundary conditions or model parameters during CFD simulation can compromise result credibility, reducing its effectiveness in clinical diagnosis.

In response to these challenges, we introduce a novel AI-enabled image-based computational modeling framework for automatic patient-specific image segmentation and rapid hemodynamic simulations, which harnesses the potency of deep learning to enable fast prediction of 3D blood flow patterns from raw image scans. Firstly, we automate vessel segmentation in medical imaging by developing a Laplacian-of-Gaussian (LoG) based Bayesian network, enhancing segmentation accuracy across diverse vascular structures. Subsequently, a shape deformation model using graph neural network (GNN) with residual connection reconstructs high-quality patient-specific simulation-ready meshes from segmented voxel images. Surface smoothness on the reconstructed geometry is ensured through the use of a large deformation diffeomorphic metric mapping (LDDMM) method. Finally, a GNN-based CFD surrogate model is established for rapid prediction of simulation results, handling unstructured meshes and featuring full gradient tracking and backpropagation for swift model adjustments and parameter optimization across complex vascular structures. The proposed models are demonstrated on a main aorta with upper branches (brachiocephalic trunk, left common carotid artery, and left subclavian artery), showcasing its merit and effectiveness. This study serves as a compelling indication that the integrated machine learning technologies hold substantial promise and have the potential to revolutionize CVD diagnosis, offering a more effective and efficient tools for cardiovascular healthcare.

MULTIPHYSICS-INFORMED MACHINE LEARNING FOR ARCHITECTED BATTERY DESIGN

Parth Bansal[1] *and Yumeng Li**[1]

[1]*University of Illinois Urbana-Champaign*

ABSTRACT

Li-ion batteries (LIBs) are critical for electrification in a wide range of applications to reach zero-net emission goal. These increasingly widespread applications warrant an improvement in the existing battery designs so as to meet this increasing demand. One such possible improvement is the use of Si anode instead of the traditionally used graphite electrode as this change allows for increased battery life, increased capacity, increased safety and better performance. The unique intercalation mechanism of Li ions into the Si anode Si anode results in a better specific capacity of the battery. In this mechanism Si atoms react with lithium, which leads to the bonds between the Si atoms giving way for the formation of the LixSi alloy. However, there is a cost associated with this design improvement. Volumetric changes of upto 300% are observed in the Si anode during the lithiation/delithiation cycles which results in the development of large internal stresses in the anode. Delamination of the Si anode from the current collector substrate and the cracking in the Si anode material itself are the consequences of this volumetric stresses, which causes a reduction in the capacity of the battery. The growth of the solid electrolyte interface (SEI) layer is another capacity fade mechanism that is coupled with mechanically induced damage in the LIBs. SEI layer growth in LIBs can lead to the increase in the internal resistance of the cell and the removal of the active Li material from the cycling process. The growth of the SEI layer on the surface of the anode mainly occur during the battery cycling phase. The continued growth of this layer increases the overall resistance and removes the active Li from the cycling system, thereby reducing the overall capacity of the battery. Hence, to be able to truly utilize Si as the active material for the LIBs, there is a tremendous need to understand these three coupled failure modes in the battery and identify electrode design that can mitigate the mechanically induced capacity degradation. One potential solution is architected electrode. In this study, multiphysics-informed machine learning has been developed to investigate the capacity degradation of architected electrodes with various designs under different operating conditions. This is the first work that can consider all major coupled failure models of Si-based electrodes in the performance analysis, which can facilitate the design of high efficiency battery with architected electrodes.

SYNERGISTIC EFFECTS OF ENVIRONMENTAL DETERIORATION ON FATIGUE AND FLEXURE PROPERTIES OF GLASS FIBER REINFORCED POLYMERIC (GFRP) COMPOSITES : A MULTISCALE AND MULTIPHYSICS MODEL.

Zhiye Li[*1] and Michael Lepech*[1]

[1]*Stanford University*

ABSTRACT

This study aims to simulate synergistic UV & moisture deterioration and demonstrate its role in changing the residual fatigue and flexure performance in architectural GFRP composites. This study develops an experimentally validated 3D Multiphysics model at structural level and gets this homogenization-based model to identify each of the degradation mechanisms observed in the experimental data and to analyze the differences that the various degradation mechanisms might make to the properties and durability of the environmental aged composite materials. Sensitivity analyses are conducted to investigate the effect of mesh density on the accuracy of functions homogenized from micromechanical models. The aging-fatigue-bend model with respect to two different deterioration mechanism assumptions is developed and analyzed. Research shows that models with homogeneous damage assumptions allow higher feasibility and convergence when aging concurrently with complicated mechanical loading, while models with surface erosion assumptions describe the actual deterioration mechanism more precisely and offer more freedom, especially when the environmental aging condition is more complicated.

This model can be incorporated into many commercial finite element codes for a sustainability study of composite structures/systems. In future work, the models developed in this study will be combined with life cycle assessment (LCA) tools to support better sustainability-focused new material design, thus reducing costs and environmental impacts in the built environment.

NUMERICAL SIMULATION METHODS AND DATA-DRIVEN MODELS FOR METAL ADDITIVE MANUFACTURING

Yanping Lian[*1], Ming-jian Li[1], Wenze Zou[1], Jiawei Chen[1], Shi Dai[1] and Zhidong Wang[1]*

[1]*Beijing Institute of Technology*

ABSTRACT

Metal additive manufacturing (AM) technologies have found the potential to revolutionize the global part manufacturing landscape for their tremendous advantages in building geometrically complex parts with tailorable microstructures and properties. However, they still suffer from unexpected formation defects of the as-built geometry, dimension, and material properties, which require a complete understanding of the process-structure-property relationship. Because the process of metal AM involves extremely multi-physical phenomena taking place at a variety of temporal and spatial scales, high-fidelity numerical simulations are preferred to the costly trial-and-error experiments to address the process-microstructure-property relationship of AM and to aid the process parameters optimization for reducing the final product defects such as surface roughness, void formation, heterogeneous grain structures, etc. In this study, we proposed multi-scale and multi-physics numerical simulation methods, including the proposed multi-physics material point method, extended cellular automaton method, crystal plasticity finite cell self-clustering analysis method, for the powder melting-solidification process, grain structure evolution, and mechanical properties for different as-built alloys with different metal AM processes. The predictions from the proposed computational methods are in good agreement with the experimental data available in the literature for both powder bed fusion and wire-based directed energy deposition processes. Furthermore, data-driven models based on deep learning algorithms for the process-structure-property problems are developed based on the dataset by the proposed numerical simulation methods. The high efficiency and accuracy of these models are demonstrated. It is shown that the proposed methods and models can shed light on the process-microstructure-property relationships and can be further applied to optimizing process parameters.

A UNIFIED THEORY FOR SHEAR DEFORMABLE COMPOSITE PLATES

Chen Liang[*1] and C.W. Lim[1]*

[1]*City University of Hong Kong*

ABSTRACT

A shear deformation-based unified theory for composite plates is established. The theory contains four unknowns which are explicit to interpret the physical response. Apart from the three common displacement components for a point on the midplane, a remaining higher-order displacement component is exclusively attributed to transverse bending and shear deformation. The transverse shear deformation of the function distribution can be represented by general shape functions. The elucidation of the thickness locking mechanism relies on the innovative displacement component introduced in this study, which improves the kinematic assumptions inherent in conventional plate/shell theories. Further, the present theory explicates the explicit physical terms associated with transverse normal stress and strain. In addition, the present unified theoretical framework, along with the corresponding assumptions, induces further simplification and transition into the conventional plate theories, namely, first-order shear deformation theory (FSDT), higher-order shear deformation theory (HSDT), and others. Exact analytical solutions of composite plates are obtained. A comprehensive numerical investigation has been performed, encompassing diverse plate theories and various composite structures, including functionally graded material (FGM) plate structures, FGM sandwich plate structures, etc. The clarity and unity in the present theory and the physical meanings can be elaborated by integrating the conventional theories under certain assumptions.

SPECTRAL DIFFERENCE SOLUTIONS OF TWO THREE-DIMENSIONAL KINEMATIC DYNAMO PROBLEMS

Russell Hankey[1], *Maxwell Stephan*[1] *and Chunlei Liang**[1]

[1]*Clarkson University*

ABSTRACT

We report a recent development of the high-order spectral difference method with divergence cleaning (SDDC) for accurate simulations of two 3D kinematic dynamo benchmark problems on unstructured grids consisting of high-order iso-parametric hexahedral elements. The divergence cleaning approach is based on the improved generalized Lagrange multiplier (GLM), which is thermodynamically consistent and Galilean invariant. The Spectral Difference with Divergence Cleaning (SDDC) method has been used to successfully model a number of nonlinear MHD problems. The spectral difference method is a versatile high order method that can be used for unstructured grids and can be massively parallelized. The first kinematic dynamo problem was solved in a cubic box with all periodic boundary conditions. The SDDC method will be verified to capture the “Cigar” structures published in the literature. The second kinematic dynamo problem adopts a spherical shell geometry and non-penetrative and stress-free boundary conditions. The SDDC method will be employed to predict Sunspot cycles.

Buckling analysis and design of thin-walled structures based on novel and intelligent computational methods

A REDUCED-ORDER METHOD WITH MIXED NONLINEAR KINEMATICS FOR GEOMETRICALLY NONLINEAR AND BUCKLING ANALYSIS OF THIN-WALLED STRUCTURES

Ke Liang[*1] and Zheng Li*[1]

[1]*Northwestern Polytechnical University*

ABSTRACT

Thin-walled structures subjected to the in-plane and out-of-plane loads are widely used as load-bearing components in the aircraft, space and various civil engineering fields. The out-of-plane deflection of thin-walled structures is normally much larger than the wall thickness when the external load is applied laterally and/or buckling occurs. In these cases, a geometrically nonlinear analysis is required to achieve a realistic load-displacement response which greatly influences the load-carrying capability of thin-walled structures.

The conventional finite element (FE) method with a Newton-Raphson incremental-iterative technique still has limitations for geometrically nonlinear analysis. The repeated linear solutions of a large full-order FE system are computationally expensive, limiting the step size of the path-following analysis. In addition, a sufficient number of path-following steps must be adopted to achieve a geometrically nonlinear response curve with a favorable smoothness. This further aggravates the computational burden of geometrically nonlinear analysis.

In this work, a novel reduced-order method in the framework of mixed nonlinear kinematics is proposed for the geometrically nonlinear analysis of thin-walled structures with large deflections and/or buckling. The mixed nonlinear kinematics are developed in the combination of co-rotational and updated von Kármán formulations. The co-rotational kinematics are used to calculate the internal force and tangent stiffness of the structure, whereas the third- and fourth-order strain energy derivatives are achieved using the updated von Kármán kinematics. For the geometrically nonlinear problem with large deflection, reduced-order models with one degree of freedom are constructed based on the perturbation theory, otherwise more degrees of freedom are involved in the presence of buckling. The use of mixed nonlinear kinematics can greatly improve the computational efficiency in construction of a reduced-order model. The solutions of reduced-order models can be regarded as nonlinear predictors to the geometrically nonlinear response. Nonlinear predictors are required to be corrected using internal force-based residuals to ensure the accuracy of the geometrically nonlinear analysis. A geometrically nonlinear response with favorable smoothness is efficiently and accurately achieved using large step sizes in the path-following analysis. Various numerical examples are applied to validate the numerical accuracy and efficiency of the proposed method.

HINGE AND SMOOTHED-HINGE MODELS FOR CLOTH SIMULATION

Qixin Liang[*1] and K.Y. Sze*[1]

[1]*The University of Hong Kong*

ABSTRACT

The hinge model commonly used in fabric and cloth simulation quantifies bending energy in terms of the angle between the triangular facets defined by four computational nodes with translational but not rotational dofs. The classical hinge model (CHM) starts with the angle between two vectors normal to the triangular facets and derives the first and second order derivatives of the angle for the subsequently nonlinear solution process. In this study, an alternate but an equivalent angle or hinge angle is employed. It leads to the same set of derivatives, but the derivation process appears to be simpler. The torsional stiffness of the hinge is often calculated from the bending energy in one-third or the total area of the two triangular facets which are assumed to be under the cylindrical bending curvature fitting the hinge and the two computational nodes away from the hinge. In this submission, a smoothed-hinge model (SHM) is proposed in which a smooth cylindrical surface is first defined by interpolation at the four computational nodes of the hinge. Under the small curvature and small strain assumptions, the curvatures along the perpendicular directions to the three edges of a triangular facet can be expressed as linear functions of the nodal displacement. The three normal curvatures are transformed into the three curvature components defined in two orthogonal axes on the tangential plane of plate/shell and the conventional bending stiffness matrix used in the plate/shell is used to compute the bending energy. By incorporating the corotational concept, the bending energy can be approximated as a quadratic function of the nodal displacement. As a result, the Hessian of the bending energy is a constant matrix and does not require to be updated in the iterative solution procedure. For the membrane energy, a six-node interpolation instead of the three-node interpolation is employed. The former, when combined with either CHM or SHM, effectively mitigates the occurrence of sharp crease artifacts. To model contact and friction conditions, the incremental potential contact (IPC) is employed. Quasi-static and elasto-dynamic problems are both examined. Through quantitative and qualitative numerical experiments, the results demonstrate that our computational models exhibit stability with large time steps and convincingly simulate a variety of draping and garment scenarios.

A GENERAL CONTACT MODEL FOR ROUGH SURFACES BASED ON THE INCREMENTAL CONCEPT

Xuan-Ming Liang[*1], Shiwen Chen[1], Chengya Li[1] and Gangfeng Wang[1]*

[1]*Xi'an Jiaotong University*

ABSTRACT

It is now widely accepted that the real contact area between rough solids rises linearly with increasing normal loads. However, the coefficient of proportionality varies among different theoretical models and simulation results. This study advances a model for analyzing the elastic contact of rough solids. By taking into account the specific shape of contacting asperities, the connection between the real contact area and geometric truncation area is established in priority. Furthermore, the relationship between geometric truncation area and normal load is addressed by adopting the incremental concept. For surfaces covered with spherical asperities, the model could reproduce the predictions provided by the celebrated GW model [Greenwood, J. A., and Williamson, J. B. P., 1966, Proc. Roy. Soc. A., 295(1442), 300-319]. Avoiding prescribing the asperity geometries, the model tends to be more robust when surfaces are random and fractal. For general fractal Gaussian random rough surfaces, the model suggests that the coefficient of proportionality lies between 1.67 and 2.56. The upper and lower limits are close to the predictions of the BGT model [Bush, A. W., Gibson, R. D., and Thomas, T. R., 1975, Wear, 35(1), 87-111] and Persson's theory [Persson, B. N. J., 2001, J. Chem. Phys., 115(8), 3840-3861], respectively. In the thermodynamic limit, the potential varying scope for the coefficient of proportionality is further narrowed ranging from 1.92 to 2.22. The resultant predictions are in accord with numerical results presented in literature. The current study might provide profound insights into understanding the role of surface morphologies in elastic rough contact.

NUMERICAL SIMULATION INVESTIGATION ON NONLINEAR FLOW CHARACTERISTICS OF ROUGH SINGLE FRACTURES WITH DIFFERENT CONTACT AREAS

Yanbo Liang[*1], Yuanfang Cheng[1], Zhongying Han[1] and Chuanliang Yan[1]*

[1]China University of Petroleum (East China)

ABSTRACT

Abstract: To comprehensively understand the influence of the contact area on the flow characteristics of rough single fractures, a rough fracture surface is initially constructed using a spatial frequency domain approach. Subsequently, rough single fractures with varying contact ratios are derived by translating and displacing the fracture surface. The Navier-Stokes equation and Mass-conservation equation are solved by utilizing the laminar flow module integrated within the COMSOL software. The simulation results show that the nonlinear correlation between fluid flow velocity and pressure gradient can be described by using Forchheimer equation. Under the same flow velocity, a higher contact rate will exacerbate the nonlinear characteristics of fluid flow. In contrast to non-contact fractures, the streamlines within contact fractures exhibit increased tortuosity, accompanied by an elongation of flow pathways. Furthermore, with an expanding contact area, the complexity of the streamline pattern amplifies. The overall pressure field distinctly exhibits non-uniform characteristics, with larger pressure gradient observed within localized contact regions, consequently facilitating an increase in flow velocity.

Keywords: Rough fractures; Contact area; Nonlinear flow characteristics; Numerical simulation.

MULTISCALE MODEL REDUCTION FOR INVERSE HEAT CONDUCTION IN HIGH-CONTRAST MULTISCALE MEDIA

Ying Liang[*1] and Siu Wun Cheung*[2]

[1]*Purdue University*
[2]*Lawrence Livermore National Laboratory*

ABSTRACT

Efficient numerical simulations for forward problems are crucial for decision-making applications like inverse problems and optimal design. However, when dealing with multiscale medium properties, direct numerical simulation of the forward problem becomes computationally expensive, requiring a fine grid to capture variations in highly oscillating material properties. To address this, model reduction techniques are necessary. In this presentation, we introduce a novel multiscale model reduction method for inverse heat conduction in high-contrast multiscale media, significant in various engineering and industrial applications. Our method, grounded in recent advances in multiscale finite element methods, computes multiple localized multiscale basis functions per coarse region using local spectral problems and the localized energy minimization principle. We provide a theoretical analysis of the proposed method and present several numerical tests to verify its performance.

THE EXTENDED MATERIAL POINT METHOD FOR MODELLING EVOLUTION AND INTERACTION OF MULTIPLE DISCONTINUITIES

ABSTRACT

The Extended Material Point Method (XMPM) has demonstrated efficacy in numerically simulating shear band evolution and post-failure behavior during large deformations. However, the current formulation of XMPM is inherently limited to representing a single discontinuity, constraining its application in modeling intricate scenarios involving multiple discontinuities. This paper introduces a comprehensive extension to the XMPM framework to overcome this limitation, enabling the simulation of realistic problems characterized by the presence of multiple discontinuities.

Our enhanced method incorporates modifications to the original particle displacement approximation, empowering the XMPM to effectively handle multiple discontinuities within the material domain. Additionally, a dedicated contact strategy is developed to deal with the interaction between these multiple discontinuities within the XMPM framework. Several numerical case studies demonstrate the proposed extension's efficacy in simulating scenarios with multiple discontinuities, which is expected to contribute significantly to the understanding and prediction of material failure in various engineering and scientific applications.

ABSTRACT

This study investigates dynamic mesh adaptation (DMA) for hybrid RANS/LES (HRLES) simulations of compressible turbulent flow. HRLES models, which blend Reynolds-Averaged Navier-Stokes (RANS) and Large Eddy Simulation (LES), are by their nature very sensitive to the computational mesh, because of the very different resolution requirements in the RANS and LES regions. The proposed DMA strategy relies on a high-order k-exact finite volume spatial discretization [1] designed to ensure robust, accurate and conservative solutions for compressible flows with strong discontinuities while limiting the numerical dissipation of vortical structures. A mesh refinement criterion related to the truncation error of the k-exact reconstruction scheme is introduced, and compared with several heuristic refinement criteria from the literature [2]. To limit the computational burden of frequent re-meshing for unsteady flow simulations, the adaptation is performed only at certain time steps, and the error criterion is averaged over the chosen adaptation period [3]. A simple and effective criterion is then introduced to automatically control the averaging and adaptation period. The proposed DMA strategy is evaluated against a series of test cases of increasing complexity, ranging from inviscid vortex advection to turbulent transonic flow past an axisymmetric backward-facing step, representative of the base flow behind a space launcher.

ANALYTICAL DESIGN SENSITIVITY INFORMATION OF COMPOSITE LAMINATE SHELLS

Jan Liedmann[*1], Franz-Joseph Barthold[1] and Nikolai Gerzen[2]*

[1]*TU Dortmund*

[2]*The Technische Hochschule Ostwestfalen-Lippe*

ABSTRACT

Fiber-reinforced composites represent a class of materials celebrated for their exceptional strength, lightweight nature, and versatility. These advanced materials are composed of a matrix, often a polymer, reinforced with fibers such as glass, carbon, or aramid. The strategic integration of these fibers provides unique mechanical properties to the composite, combining the high strength of the reinforcing fibers with the flexibility and formability of the matrix material. This synergy results in materials that are widely employed across various industries, ranging from aerospace and automotive engineering to construction and sports equipment manufacturing. The tailored design possibilities and superior performance characteristics of fiber-reinforced composites make them a focal point of research and innovation in materials science and engineering.

In the optimization of laminated composite shells, diverse objective functions are sought depending on the intended use of the structure. This also applies to the selection of design parameters, where, in some cases, alterations in fiber orientations are desired without affecting the thickness of the structure, while in other instances, only specific layer thicknesses, and possibly their fiber orientations, may be subject to variation. This study explores fundamental types of design parameters for composite laminates, including total thickness, specific layer thicknesses, and fiber orientations, with the derivation of sensitivity relations.

Based on the solid shell formulation described in [1], investigations have been conducted for the extension to anisotropic material behavior, cf. [2], and exploring sensitivity relations concerning the shell geometry, cf. [3]. In this work, these methodologies have been used to formulate efficient sensitivity relations of composite shell structures. Employing a variational approach that embeds sensitivity analysis into the continuum mechanical framework, sensitivity relations for layer thicknesses and fiber orientations are established. These continuously derived quantities can be readily discretized and incorporated into a finite element environment.

Numerical examples are referenced to discuss various aspects, such as computational performance, numerical accuracy, and algorithmic treatment.

A HYBRID VIRTUAL ELEMENT FORMULATION FOR PLANE ELASTICITY

Francesco Salvatore Liguori[1], Antonio Madeo*[1], Sonia Marfia[2] and Elio Sacco[3]*

[1]*University of Calabria*
[2]*Roma Tre University*
[3]*University of Naples Federico II*

ABSTRACT

The enhanced Virtual Element Method (VEM) formulation, recently proposed by D'Altri et al. [1] for plane elasticity, provides numerous advantages over the classic VEM. The main innovation resides in the expression of the projection condition through an energy norm in which a divergence-free interpolation is assumed. This leads to the absence of stabilisation terms and a considerable accuracy improvement.
This work shows how the minimisation of Total Potential Energy and the projection operation typical of enhanced VEM can be obtained from the stationarity condition of the Hellinger-Reissner mixed functional. Starting from this theoretical result, a family of polygonal elements for plane elasticity is proposed, named as Hybrid Virtual Element Method (HVEM). The primary unknowns are the displacements along the element contour, as usual in classic VEM, and the stress field. The latter is assumed to within a polynomial basis that a-priori satisfies the equilibrium equations expressed on a Cartesian frame and corresponds to the divergence-free assumption in the projector term in enhanced VEM formulations. Then, all the discrete operators can be evaluated through line integrals, facilitating the formulation for polygonal elements with a generic number of edges [2].
The HVEM not only provides a wider theoretical background, but also reveals a close relationship with mixed hybrid-stress Finite Elements (FEs) [3], traditionally limited to triangular or quadrilateral geometries. Then, leveraging the broad literature on the hybrid-stress FEs behaviour, we discuss the critical role of selecting appropriate stress interpolation functions, not only for the element stability, but also for the accuracy improvement. In particular, a so-called iso-stable interpolation, that adopts the minimum number of stress parameters to ensure the element stability, turns out to be the optimal choice for achieving accurate solutions also for coarse meshes.

INVESTIGATING EVOLUTION OF VOIDS IN AL2219 USING 3D CHARACTERIZATION AND CRYSTAL PLASTICITY SIMULATIONS

Hojun Lim[1], Philip Noell[1], Matthew Vaughan[2], Andrew Polonsky[1], John Emery[1] and Kyle Johnson[1]*

[1]*Sandia National Laboratories*
[2]*Texas A&M University*

ABSTRACT

In this work, emerging high-resolution computed tomography (CT) and crystal plasticity (CP) simulations are used to understand void growth mechanisms in aluminum alloy 2219. By combining experimental and computational results, we investigate how microstructural features such as grain boundaries, triple junctions and particles influence void growth. Both DCT (Diffraction Contrasted tomography) and XCT (X-ray Computed Tomography) techniques are used to characterize initial crystal orientations, voids and phases, and their evolution at various applied strains. On the modeling side, high-fidelity crystal plasticity simulations are performed at the same resolution as CT measurements to obtain local stress/strain fields, stress triaxiality and Lode parameter that are frequently used to understand the void growth. Developed framework enables direct and quantitative comparisons between experimental and computational results for understanding void growth mechanisms in metal alloys.

IDENTIFYING CRACKED/DAMAGED STRUCTURES AND THEIR LOCATIONS USING PHYSICS-INFORMED MACHINE LEARNING WITH SPARSE MEASUREMENTS

Jae Hyuk Lim[*1], Myeong-Seok Go[1], Hong-Kyun Noh[1] and Seungchul Lee[2]*

[1]Jeonbuk National University
[2]Korea Advanced Institute of Science and Technology

ABSTRACT

In this paper, we introduce a novel method for identifying cracked or damaged structures and precisely locating these flaws by integrating physics-informed machine-learning techniques. Our approach combines principles from physics with advanced machine learning algorithms to address longstanding challenges in structural damage detection. By analyzing the vibrational, acoustic, and quasi-static properties of structures, we extract valuable insights from sparse measurement data to detect subtle indicators of structural degradation. Through rigorous experimentation, we validate the effectiveness and precision of our method in detecting structural damage, highlighting its potential to revolutionize current practices in structural health monitoring and maintenance. To demonstrate the performance of the proposed work, several practical examples, such as cracked and damaged structures, were treated. Finally, it was found that the proposed approach is sufficiently accurate despite a few sensor measurement data. It means that it has great potential to evaluate the anomaly detection of large engineering structures.

HYBRID SURROGATE MODELING FRAMEWORK AND REINFORCEMENT LEARNING FOR DIGITAL TWIN APPLICATIONS

Jasmin Lim[*1], Dimitrios Pylorof[2], Humberto Garcia[2] and Karthik Duraisamy[1]*

[1]*University of Michigan*
[2]*Idaho National Laboratory*

ABSTRACT

Nuclear energy has high operational risks that a digital twin (DT) can aid in the areas of operations & management (O&M); reactor safety analysis and improvement of plant efficiency. A system surrogate model is developed to predict physical asset quantities (e.g. reactor, heat exchanger, pumps) and computational assets responses (e.g. control system). The system surrogate model is labeled hybrid because it leverages the accuracy of physical models for robustness while also integrating low-fidelity models for speed and predictive capabilities. The framework is applied to a Pebble-Bed Fluoride-Salt-Cooled Reactor (PB-FHR), a new-generation reactor that has drawn interest from both research institutes and commercial companies. The physics-based models are used to compute the relative xenon concentrations and pump degradation, both essential quantities that determine the current reactor conditions. The remaining quantities are predicted using a Vector Autoregressive Moving Average with Exogenous term (VARMAX) model trained with data generated from the System Analysis Module (SAM); a transient system analysis tool for advanced reactor concepts. This model can also update itself by assimilating online measurements. The system state awareness provided by the surrogate model is utilized for the reinforcement learning (RL) of weighing plant operations, predictive maintenance and market performance.

[2]*Hanyang University*

ABSTRACT

Since the driving performance of a magneto-mechanical system is dominated by the magnetic flux distribution, optimizing the shape of the ferromagnetic material (FM), which determines the path and intensity of the magnetic flux, is the most important design process for improving system performance. The important properties of FMs considered here are the magnetic permeability, which describes the amount of magnetic flux generated due to the magnetic field intensity, as well as the energy loss characteristics due to magnetic hysteresis and eddy currents. In particular, since most magneto-mechanical systems currently under development for industrial devices use alternating electric fields, energy loss occurring within FMs is a critical factor that increases the operating temperature of the system and impairs performances. Therefore, in order to design a high-performance system, it is necessary to use a FM that simultaneously satisfies high permeability, low hysteresis, and low eddy current loss, however it is difficult to develop a new material with these properties.
This study aims to optimize both the microstructure of the FM composite and the shape of the magnetic core using the topology optimization method with a large degree of design freedom [1], and apply the optimized magnetic core with high magnetic permeability and low loss coefficient to a magnetic actuator. To do this, a high-frequency homogenization method, which uses a complex permeability tensor to consider the frequency of the applied magnetic field and predict the eddy current loss density of FMs [2], is applied to magnetic field analysis and design. The optimization problem is formulated to optimize the element density and orientation of the core for achieving the target force and flux distribution, while optimizing the microstructure of the FM that can reduce loss even at high frequency of the applied magnetic field. To verify the effectiveness of the proposed design method, optimized results of a linear oscillatory actuator with high operating frequency are introduced.

PATIENT-SPECIFIC OPTIMIZATION OF THERAPEUTIC REGIMENS VIA DIGITAL TWINS TO IMPROVE TRIPLE NEGATIVE BREAST CANCER RESPONSE TO NEOADJUVANT THERAPY

Chengyue Wu[12], Ernesto Lima[1], Casey Stowers[1], Zhan Xu[2], Clinton Yam[2], Jong Bum Son[2], Jingfei Ma[2], Gaiane Rauch[2] and Thomas Yankeelov[12]*

[1]The University of Texas at Austin

ABSTRACT

Neoadjuvant therapy (NAT) is the standard of care for locally advanced triple-negative breast cancer (TNBC). However, pathological complete response (pCR) rate in TNBC patients to current NAT regimens is 50-60% [1]. Aside from the need to develop new therapies with higher efficacy and lower toxicity, a critical barrier to improving TNBC response is the lack of rigorous ways to personally tailor therapeutic regimens. We seek to address this challenge by employing digital twins (i.e., mathematical models that provide a virtual representation of individual patients to predict changes in tumor status) to systematically evaluate TNBC patient's response to different NAT regimens, thereby patient-specifically optimizing treatments.

A cohort of TNBC patients (n = 37) from the ARTEMIS trial (NCT02276433) [2] was used for this study. For each patient, standard-of-care NAT chemotherapy was administered (i.e., 4 cycles of Adriamycin/Cytoxan (A/C) every 2-3 weeks, followed by 12 cycles of weekly Taxol (T)) and longitudinal MRIs were collected before and during NAT. Post-surgical pathology was performed to assess final response status. A digital twin framework has been developed by integrating longitudinal MRIs with a mechanism-based model to predict the treatment response [3]. The model was based on a reaction-diffusion equation that describes the change in tumor cellularity due to migration, proliferation, and drug-induced death. With parameters personalized using the MRIs, the patient-specific model (i.e., digital twin) was used to estimate individual patient's response to 128 simulated but clinically feasible schedules of A/C/T. The predicted response (pCR or non-pCR) from each alternative schedule was compared to the patient response from their actual treatment to evaluate the effect of altering treatment regimens.

We observed that, without changing the total dose, shortening the duration of A/C/T administration increased the treatment efficacy. The effectiveness of altering the schedules varied substantially in different patients. In particular, 8 out of 18 patients who had non-pCR responses to their actual treatment were predicted to achieve pCR with the dense-dose Taxol (i.e., 4 cycles of biweekly Taxol), indicating a 21.62% improvement of pCR rate in the study cohort. We are currently applying the optimization to a larger cohort (n > 130).

The preliminary results of our approach provided a unique opportunity of improving TNBC response to NAT through patient-specific optimization of therapeutic schedules. Ongoing efforts focus on accounting for toxicity and investigating the effects of altering therapy type, dose, and schedule on patient response.

A SIMPLIFIED FLUID STRUCTURE ANALYSIS OF AN ELASTOMERIC SINGLE-LOBE PROGRESSIVE CAVITY PUMP

Diego Peña[1] and João Lima[1]*

[1]Federal University of Paraiba

ABSTRACT

Widely used in the petroleum industry, progressive/progressing cavity pumps (PCPs) were conceived by René Moineau in the 30s and are in continuous design and efficiency improvement. Notwithstanding, PCPs with an elastomeric stator suffer an efficiency decrease due to elastic deformation provided by the fluid pressure rise along the rotor: in cases with interference, the pressure can cause a clearance, and in cases with clearance, the gap expands. To simulate this phenomenon, the present work improves the model proposed by [1] for the analysis of two-way fluid-structure interaction (FSI) in PCPs, by coupling the element-based finite volume method (EbFVM) for the fluid flow field with more general analytical models for the structural deformation field. The previous simplified structural model was implemented as a FORTRAN subroutine accounting for the local fluid pressure as the structural load in a Hookean linear model for radial deformations only [1]. Although the proposed model can still be considered simplified, it extends the previous one-dimensional structural model to a linear plane stress state considering the Poisson effect, thus making it more realistic. The main goal is to establish a reliable procedure for the development of a three-dimensional structural model for analysis of two-way FSI in PCPs that does not require expensive computational costs, as it is currently required in this type of analysis. The EbFVM was implemented in ANSYS/CFX with a developed FORTRAN code (a DLL routine) for structured mesh generation for each time step analysis accounting for the PCP rotor/stator relative motion [1,2,3]. The results were compared with those obtained with the ANSYS/CFX native mesh deformation algorithm, and with those obtained with the previous one-dimensional approach, showing better accuracy, since the first method causes mesh distortions and hysteresis, whereas the second method does not capture the deformations developed in the angular directions of the stator cross-section.

AN EFFICIENT SEMI-ANALYTICAL APPROACH FOR THE STOCHASTIC ANALYSIS OF SOFT BIOLOGICAL STRUCTURES

Georges Limbert[1,2], Teja Melink[3] and Joze Korelc[3]*

[1]*University of Southampton*
[2]*University of Cape Town*
[3]*University of Ljubljana*

ABSTRACT

Introduction: Integration of variability and stochasticity in predictive finite element models of biological systems is of critical importance, particularly in the context of diverse populations, whereby, besides intra-individual variability, there are statistically significant differences in biophysical and microstructural properties across ancestry and age groups. In a mechanobiological context other sources of variability include boundary and loading conditions as well as biochemical factors and their driving forces [1]. Stochastic finite element (SFE) analyses aim to propagate stochastic properties of a system directly through the governing partial differential equations but are more complex to implement and computationally expensive than their deterministic counterparts [2]. It is therefore advantageous to develop general and efficient methodologies to conduct such analyses, especially those that can capture spatial variations of random variables (i.e. stochastic fields).

Method: Here, it is proposed to represent stochastic fields using the Karhunen-Loève (KL) decomposition and calculate the stochastic response of the system using a second-order sensitivity analysis [2, 3]. The numerical implementation, based on automatic differentiation, is general and modular, valid for arbitrary kinematics and constitutive laws, making it particularly attractive to model biological soft tissues and their inherent heterogeneities. KL decomposition is computed via the formulation of a macro-element associated with a Fredholm integral equation of the second kind involving the covariance kernel of the stochastic field, and whose solution is obtained via standard Galerkin procedure.

Results: The SFE framework was assessed on various examples by accounting for geometric and material stochastic fields on 2D geometries, and solutions compared to Monte-Carlo simulations. A path-following method was used to solve the geometrically and materially non-linear problems. The gain in computational speed afforded by the semi-analytical approach could reach four orders of magnitude.

Discussion and Conclusion: The ability of a perturbation approach to capture propagation of uncertainties in highly non-linear systems is inherently limited by the expansion order (here, second order). However, the use of automatic differentiation combined with optimisation of computer code means that extension of the SFE framework to higher orders is possible and should be explored in the future. The numerical framework presented here provides an attractive platform to rapidly and statistically explore the influence of multiple factors on the physics of biological tissues and structures.

QUANTITATIVE NUMERICAL STUDIES OF LITHIUM ELECTROPLATING: VISCOPLASTIC INFILTRATION AND CRACKING IN A SOLID ELECTROLYTE

Chen Lin[*1]*

[1]*Sun Yat-sen University*

ABSTRACT

This talk proposes a mechano–electrochemical multi-phase field (MPF) model to study electroplating in ASSLB, which induces cracking and short–circuiting. Different from previous models [1 - 4], in this model, large viscoplastic deformation is involved to account for huge eigenstrain induced by electroplating; The plating reaction is described by generalized BV equation involving Eshelby stress tensor, which introduces effects of conformational volume change and deformation energy on overpotential; Contact between solid phases is considered to simulate different modes of Li growth associated with mechanical constraint; MPF framework incorporated fracture–PF model to describe cracking and viscoplastic infiltration of Li. Accuracy of proposed model is validated by quantitatively comparing simulated and experimental findings [5].

This model provides a comprehensive depiction of the transition from vertical elongation to shank–expansion of Li whisker for low–voltage plating scenario with variable constraints. It indicates a transition from reaction–controlled root–growth of Li whisker to viscoplastic flow of Li in gaps or cracks. Critical time for transition, depending on bias voltage and stack pressure is quantitatively predicted.

In high–voltage plating with rigid constraints, simulation shows that cracking is caused by wedge-opening mechanism. Specially, if LLZO particle is tightly constrained, Li can only fill in narrow crack via viscoplastic flow rather than pushing sidewalls apart to increase deposition space, quickly resulting in a short circuit. If the LLZO particle is not constrained, the growth of Li changes from the fissure eruption to root–growth that widens the crack and considerably extends short–circuit time. It indicates that reducing mechanical constraints of electrolyte particles instead of increasing their mechanical strength or decreasing defect size can improve cyclability of solid–state battery or mitigate short–circuit.

INTEGRATING DEEP ENERGY METHODS IN THERMOELASTICITY AND PIEZOELECTRICITY

Kuan-Chung Lin[*1], Kuo-Chou Wang[1] and Cheng-Hung Hu[1]*

[1]*National Chen Kung University*

ABSTRACT

This comprehensive study combines two pioneering research works that investigate the use of the deep energy technique for difficult multi-physics issues, especially in thermoelasticity and piezoelectricity. The deep energy approach, which is well-known for its resilience in dealing with nonlinearities and producing exact findings, has been intensively investigated for its efficiency and accuracy in these sectors. The first section of the research looks at its use in thermoelasticity [1], examining how network parameters such as layers, neurons, and activation functions affect result accuracy. Successfully resolving 1D and 2D thermoelasticity issues, which compare favorably with analytical solutions and empirical data, has confirmed this technique. The second portion applies this concept to piezoelectricity [2], solving complex 2D piezoelectric issues as well as piezoelectric composite plate actuators. The tanh activation function emerges as a really useful tool, considerably improving accuracy. This two-part study not only proves that the deep energy method can be used instead of traditional numerical methods to solve multi-physics problems, but it also shows how to set up neural networks in the best way to make them work better and more accurately. This will help both computational physics and engineering.

STABILITY AND ERROR ANALYSIS OF GENERALISED SAV SCHEMES FOR A DIFFUSE-INTERFACE TUMOUR GROWTH MODEL

*Ping Lin**[1]

[1]*University of Dundee*

ABSTRACT

In this talk we consider a diffuse-interface (phase-field) model for tumour growth that takes into account nutrient consumption and chemotaxis. The model is described by a nonlinear system consisting of a Cahn-Hilliard-type equation coupled with a reaction-diffusion equation. We first prove the existence of its weak solutions. Efficient schemes are then constructed based on the idea of scalar auxiliary variable (SAV), which we show are not only decoupled and easy to implement, but also have the properties of mass conservation and unconditional energy stability. Furthermore, we derive rigorous error estimates of one of the schemes. Several numerical examples are presented to validate the accuracy and stability of the proposed schemes. It is worth noting that when the scheme is equipped with an adaptive time-stepping strategy, it effciently simulates the typical phenomena of aggregation of multiple tumours with different shapes and tumour chemotactic growth. This is a joint work with Zhaoyang Wang and Junxiang Yang.

[3]National Taiwan University

ABSTRACT

Recently, Autonomous Mobile Robots (AMRs) have become promising solutions for the tasks of picking, transporting and placing objects within dynamic environments in smart factories. AMRs are required to position and navigate themselves within an indoor space that is filled with stationary obstacles such as walls, shelves, tables, machines, etc. as well as moving personnel. Ensuring high precision in the positions and configurations of AMRs is difficult due to factors such as wheel slippage, mechanical part backlash, unstable vibrations, sensor inaccuracies and environmental changes. In this paper, the uncertain motions of a 9-degree-of-freedom AMR (i.e., 3 for the ground vehicle and 6 for the robot arm) have been studied and a probabilistic approach for path and motion planning of AMR has been proposed. The probability that the shortest distance between the AMR and the nearby obstacles exceeds the allowable limit was consistently kept at a safe level. In the optimization process of AMR path and motion planning with obstacle avoidance, a linear probabilistic constraint with respect to the AMR control parameters was utilized to maintain the desired reliability level. In this approach, a Most Probable Target Point (MPTP) was found at the tail of the random distribution of the AMR configuration, which has a shortest distance to a Most Probable Failure Point (MPFP) on the nearby obstacle. Both MPTP and MPFP, which were simultaneously determined by a sub-optimization process, were essential for the formulation of the linear probabilistic constraint. Various numerical examples were utilized to show the performance of the proposed Probabilistic Indoor Navigation and Object Manipulation (PINOM) of AMR.

A FAST PREDICTION METHOD FOR BEARING STRENGTH OF AIRCRAFT COMPOSITE BOLTED STRUCTURES CONSIDERING INITIAL ASSEMBLY DEVIATION

Qingyuan Lin[*1], Yong Zhao[1], Yuming Liu[1], Wei Pan[1], Wencai Yu[1] and Yu Ren[1]*

[1]Shanghai Jiaotong University

ABSTRACT

The application of advanced composite materials is currently a key approach to improving the performance of high-end equipment such as aerospace. Joints are the weak points of composite structures. More than 60% of the failure of composite structures occurs in the connection position. Mechanical behavior analysis and joint performance prediction of the assembly and loading process of the composite structure is the key guarantee to realize its expected performance. Bolted joins are the most important form of assembly for composite structures. In the assembly process of composite bolted structures such as airplane wings, due to the influence of the complex multi-source uncertainty factors such as the manufacturing errors of the parts, the accumulation of errors in the pre-procedure assembly process, and the deviation of the assembly tooling, composite laminates always have initial assembly deviations, which are mainly manifested in the shape deviation of the parts and the relative position deviation between the parts. The above shape-position deviations will have a significant impact on the assembly state of the composite bolted joint and result in the joint strength deviating from the design value. This is a key bottleneck in improving the performance of composite bolted structures. Existing related studies have given less consideration to initial assembly deviations, usually focusing on the effect of a single deviation when it acts alone. In fact, there is a significant coupling effect of multi-source shape-position deviations on the assembly results and joint strength. In this study, a fast prediction method for the strength of the composite bolted joints considering the effects of initial shape-position deviation is proposed. This method firstly quantitatively expresses, and data fuses the multi-source initial assembly deviation information of the composite bolted joint. Using the fused deviation information as input, the joint strength is obtained through the virtual assembly-loading analysis. Prepare datasets by parametric sampling and batch simulation. Construct a neural network model and train it using this dataset. Finally, the fast model for the strength prediction considering the initial shape-position deviation of composite bolted joints is established. This model can provide assistance in performance evaluation and calibration of composite bolted joints.

INVESTIGATING THE EFFECTS OF THE MECHANICAL VENTILATION STRATEGIES ON PULMONARY MECHANICS PROPERTIES FOR CHILDREN WITH ACUTE RESPIRATORY DISTRESS SYNDROME

Siang-Rong Lin[*1], Jeng-Hung Wu[2], En-Ting Wu[2] and Chia-Ching Chou[1]*

[1]National Taiwan University
[2]National Taiwan University Hospital

ABSTRACT

This study aims to investigate the mechanical ventilator support management and pulmonary physiological characteristics of pediatric patients with Acute Respiratory Distress Syndrome (ARDS) in the Pediatric Intensive Care Unit (PICU).

The lung parenchyma of patients with ARDS often exhibits inhomogeneity, leading to local stress concentration and causing local lung injury, triggering a local inflammatory response. Pulmonary recruitment maneuvers, such as the application of positive end expiratory pressure (PEEP), are common treatments for patients with ARDS. Pulmonary recruitment involves the sustained application of pressure in the airways, allowing collapsed alveoli to reopen. This not only improves oxygenation in patients with ARDS but also helps prevent shear injuries caused by the repetitive opening and closing of alveoli. However, excessive PEEP can also cause lung damage, leading to Ventilator-Induced Lung Injury. At present, the optimal PEEP setting strategy remains unclear and has not yet been determined.

Therefore, we collect ventilator settings records and pulmonary compliance and inflammation evaluation data from patients with ARDS in the PICU. Through data processing and machine learning (including supervised learning and reinforcement learning), we evaluate the impact of different ventilator settings on lung compliance. Additionally, we apply the Ontology Web Language to encode the structural information of respiratory system anatomy and pulmonary mechanics, integrating this information into the machine learning models to enable them to learn from these data. This analysis enhances our understanding of how strategies of mechanical ventilator influence the physiological status of patients, providing more concrete guidance for clinical practices.

UPPER AND LOWER BOUNDS CONFIDENCE BAND COMPUTING FOR ACCURACY AND ERROR ESTIMATION USING SEFEA (STRAIN-ENRICHED FINITE ELEMENT ANALYSIS) FORMULATION

Theodore Lin[1] and Yu Hou*[2]

[1]*AMPS Technologies Company*
[2]*HuaXi Technology Innovation LLC*

ABSTRACT

Sefea (Strain-Enriched Finite Element Analysis) formulation[1] has been incorporated into several Industrial CAE products for design analysis for over a decade now. In the latest update, Sefea further refines the enrichment method by incorporating the nodal/element cluster density into the heterogeneous enrichment process. Additional convergence in accuracy is observed even with extremely coarse meshes.

Sefea technology allows general users with minimum or no FEA experience to perform routine design analysis with ease and achieve accurate and robust results. Experienced analysts can leverage speed, accuracy, convenience, and robustness to achieve superior outcomes. As CAD design analysis becomes more prevalent, users are increasingly seeking more guidance on the accuracy and reliability of the analysis results. This is the motivation for the ongoing research.

We first review the Sefea formulation and the critical nature of the zero integral-sum of the enriched strain. The method preserves the constant stress state required for convergence while elevating the low-order constant strain tetrahedron and triangle elements to the 2nd-order element accuracy without additional equations.

We observed that the lower and upper bounds of a given mesh can be derived from the enrichment process in the optimal strain enrichment development[2]. Without any enrichment, the method effectively degenerates into a constant strain low-order element with over-conservative results. Conversely, when uniformly enriched, it exhibits a softened behavior similar to the nodal integration method[3]. In comparison, the proposed enrichment formulation selectively enriches the strain during the integration process based on nodal density, element clustering, and strain variations and produces optimal results within the upper and lower bounds for the given discretization.

The implementation offers a quick feedback on the solution bounds and accuracy with small computational costs by adjusting only the enrichment component without the need for a costly element integral loop. It greatly improves the usability and accuracy projection for general CAE design analysis.

We will present the comparison with the analytical and other numerical methods, evaluating the accuracy, computational efficiency, and general usability. Comparison with traditional error evaluation techniques such as the energy error method is also reviewed. Finally, we highlight the potential areas for future research and development.

DISTRIBUTIONAL COMPLEXES AND THEIR COHOMOLOGY: HESSIAN, DIVDIV, AND ELASTICITY

Ting Lin[*1], Kaibo Hu[2], Qian Zhang[3] and Snorre Christiansen[4]*

[1]*Peking University*
[2]*University of Edinburgh*
[3]*Michigan Technological University*
[4]*University of Oslo*

ABSTRACT

Recently, there has been a growing interest in discretizing differential complexes beyond the de Rham case, including the Hessian, divdiv, and elasticity complexes. A conforming finite element discretization may involve high polynomial degrees. In contrast, using distributional spaces is much more computationally efficient. Moreover, distributional spaces can be categorized as elements from the dual mesh, which formally establishes a connection between finite element exterior calculus and discrete exterior calculus.

In this talk, I will discuss the distributional Hessian, divdiv, and elasticity complexes and their cohomologies in both 2D and 3D settings. We will prove that the cohomologies are isomorphic to their continuum counterparts. For the Hessian and divdiv complexes, we will first construct the discretization. As for the elasticity complex, we will delve into the Regge complex. Additionally, we will explore the twisted complex of the Regge complex, which can be seen as a differential complex perspective of the microstructure elasticity model.

A HIGHLY PARALLEL SIMULATION OF PATIENT-SPECIFIC HEPATIC FLOWS

Zeng Lin[*1]*

[1]*Chinese Academy of Sciences*

ABSTRACT

Computational hemodynamics is being developed as an alternative approach for assisting clinical diagnosis and treatment planning for liver diseases. The technology is non-invasive, but the computational time could be high when the full geometry of the blood vessels is taken into account. Existing approaches use either one-dimensional model of the artery or simplified three-dimensional tubular geometry in order to reduce the computational time, but the accuracy is sometime compromised, for example, when simulating blood flows in arteries with plaque. In this work, we study a highly parallel method for the transient incompressible Navier-Stokes equations for the simulation of the blood flows in the full three-dimensional patient-specific hepatic artery, portal vein and hepatic vein. As applications, we also simulate the flow in a patient with hepatectomy and calculate the portal pressure gradient. One of the advantages of simulating blood flows in all hepatic vessels is that it provides a direct estimate of the portal pressure gradient, which is a gold standard value to assess the portal hypertension. Moreover, the robustness and scalability of the algorithm are also investigated. A 83% parallel efficiency is achieved for solving a problem with 7 million elements on a supercomputer with more than 1000 processor cores.

A TWO-STEP CONSTITUTIVE MODELING FRAMEWORK BASED ON DATA-DRIVEN IDENTIFICATON AND PHYSICS-AUGMENTED NEURAL NETWORKS

Lennart Linden[*1], Karl Kalina[1], Jörg Brummund[1] and Markus Kästner[1]*

[1]TU Dresden

ABSTRACT

The formulation and calibration of constitutive models remain a difficult task for materials that exhibit complex nonlinear elastic or inelastic behavior. Therefore, new approaches, generally referred to as data-based or data-driven methods, have become increasingly popular in the computational mechanics community in recent years. However, these approaches require a large amount of data, usually stresses and strains for problems in solid mechanics. In this contribution, we present a consistent two-step approach for the automated calibration of hyperelastic constitutive models which only requires experimentally measurable data.

In the first step of our approach, data-driven identification (DDI) is applied to determine tuples consisting of stress and strain states [1]. This method enables to identify these data by only prescribing the applied boundary conditions and the displacement field which can be determined from full-field measurement methods such as digital image correlation (DIC). In the second step of the proposed framework, the data are used to calibrate a physics-augmented neural network (PANN) [2]. This model fulfills all common conditions of hyperelasticity by construction and is very flexible at the same time. The implementation of the PANN model into a finite element (FE) code is straightforward.

We demonstrate the applicability of our approach by several descriptive examples. Therefore, two-dimensional synthetic data are exemplarily generated by using a reference constitutive model. The calibrated PANN is then applied in three-dimensional FE simulations, where the solution is compared to the reference model.

BAYESIAN MULTIMODEL INFERENCE IN SYSTEMS BIOLOGY AND MEDICINE

Nathaniel Linden[*1], Padmini Rangamani[1] and Boris Kramer[1]*

[1]*University of California, San Diego*

ABSTRACT

When modeling biological systems, one must often choose from several possible models based on different sets of simplifying assumptions and theories. However, conditioning predictions on a specific model formulation can introduce uncertainty and bias due to the selection of one particular model. Thus, to ensure accurate prediction and uncertainty quantification, we must account for uncertainty in the model formulation in the resulting predictions.

Model selection and discrepancy modeling approaches allow one to choose the “best” model and directly account for model uncertainty. However, given the limited data in many biological applications, these approaches may lead to biases due to the selection of a single model. In this talk, we highlight several methods for multimodel inference that leverage the entire set of available models to avoid selection biases and account for model uncertainty by incorporating contributions from all models. Methods including Bayesian model averaging, pseudo-Bayesian model averaging, and stacking of predictive densities construct robust predictors using the entire model family and avoid conditioning predictions on one model.

In this talk, we characterize multimodel inference with several examples from systems biology, including mitogen-activated protein kinase (MAPK) signaling and prediction of pancreatic function for diabetes diagnosis. Our results show how multimodel inference accounts for model uncertainty and, thus, improves predictive certainty and reduces model selection bias. Furthermore, we demonstrate how multimodel inference yields models that better agree with experimental data and provide more reliable predictions.

A MULTISCALE ANISOTROPIC POLYMER NETWORK MODEL WITH PHASE FIELD FRACTURE AT FINITE STRAINS

Christian Linder[1] and Prajwal Kammardi Arunachala*[1]

[1]*Stanford University*

ABSTRACT

This presentation focuses on modeling fracture in rubber-like materials. Our study proposes a multiscale fracture model for elastomers, considering isotropic and anisotropic network responses, using the non-affine microsphere model and the maximal advance path constraint network model, respectively [1,2]. For the latter, macroscale fracture is driven by micromorphic regularization, introducing local-global damage variables. The model is validated using double-edge notched tensile tests and compared with experimental data. Uniaxial tensile experiments on PDMS rubber films with notches are conducted, and simulations are compared with experimental observations. Visualization of stretch and damage evolution in chains oriented differently assesses predictive capacity. Results are compared with alternative models, demonstrating the utility of our approach in accurately simulating rubber-like material fracture behavior.

SOME STRUCTURES PRESERVING KERNEL-BASED METHODS

Leevan Ling[*1] *and Sun Zhengjie*[2]

[1]*Hong Kong Baptist University*
[2]*Nanjing University of Science and Technology*

ABSTRACT

In this talk, we present innovative kernel-based meshless methods devised to preserve critical structures when solving Hamiltonian and dissipative PDEs. Our first method introduces a conservative Galerkin approach with radial basis functions for Hamiltonian wave equations, ensuring energy conservation through projection operators and a second-order average vector field scheme. The second method details a meshless Galerkin technique for dissipative PDEs on surfaces, which upholds energy dissipation inherently. Both methods are supported by rigorous error and convergence analyses, and their effectiveness is demonstrated with numerical experiments, confirming their theoretical properties.

Constitutive modeling of complex materials with machine learning and artificial intelligence

ABSTRACT

The classical, theory-driven approach to describe the deformation of a material body relies on the formulation of constitutive equations relating strains and stresses. A drawback of this approach are the efforts typically required to develop appropriate functional relations and identify material parameters .

These efforts are not required in data-driven approaches to constitutive modeling. To combine the advantages and overcome the disadvantages of both theory- and data-driven constitutive modeling, we have developed the novel concept of Constitutive Artificial Neural Networks (CANNs). This machine learning approach to data-driven constitutive modeling does not require any major a priori assumptions about the constitutive law but yet incorporates substantial theoretical knowledge about continuum mechanics and constitutive theory. This way, CANNs are able to learn the constitutive law of a material from relatively small amounts of stress-strain data. Moreover, our results suggest that CANNs can robustly discover various flavors of material models from data and by design have clear physical interpretation. These abilities will be illustrated using various data collected from arterial and brain tissue.

TOPOLOGY OPTIMIZATION APPLIED TO PROBLEMS WITH LOCAL FATIGUE CONSTRAINTS BASED ON AUGMENTED LAGRANGIAN METHOD

Carlos Eduardo Lino[*1], Emilio Carlos Nelli Silva*[1] *and André Luis Ferreira da Silva*[1]

[1]*University of São Paulo*

ABSTRACT

Authors:Carlos Eduardo Lino, André Luis Ferreira da Silva, Emilio Carlos Nelli Silva

Fatigue is the most usual failure mode of any mechanical structure subject to loading. There are several methods to predict the structure life, and different approaches can be applied to extend this life. From the point of view of materials engineering, new materials can be proposed to deal with this issue. However, developing and producing these materials can be expensive. A different approach consists of optimizing the design using some optimization algorithm, determining the optimized material distribution that ensures a higher fatigue life. This work proposes to use topology optimization to design structures subjected to permanent loads to increase the component life. The objective is to minimize the volume, considering fatigue constraints. The works in the literature deal with fatigue constraints using aggregate methods, which are common in problems considering stress constraints. Our proposed approach uses a norm of the stress field to represent the stress constraint. However, stress and fatigue are local phenomena. Thus, in this work, the Augmented Lagrangian method is used to deal with the large number of constraints in the problem. This approach, previously used in stress-constraints problems, makes treating fatigue as a local phenomenon. The Modified Goodman method is used to measure local fatigue. This method considers a sensitivity factor that accurately estimates fatigue life. Numerical examples show the efficiency of the proposed method.

RESIDUAL STRESSES COMPUTATION AND OPTIMIZATION FOR DIRECTED ENERGY DEPOSITION PROCESSES

Usman Tariq[1], Sung-Heng Wu[1], Ranjit Joy[1] and Frank Liou[*1]*

[1]Missouri University of Science and Technology

ABSTRACT

The adoption of metal additive manufacturing by various industries is being hindered by the presence of residual stresses and distortion in the deposited parts. One of the important challenges that hinder the adoption of metal AM parts is the formation of residual stresses. Layer-by-layer deposition during metal AM causes cyclical heating and cooling of the metal deposit, resulting in the formation of residual stresses [1]. The presence of residual stresses is often undesirable as it could lead to delamination and cracking of deposited parts. Parameter optimization is predominantly used for residual stress mitigation. Finite Element Analysis (FEA) is a valuable tool for predicting residual stresses, but it requires substantial computational power. Direct energy deposition (DED) is a promising additive manufacturing technique that enables the fabrication of complex structures with excellent mechanical properties. This study aims to reduce computational time by incorporating a thermo-mechanical model specifically designed for the DED processes. This model predicts the thermal history and subsequent residual stresses in the deposited material. Various FEA methods are examined to provide a comparative analysis of computational cost and numerical accuracy. These findings contribute towards the realization of a faster modeling approach, where the incorporation of efficient and accurate FEA models can optimize part quality and strength while reducing computational time.

ELASTIC-PLASTIC SEMI-ANALYTICAL METHOD AND OPTIMIZATION FOR CURVED SCARF BONDING REPAIRS OF COMPOSITE STRUCTURES

Bin Liu[1] and Yancheng Liu*[1]

[1]*Northwestern Polytechnical University*

ABSTRACT

For the semi-analytical method, Hart-Smith[1] first derived a two-dimensional analysis model for scarf repaired and step repaired isotropic materials. Basing on this method, Harman and Wang[2] introduced average reduction method of composite section elastic modulus, and derived a method for calculating stress distribution of two-dimensional scarf repaired composites. Additionally, they proposed an optimization method to minimize the peak shear stress of adhesive layer by optimizing the bonding angle distribution controlled by first order equation. To restore the stress concentration caused by the change of angles of fiber orientation accurately, Liu[3] improved the method with stiffness-distribution principle and provided a modified analytical method(MAM), which has achieved a more precise and believable result in calculating stress distribution on flat adhesive surfaces. MAM and the application of stiffness-distribution principle has been proven concise effective by Yan[4] with experiments.

In this paper, a semi-analytical stress distribution calculating method that is applicable to arbitrary shape surfaces of scarf repaired composites are proposed. To take not only the cohesive failure caused by shear stress, but also the yield of adhesive under consideration, the adhesive is regarded as an elastic-plastic material. Furthermore, an optimization algorithm basing on this method which could significantly improve the carrying capability of scarf repaired composite laminates is developed. Several examples have revealed high universality and accuracy of this method, and the optimization algorithm developed from which has achieved an excellent effect on reducing peak shear stress. Although it would be difficult to manufacture the optimized surface, this paper still provides a simple but efficient way to evaluate designs of scarf repair and reliable schemes for advancing carrying capacity of scarf repaired composites.

A HIERARCHICAL QUADRATURE ELEMENT METHOD FOR FRACTURE PARAMETERS CALCULATION AND CRACK PROPAGATION SIMULATION

Bo Liu[*1], Pai Xu[1], Siqi Jia[1] and Wei Xiang[2]*

[1]*The Solid Mechanics Research Center, Beihang University*
[2]*Southwest Jiaotong University*

ABSTRACT

This paper presents a hierarchical quadrature element method (HQEM) with p-convergence for the calculation of fracture mechanical parameters and the simulation of crack propagation with very coarse meshes and high accuracy and efficiency. The stress intensity factor (SIF), strain energy release rate (SERR), J-integral and weight function are computed using minimum mesh refinement and high accuracy. The SERR is directly computed though virtual crack closure method (VCCM) with high accuracy. Although extrapolation is needed in computing SIF and J-integral, they can also be automatically obtained by choosing a certain local mesh size. The computed fracture mechanical parameters are then used to simulate crack propagation using minimum number of elements. The number of elements is significantly reduced through interpolating the crack trajectory as a single curve and modelling the opened crack as two elements only. Thus, the number of elements is unchanged in the whole simulation process, which greatly improves the computational efficiency. The feasibility of applying the HQEM to fracture mechanical parameters computation and crack propagation simulation is demonstrated through several benchmark examples of mode I and mode II fractures (or mixed mode) with homogeneous materials as well as bimaterials. Numerical comparisons with available results in literatures validated the high accuracy and efficiency of the HQEM, which indicates it has promising potential for complex large-scale fracture problems.

SIGNED DISTANCE FIELD ENHANCED VIRTUAL ELEMENT METHOD FOR LARGE DEFORMATION FRICTIONAL CONTACTS IN FLEXIBLE MULTI-BODY SYSTEMS

Chuanqi Liu[*1]

[1]*Chinese Academy of Sciences*

ABSTRACT

We propose the signed distance field virtual element method (SDF-VEM), which is a virtual element method variant able to model large deformation frictional contact problems in flexible multi-body systems with signed distance field assisted as a geometrical tool. Leveraging the geometrical versatility inherent in the virtual element method, we could represent each flexible body with either a single-element or a multi-element polygonal mesh of arbitrary shape. This enables node-to-node contact enforcement through adaptive mesh insertion and adjustment. Addressing the complexity of contact detection scenarios in multi-body models, arising from the irregular shapes and numerous bodies involved, we introduce an SDF-assisted unified and automatic contact detection framework. Numerical examples in 2D, including Hertzian contact, spur gears engagements, and granular particles contacts, demonstrate the accuracy and effectiveness of our method.

GRADIENT-ENHANCED MODELING OF PORO-VISCO-HYPERELASTICITY-INDUCED TIME-DEPENDENT FRACTURE OF BLOOD CLOTS

Dongxu Liu[*1], Nhung Nguyen[1] and Luka Pocivavsek[1]*

[1]*University of Chicago*

ABSTRACT

A blood clot is a natural soft tissue composed of fibrin networks, red blood cells, and platelets. It contributes to hemostasis when it forms on wounded blood vessel walls, while intravascular clots can cause pathological thrombosis. Due to complex physiological loading, their fracture resistance is crucial for physiological hemostasis and pathological thrombosis. However, the mechanism of blood clot fracture is still not well understood. Quantifying blood clots' deformation and fracture is essential for diagnosing and treating bleeding disorders and thrombotic diseases. This work aims to formulate a thermodynamically consistent, multi-physics theoretical framework for describing blood clots' time-dependent deformation and fracture. This theory concurrently incorporates fluid transport through porous fibrin networks, non-linear visco-hyperelastic deformation of the solid skeleton, solid/fluid interactions, mechanical degradation of tissues, gradient enhancement of energy, and protein unfolding of fibrin molecules. The constitutive relations of tissue constituents and the governing equation of fluid transport are derived within the framework of porous media theory by extending non-linear continuum thermodynamics at large strains. A physics-based, compressible network model is developed to describe the mechanical response of the fibrin network of blood clots. The kinetic equations of the internal variables, introduced for describing the non-linear viscoelastic deformation, non-local damage driving force, and protein unfolding, are formulated according to the thermodynamics principles by incorporating a non-equilibrium energy of fibrin networks, a gradient-enhanced energy, and a stretch-induced internal energy of fibrin molecules, respectively, into the total free energy density function. An energy-based damage model is developed to predict the damage and fracture of blood clots. The proposed model is implemented into finite element code by writing subroutines and is experimentally validated using single-edge cracked clot specimens with different constituents. Computational results show that this model can accurately capture the experimentally measured deformation and fracture. The fracture of blood clots subjected to multiple loading conditions is simulated, and the results demonstrate that the deformation and fracture are sensitive to loading rate. The tissue subject to a higher loading rate is stiffer. The damage at the crack tip initiates earlier and propagates faster when the loading time approaches the characteristic time of intrinsic viscoelastic. The fluid transport influences the fracture by tissue swelling. The mechanisms of blood clots fracture are analyzed systematically. The results hypothesize the importance of fibrin network viscoelasticity and fluid transport in the stability of blood clots.

CORRELATION-BASED LIKELIHOOD-FREE CALIBRATION FOR REALISTIC INVERSION OF MODEL UNCERTAINTY PARAMETERS

Shaojun Feng[1], Hao Liu[1] and Peng Hao[1]*

[1]Dalian University of Technology

ABSTRACT

The Computational model is widely used to represent physical process property, but the prevalence of uncertainty leads to a failure to match the two. Calibration is often used to tune unknown calibration parameters of a computational model. However, model discrepancy can exist even if all calibration parameters are known. One of the main challenges in model calibration is the difficulty in distinguishing between the effects of calibration parameters versus model discrepancy. Thus, the paper illustrates in detail the reason for the identifiability problem of existing methods, and based on this, we propose a new concept that the computational model and the real physical process should be “the most similar” rather than “the closest”. Further, we propose the correlation-based likelihood-free calibration, which avoids the difficulty of solving the maximum likelihood function while obtaining the most realistic calibration parameters. By comparing all the basic function cases and one common engineering case with the existing methods, the results show that our proposed method can obtain a realistic inversion of the model parameters, and the consistency of the parameters will also significantly improve the prediction accuracy of the model.

A NOVEL DUCTILE FRACTURE PREDICTION OF ADDITIVE MANUFACTURED TI6AL4V ALLOY

Hui Liu[*1], Xuan Yang[1], Biao Li[1] and Yazhi Li[1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

Selective Laser Melting (SLM) is one of the revolutionary additive manufacturing (AM) technologies to produce metallic mechanical parts. To thoroughly understand the damage and fracture behavior of SLM-fabricated Ti6Al4V alloy under complex stress states, the article conducted experimental and simulation studies on various types of Ti6Al4V alloy specimens. By incorporating a novel stress state function into an enhanced GTN (Gurson-Tvergaard-Needleman) model, the study successfully predicted the ductile fracture behavior of the Ti6Al4V alloy.

(1) A number of tensile, compressive and torsional experiments covering various stress states were conducted with different types of the specimens, the study has clearly identified the failure modes under different stress states.

(2) A modified GTN model developed by the Authors' team was adopted in the ductile fracture analysis of SLM-fabricated Ti6Al4V alloy. The introduction of a shear damage variable and a stress state-dependent function extends the application of GTN model to a broader range of stress states.

(3) A parameter calibration strategy of the dual damage variable GTN model was proposed, based on the finite element inverse analysis and referring to a group of experimental results. These parameters encompass quenching parameters and damage parameters, with the latter consisting of 6 parameters related to void volume fraction, 4 parameters related to shear damage, as well as 1 parameter within the stress state function. The applicability of the parameters was well validated via the simulation of another group of experiments.

(4) The morphologies of the fracture surfaces were successfully predicted by using the developed damage constitutive model, and the results demonstrated that the deformation, strength and fracture modes of SLM-fabricated Ti6Al4V alloy can be well described by the developed dual damage variable GTN model. Both damage variables contribute to the different failure mechanisms. The variable of void fraction controls fibrous zone failure based on the void growth mechanism, and the shear damage variable facilitates shear fracture based on the void shear mechanism.

INCREASED POWER OF HEMODYNAMIC LOW-FREQUENCY OSCILLATIONS CAN IMPROVE CEREBRAL OXYGENATION

Shilin Yang[1], Pandeng Zhang[1], Zhixian Zhang[1], Xinyu Chen[2], Xia Long[2], Yanxia Zhou[2] and Jia Liu[1]*

[1]Shenzhen Institute of Advanced Technology, Chinese Academy of Sciences
[2]Shenzhen Second People's Hospital

ABSTRACT

Cerebral hemorrhage or ischemia can significantly increase the low-frequency oscillations of blood pressure and cerebral blood flow. Recent studies have shown that such low-frequency oscillations can improve the brain's oxygenation even in the context of reduced cerebral blood flow, which necessitates further investigation. However, this type of study requires special devices, and although previous results have suggested an increase in cerebral oxygenation associated with low-frequency oscillations, it is still unclear whether this increased oxygenation requires a certain power of low-frequency oscillations. We therefore designed and carried out this study.

We recruited 11 healthy subjects aged 18-30 years old, and the experiment was carried out at the Second People's Hospital of Shenzhen. Using the routine clinical syncope test procedure, each participant completed four consecutive stages of the test on a tilt table for syncope testing, including: 10 minutes of supine rest, then the tilt table was raised to a 70-degree angle from the ground within 6 seconds, maintained for 20 minutes, followed by oral administration of 0.25 mg of nitroglycerin, continuing for another 20 minutes, and finally returning to the initial supine position. During the test, we continuously collected blood pressure, bilateral middle cerebral artery blood flow velocity using transcranial Doppler, and near-infrared cerebral blood oxygen signals. Subsequently, we analyzed changes in the power of low-frequency oscillations using power spectral analysis of continuous blood pressure and cerebral blood flow velocity, and calculated changes in the cerebral oxygenation index based on the cerebral oxygen signal.

Our study found that the participants' cerebral blood flow velocity gradually decreased from supine (62.74±1.11 cm/s) to upright (55.65±1.83 cm/s, $P<0.05$) position, and then further after nitroglycerin administration (upright: 55.65±1.83 cm/s vs drug: 43.46±3.93 cm/s, $P<0.05$). At the same time, the power of hemodynamic low-frequency oscillations at approximately 0.1 Hz frequency progressively increased (supine: 45.37±31.38 (cm/s)2Hz-1 vs upright: 133.33±55.71 (cm/s)2Hz-1, $P<0.05$; upright: 133.33±55.71 (cm/s)2Hz-1 vs drug: 243.19±98.82 (cm/s)2Hz-1, $P<0.05$). Interestingly, although the change in cerebral oxygenation index during the upright phase was consistent with the trend of decreasing cerebral blood flow, the cerebral oxygenation index significantly increased when low-frequency oscillations were further enhanced after taking nitroglycerin (upright: 0.0101±0.0008 μM vs drug: 0.0128±0.0008 μM, $P<0.05$).

Therefore, our study suggests that the routine clinical syncope test can effectively induce hemodynamic low-frequency oscillations. We observed for the first time that the increase in cerebral oxygenation index is related to the power of low-frequency oscillations.

ENHANCING PREDICTIVE MODELING IN REACTOR BUILDING DOSE DISTRIBUTION: A NEURAL NETWORK-AIDED APPROACH

Jihong Liu[1], Koji Koyamada[1], Hiroaki Natsukawa[1] and Shuhei Kamioka[1]*

[1]*Osaka Seikei University*

ABSTRACT

Theoretical predictions of dose distribution inside a reactor building using Boltzmann transport equation present a computational challenge due to its substantial resource requirements [1]. To address this issue, we simplify the approach to a diffusion equation in situations where the mean free path of neutrons is relatively short, assuming random scattering [2]. This simplification enhances the manageability of calculations, particularly in scenarios where the scale of computational demands makes Boltzmann equation impractical.

This study involved altering the building shape and radiation source to calculate the Boltzmann transport equation. This methodology enables us to consider various scenarios and conditions influencing neutron transport within the reactor building. The obtained results were then used to derive the diffusion equation through a neural network based on physical information [3]. The incorporation of a neural network introduces computational efficiency and adaptability, thereby improving the practicality of the diffusion equation approach.

The distribution of derivation errors within the building space was visualized, aiding in comprehending the model's accuracy. This visualization highlights areas where the derived diffusion equation may deviate from the more computationally intensive Boltzmann transport equation. The identified regions where the diffusion equation approximation is effective offer valuable insights for practical applications, guiding users on when and where this simplified approach can yield accurate results.

A CONTINUUM AND COMPUTATIONAL FRAMEWORK FOR NONLINEAR VISCOELASTICITY: BEYOND THE HOLZAPFEL-SIMO APPROACH

Ju Liu[1], Jiashen Guan[1], Chongran Zhao[1] and Jiawei Luo[1]*

[1]*Southern University of Science and Technology*

ABSTRACT

Viscoelasticity is a ubiquitous mechanical property in soft matter. The constitutive and computational modeling of nonlinear viscoelasticity is particularly relevant to the understanding and prediction of the performance of various engineering and biomedical materials. There are several desirable features in the design of a model: the soundness in its theoretical root; the potential in accounting for additional materials features (e.g., anisotropy, damage, etc.); the capability to faithfully represent material behavior using as less parameters as possible; the convenience of finite element implementation.

The Holzapfel-Simo model [1] has gained popularity over the past several decades, mainly because it is amenable to finite element implementation and convenient in accounting for material anisotropy. The lack of a thermodynamic foundation has been viewed as a major drawback of this model. In our recent work, we constructed a complete thermomechanical theory for this model and thereby addressed previous concerns [2]. In particular, the study elucidates the origin of the evolution equations of the non-equilibrium stress. It also emphasizes the importance of satisfying the relaxation property for the free energy in the equilibrium limit.

Interestingly, our analysis also reveals that the Holzapfel-Simo model can be regarded as a theory built based on the Green-Naghdi kinematic assumption and the St. Venant-Kirchhoff model for the non-equilibrium elastic behavior. Based on this observation, we extend the Holzapfel-Simo model by incorporating nonlinear effects. A two-parameter strain measure family, which incorporates the well-known Seth-Hill strain family, is introduced. The Green-Naghdi kinematic assumption allows a convenient modular modeling strategy for the inelastic effects using the generalized nonlinear strain measures.

A suite of combined numerical methods is proposed for the computational modeling of the viscoelasticity model. In particular, a smooth generalization of the Taylor-Hood element based on Non-Uniform Rational B-Splines serves as the element technology and is used within a generalized Herrmann mixed variational formulation. A class of strain-drive constitutive integration schemes is discussed, which allows the energy-consistent integration of the overall system. Analysis results and numerical examples will be provided to justify the effectiveness of the proposed methodology.

RELIABILITY DESIGN OF MONOPILE FOUNDATIONS IN SPATIALLY VARIABLE SOIL CONSIDERING RANDOM LOADS

Jun Liu[1], Xinshuai Guo[1] and Ping Yi[1]*

[1]*Dalian University of Technology*

ABSTRACT

Due to the spatial variability of soil properties and the uncertainty of marine environmental loads caused by wind, waves and currents, it is indispensable to perform reliability-based design of monopiles that are extensively utilized in the offshore wind industry. In this study, the random individual capacities and probabilistic VHM failure envelopes of monopiles in spatially variable undrained soil are first obtained using the random finite element method combined with Kriging meta-modelling technique and Monte Carlo simulation. Then, the relationship between the appropriate design (characteristic) quantile of soil shear strength and normalized scale of fluctuation and coefficient of variation of soil strength is investigated when considering the spatial variability of soil as well as the uncertainty of loads. Finally, a design framework of monopiles using appropriate design quantile of soil strength is proposed and verified via an example. The results show that the designed monopile can not only meet the two reliability design requirements set in DNV (2013), but also significantly save costs. The study could be helpful to the design of monopile foundations in practical engineering.

MATHEMATICAL MODELING AND NUMERICAL SIMULATION OF MECHANICAL-THERMAL-CHEMICAL MULTI-FIELD PROCESS

Ke Liu[1], Yazhi Li[1] and Biao Li[1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

Solid materials are subjected to the interactions of multiple physical and chemical fields when they serve in extreme environments. Their response, such as deformation, mass transfer, heat transfer, and chemical reactions, is intimately related to the failure of structures. Multi-field coupling problems implicate interactions among different physical and chemical fields. Considering the multi-field coupling problem which were affected by the force, heat and chemistry, involves complex dynamic process of multi-component substance in an open system, this work chosen a macroscopically homogeneous body composed of a chemically active medium as the research object. And the force balance, mass balance, and internal energy balance equations were provided based on the fundamental laws of thermodynamics. A fully coupled constitutive model that combines mechanical, thermal, diffusion, and chemical reaction effects was then developed to describe the intricate interplay between these effects. The inertial effects of force, entropy and chemical potential were introduced into a macroscopic uniform body by considering the propagations of elastic waves, temperature waves and diffusion waves. Considering the various influential mechanisms, the contributions of mass diffusion and chemical reaction were separated. The evolution equations of heat conduction, diffusion, and chemical reaction were constructed according to the energy dissipation inequality. This coupling model can effectively describe the transient evolution and quasi-static response of multi-field coupled system. Furthermore, the weak form of governing equations were derived by applying the chemical Gibbs function variational principle, which is based on the universal variational principle of thermodynamics. In particular, the model has the ability in predicting the concentration and entropy jump conditions on the moving interface.
In order to verify the proposed model, the oxidation process of silicon nitride was numerically calculated, and the evolutions of oxide thickness and stress were presented. The results agree with the reference results, indicating that the mechanical-thermal-chemical multi-field coupled model is able to reflect the evolution laws of the stress field, concentration field, temperature field and displacement field of silicon nitride under the coupling effect of multi-physical fields.

A NOVEL GPU IMPLEMENTATION OF NONLINEAR EXPLICIT DYNAMIC ANALYSIS FOR COMPLEX CIVIL STRUCTURES

Lanqi Liu[*1], Pu Chen[1], Xianlei Wang[2] and Zhongliang Su[2]*

[1]*Peking University*
[2]*YJK Building Software*

ABSTRACT

The explicit integration method is recognized as the main approach for solving nonlinear transient dynamic responses involving material failure and large deformation. Since computation of the explicit integration is intrinsically decoupled, an efficient implement should consider parallel acceleration, especially GPU acceleration. However, there are still some challenges using GPU as the accelerators when large structures contain multiple element types or complex material constitutive models. To this end, this work presents a novel GPU acceleration strategy for explicit integration method for complex structures.

A basic parallelized computational framework is established using the Compute Unified Device Architecture (CUDA). All stages of the explicit dynamic analysis are ported to GPU, including calculating element strains, stresses and internal forces, assembling the nodal effective force and solving the kinetic equations for nodes at every time step. CPU is responsible for data output. Data transfer between the CPU and GPU is necessary only at the output time step. A concurrent execution strategy is designed to solve problems with non-uniformity of element and material types. The FE model is decomposed into a few domains depending on element or material types as well available memory. The aforementioned parallel computing processes for each domain are performed concurrently on GPU. Once the computation of nodal effective forces at each time step of all domains finishes, data communication between different domains is achieved using MPI. Different data for computation mainly reside in global memory, which is the largest memory available on GPU. These data have to be organized in optimal layouts to allow the coalesced memory access. In our data structure, data for elements and nodes are organized in structure-of-arrays. Element matrices with identified size and sparsity in one domain are rearranged as a collection of arrays with each array corresponding to the values at the same matrix position. Additionally, loop unrolling strategy are employed to reduce instruction latency on GPU. Data in one domain are divided into sets with each set of the same size as the thread block. A block with n threads treats p data sets with n entries, each thread handles entries in the same position in p data sets within one execute iteration.
Performance tests from engineering designs show that a speedup of more than 40 is achieved compared to the CPU serial code computing by commercial YJK building software with validated accuracy of the results.

MICROSTRUCTURAL CONTROL AND DEFECT ANALYSIS FOR FLOW-MEDIATED CRYSTALLIZATION USING PHYSICS-INFORMED DEEP LEARNING

Larry Willis[1], Rekha Rao[2] and Leo Liu[*1]*

[1]FAMU-FSU College of Engineering
[2]Sandia National Laboratories

ABSTRACT

Crystallization, more generally, liquid-solid phase transitions, is a ubiquitous process of significance for industries ranging from manufacturing to pharmaceuticals. Defect analysis and quality control of crystal microstructure are most important in those processes. To that end, reliable and efficient techniques that can give insight into controlling parameters for achieving desired crystal microstructures are critical. Recently, physics-informed neural networks (PINNs) have shifted the paradigm for scientific computing as a data-efficient computational tool for solving scientific inverse problems.

Based on a novel phase field crystal (PFC) formalism, we will discuss how we construct PINNs to identify key parameters controlling crystallization for systems such as CsPbI_3 perovskites. We will also demonstrate the validation and capability of the inverse problem solver for identifying crystal-level controlling strategies for defect mitigation based on first-principle synthetic data and real experimental data.

DEVELOPMENT AND EVALUATION OF MG-CA DEEP LEARNING INTERATOMIC POTENTIALS WITH AID OF AB-INITIO CALCULATIONS

Lijun Liu[1] and Yoji Shibutani*[1]

[1]*Osaka University*

ABSTRACT

Key Words: Interatomic Potential, Mg-Ca alloys, First-principles calculations, Molecular dynamics, Deep learning.

Ab initio molecular dynamics (AIMD) has become a significant tool for microscopic understanding of a wide range of problems. However, the spatial and temporal scales that AIMD can access are limited. Most AIMD calculations can only handle systems containing hundreds of atoms on picosecond timescales. On the other hand, conventional molecular dynamics (MD) can be computed efficiently, but its accuracy is limited to empirically determined atomic interaction potentials.

Nanocrystalline structures of metals, which are real-world applications, are composed of tens to hundreds of millions of atoms, which is far beyond the capabilities of ab-initio calculations. However, the main problem with empirical potentials is the need for more accuracy for structures with defects, such as point defects, dislocations, nanoclusters, etc. Therefore, the development of interatomic potentials with high accuracy is crucial.

Recently, some experimental [1] and molecular dynamic results [2] have reported that the ductility of Mg alloys is improved by the solid solution of Ca. In the design of high-performance Mg-Ca alloys, besides the solid solution effect of Ca atoms, the interactions of dislocations, twins, and grain boundaries with microstructures such as Ca solid solution clusters and precipitates are also essential factors to be considered [3]. Most developed Mg-Ca potentials can reproduce some basic properties under an equilibrium state. However, these potentials are not able to give accurate predictions when the state is unstable or defects are included. The present study used datasets from ab-initio calculations to develop Mg-Ca interatomic potentials by deep learning. Our developed Mg-Ca deep potentials can accurately predict not only basic physical, mechanical, and thermal properties but also phase transition under high temperatures and pressures, which is not able to be done by empirical potential.

CREEP LIFE PREDICTION OF COATED TURBINE BLADES CONSIDERING THE INFLUENCE OF FILM COOLING HOLE BLOCKAGE

Linchuan Liu[1], Chaoji Wang[2], Shengwei Pan[2] and Xueling Fan[1]*

[1]*Xi'an Jiaotong University*
[2]*AECC Guiyang Engine Design Research Institute*

ABSTRACT

Blockage of film cooling holes significantly impacts the operational life of coated turbine blades in harsh environments. Understanding the thermo-mechanical behavior of blades under actual film cooling hole blockage conditions is crucial for predicting failure and enhancing reliability. In this study, firstly, blockage morphologies and ratios of all film cooling holes on a full-scale turbine blade were statistically analyzed, leading to the development of a blade model incorporating blockage characteristics. Subsequently, the thermo-mechanical loads of cross-scale membrane-based structures on blades were explored using the shell conduction model and the Chaboche constitutive model. Finally, the Larson-Miller Parameter (LMP) method was adopted as the creep life evaluation criteria, considering both blocked and unblocked scenarios. The results revealed that the blockage degree of film cooling holes was lowest near the leading edge of the blade and gradually increased towards the trailing edge. Additionally, the highest temperature on the blade was located near the blade tip, with the most dangerous zone situated at the root position on the pressure surface. Blockage reduced the surface cooling efficiency and diminished the creep life, increasing the risk of blade failure. In this paper, a calculation method of cross-scale structural life model is proposed to reveal the effect of hole blockage on the creep life of turbine blades, providing valuable insights for durability assessment of coated high-temperature components.

AN EXPLORATION FOR VISCOELASTIC AND DYNAMIC PROPERTY OF 2D CELLULAR MATERIALS

Li-Wei Liu[1] and Zhen-En Jian*[1]

[1]*National Taiwan University*

ABSTRACT

Cellular materials, mimicking natural architectures inside the wood and honeybee’s honeycomb, exhibit a unique combination of high stiffness and low weight. Bridging the gap in prior research on the rate-dependent and the dynamical performance of 2D cellular materials, this study proposes models and explores the viscoelastic behavior and wave propagation of 2D cellular materials. For the viscoelastic property of the material, our study finds that an increase in energy dissipation with rising relative density under strain control but a decrease under stress input. On the other hand, when the angle of cell wall increases, the strong axis of energy dissipation shifts under strain-controlled conditions. Furthermore, the anisotropic feature of energy absorption for auxetic cellular materials is observed. These results highlight the significant effects of microstructure on the viscoelastic performance of 2D cellular materials. In addition, the exploration of dynamical property of the material reveals a remarkable increase in effective Young's modulus and a significant increase in effective natural frequency when the width of cell wall approaches the characteristic material length. This enhancement is pronounced and points out the critical role of size effect in predicting dynamic responses. Moreover, our study indicates that the existence of band gaps in plane wave propagation within 2D cellular materials signifies its inherent ability to suppress energy at specific frequencies. In essence, our exploration offers insights into the intricate relationship between viscoelasticity and dynamic performance in cellular materials, emphasizing the significant influence of microstructure and size effect.

DIGITAL DESIGN OF GRINDING WHEEL FRAME OF GRINDING MACHINE

Mingshuo Liu[*1] and Dongyan Shi*[1]

[1]*Harbin Engineering University*

ABSTRACT

This research paper explores the grinding wheel holder and feed mechanism to automate the grinding wheel holder. The specific objectives of this research are: (1) Through the determination of the overall programme of the grinding wheel holder of the grinding machine, the disadvantage of low processing efficiency of the ordinary grinding machine is overcome. Through the calculation and verification of the structure, including the lifting beam, serving grinding wheel spindle of the grinder, etc., the design and strength of the parts are verified to be safe and reliable through calculation and verification, and meet the design requirements. Completed the design and selection of the parts, thus improving the machining efficiency and quality of the workpiece. The grinding wheel holder structure is designed to improve the grinding efficiency of the grinding wheel, so that the grinding wheel can work smoothly in the grinder. This structural design extends the service life of the grinder and reduces costs. (2) Finite element analysis and simulation of the parts were carried out to make the structural design of the grinding wheel holder more reasonable, and to improve the reasonableness of the material and structure selection of the grinding wheel holder.

ASYMPTOTIC HOMOGENIZATION FRAMEWORK FOR PHASE FIELD FRACTURE OF HETEROGENEOUS MATERIALS AND APPLICATION TO TOUGHENING

Sen Liu[*1] and Yongxing Shen*[1]

[1]*University of Michigan, Shanghai Jiao Tong University*

ABSTRACT

We propose an asymptotic homogenization framework to account for the fracture of heterogeneous materials. This framework upscales the phase field model for microscale fracture and outputs anisotropic effective properties such as the degraded elasticity tensor and the fracture toughness. Furthermore, it quantitatively accounts for the toughening effect in a succinct way. More specifically, when the critical energy release rate of a heterogeneous material is uniform, the framework reveals that toughening is essentially determined by the disparity of the toughnesses, the energy absorbed by the material before cracking.

AN INTERFACE-ENRICHED TOPOLOGY OPTIMIZATION FOR MITIGATING THE EFFECT OF SURFACE FLAWS IN 3-D BRITTLE SOLIDS

Shangru Liu[*1] and Alejandro M. Aragón*[1]

[1]*Delft University of Technology*

ABSTRACT

We propose a fracture-based topology optimization procedure for tailoring the fracture resistance of 3-D brittle solids. Developing on our previous work [1], topology is described by means of a level set function that is parameterized by radial basis functions, and the structural response is computed via the Interface-enriched Generalized Finite Element Method (IGFEM). Semi-circular cracks are assumed to nucleate at the location of enriched nodes that are crated throughout solid boundaries. Energy release rates (ERRs) for all cracks are evaluated by means of topological derivatives, for which we only require the stress field of a single finite element analysis of the uncracked geometry. To that end, an accurate nodal stress field is obtained by means of a non-local stress improvement procedure. The objective function of the topology optimization aggregates all ERRs using the P-mean function. Two schemes are proposed in relation to the direction of cracks: We first fix the crack opening direction to be parallel to either the xz or yz planes. We then relax this restriction and assume the crack opening direction to be perpendicular to the direction of the first principal stress. 3-D numerical examples, including the commonly studied L-bracket benchmark problem, showcase the capability of the procedure.

TOPOLOGY OPTIMIZATION OF VIBRATING STRUCTURES AND PHONONIC CRYSTALS WITH PRESCRIBED FREQUENCY BANDS

Qiangbo Wu[1], Quhao Li[2] and Shutian Liu[*1]*

[1]Dalian Univerisity of Technology
[2]Shandong University

ABSTRACT

Vibration brings lots of harmful effects for engineering structures in aerospace, high-speed train, and high precision machine, et. al. Thus, how to reduce structural vibration has been a hot topic in engineering and academics. For lots of engineering structures, such as machine tools, vibration isolators, et al., they usually work in some frequency bands[1,2]. When the working or external excitation frequency is equal to or close to the natural frequency of a structure, the resonance phenomenon will happen. Therefore, by reasonably designing the structures and adjusting the natural frequencies to keep away from the common manufacturing or working frequency bands can effectively mitigate the vibration level. In this study, a new continuous and differentiable mathematical formulation of the frequency band constraint[3] based on the modified Heaviside function is proposed to achieve the prescribed frequency bands of vibrating structures. Furthermore, compared to the vibration structural design, the difficulty of phononic crystals' prescribed frequency bands design lies in the correlation between stiffness matrix and wave vector, which is a typical multi-condition eigenvalue problem. Directly utilizing the frequency band constraints may lead to numerical convergence difficulties. Thus the ipsilateral frequency constraint based on a modified Heaviside function is further proposed. Since the developed functions are continuous and differentiable, the sensitivity of the constraint functions can be derived for using the gradient-based optimization solver. The proposed formulation can treat with multi-frequency band constraints and is easily integrated into a topology optimization model. Several numerical examples, including single- frequency band and double-frequency bands problems, are solved by the proposed method. The results validate the effectiveness of the developed method.

DEVELOPMENT AND ANALYSIS IN DATA-DRIVEN SYSTEM IDENTIFICATION METHODS WITH APPLICATIONS IN FLUID DYNAMICS

Xinyang Liu[*1]

[1]*University of Calgary*

ABSTRACT

This work will focus on the development and analysis of data-driven system identification methods and applications in fluid dynamics. The objective is aiming to uncover the underlying pattern of the flow based on model-order reduction methods, in addition to the insights of the flow mechanics. The nature of fluid is very intricate mainly because of being nonlinear, immense in spatial-temporal dimensions, sensitive to the boundary conditions and it's interfered by the noise of irrelevant behaviors during the data measurement. The reduced-order models achieve to identify and reconstruct the principal dynamics indicating the physics of the respective flow. In addition, they filter the noise to prevent from the over-fitting problem. The understanding of the nature of fluid dynamics bridges from the broad existence to the numerous applications in diverse fields, such as performance improvement and energy saving in manufacturing which is a priority area in Canada.

A VISCO-HYPERELASTIC CONSTITUTIVE MODEL OF HYDROGEL BY CONSIDERING CHAIN'S SLIP MECHANISM

Qingsheng Yang[1] and Xinyu Liu[1]*

[1]Beijing University of Technology

ABSTRACT

Polymer is a typical entropic elastic material, and its mechanical response is highly decided by the change of network's conformation. The micro conformation's changing introduces the macro mechanical behavior. For finite deformation, the conformation changes not instantaneously, which leads to visco-hyperelasticity on macro. This process is not only related to loading time but also a multiscale question. In general, the conformation changes in two fields: 1) the single chain's deformation; 2) the relative position's change between chains. To build the bridge from micro to macro, a new transition is put forward in this work. The one-dimensional chain is extended to a three-dimensional cylinder to consider the effect of slippage. Another two free degree is introduced to capture the spatial-temporal characteristic of chain's conformation. The microscopic behavior of chain is then discussed and related to macro behavior of material. The slippage of chain is considered as the main reason leading to the viscosity by this model. This work provides an explanation for the origin of the viscosity in hydrogel by the opinion of chain's motion and gives a new method to build visco-hyperelastic constitutive model.

OPTIMUM DESIGN METHOD FOR ARTIFICIAL EAR OSSICLES BASED ON A HIGH-PRECISION VIBRATION ANALYSIS MODEL

Yang Liu[1]*

[1]*Sojo University*

ABSTRACT

The conductive hearing loss occurs when the middle ear is damaged by various ear diseases, that results in hard sound conduction through the eardrum and three ossicles to the inner ear. The tympanoplasty operation is often carried out to reconstruct the damaged ossicular chain, and to improve the sound conduction efficiency. In the ossicular chain reconstruction, an artificial part called “columella” is produced and used instead of incus which is generally broken. In this operation, the sound conduction efficiency changes by the variations in the shape, material and mounting position of the columella. Currently, the operation is carried out based on the workmanship and experience of the surgeon. In our previous studies, dynamic characteristics of the middle ear in sound conduction have been investigated using three-dimensional finite element method. Based on the analysis results, we have proposed that the hearing restoration effect can be estimated by a comparison of the displacement of the steps footplate between a healthy model and an operation model. Then, designing a reasonable artificial auditory ossicle prior to the operation seems to become possible. However, most of these researches are confined to analytical research dealing with the effect of shapes or mounting positions of the columella, and the optimization based on numerical methods has not been studied.
In the present investigation, an intricate model for the analysis of middle ear vibrations with high precision was formulated, utilizing empirically obtained measurements. A finite element model was also established to simulate the operational dynamics of an impaired ossicular chain induced by chronic otitis media. Subsequently, topology optimization procedures were executed to systematically generate the most optimal configuration for the columella, a pivotal replacement component. The efficacy and soundness of the methodology advanced in this study were substantiated through rigorous verification processes. Notably, the topology optimization of the columella resulted in an augmented vertical displacement of the stapes baseplate, thereby exhibiting potential enhancements in auditory performance post-surgery.

GOAL-ORIENTED ADAPTIVE MULTILEVEL QUASI-MONTE CARLO FOR RANDOM ELLIPTIC PDES

Yang Liu[*1], Joakim Beck[1], Erik von Schwerin[1] and Raul Tempone[12]*

[1]*King Abdullah University of Science and Technology*
[2]*RWTH Aachen University*

ABSTRACT

We present our work titled "Goal-oriented adaptive multilevel quasi-Monte Carlo (MLQMC) for elliptic random PDEs," building upon [Beck, Joakim, et al., "Goal-oriented adaptive finite element multilevel Monte Carlo with convergence rates." Computer Methods in Applied Mechanics and Engineering (2022)] and other ongoing research. Our objective is to solve an elliptic partial differential equation (PDE) with lognormal random input data, when the PDE model faces geometry-induced singularity.

Earlier research [Moon, K-S., et al. "Convergence rates for an adaptive dual weighted residual finite element algorithm." BIT Numerical Mathematics 46.2 (2006)] established convergence rates for a goal-oriented adaptive algorithm. This algorithm utilized isoparametric d-linear quadrilateral finite element approximations and the dual weighted residual error representation in a deterministic context. Notably, this algorithm refines the mesh based on the error's impact on the Quantity of Interest (QoI).

Our current work seeks to merge MLMC/MLQMC with the adaptive finite element solver. Unlike traditional Multilevel Monte Carlo methods, where each sample is determined using a discretization-based numerical method (with resolution tied to the level), our adaptive MLMC (AMLMC) algorithm employs a series of tolerances as its levels. Specifically, for a particular realization of the input coefficient and a set accuracy level, the AMLMC formulates its approximate sample using the initial mesh from the sequence of deterministic, non-uniform meshes. These meshes are produced by the previously mentioned adaptive algorithm and meet the sample-dependent bias constraint. Additionally, the incorporation of QMC enhances the convergence rate.

A PHASE-FIELD APPROACH FOR THE NUCLEATION AND PROPAGATION OF DYNAMIC CRACKS

Yangyuanchen Liu[1], Oscar Lopez-Pamies[2] and John Dolbow[1]*

[1]*Duke University*
[2]*University of Illinois Urbana-Champaign*

ABSTRACT

Recently, Kumar et al. [1] proposed and revised a phase-field approach for the nucleation and propagation of fracture under arbitrary quasistatic loading conditions. The model accounts for an arbitrary material strength surface through an external driving force in the evolution equation for the phase-field. In this talk, we extend this model through the addition of inertial forces. The dynamic version of the model is then validated against a broad range of benchmark experiments for dynamic brittle fracture, including the experiments by Kalthoff and Winkler, the Brazilian fracture test, and a recent experiment investigating crack initiation, propagation and branching in soda-lime glass specimens [2]. Numerical simulations illustrate the proposed dynamic phase field model provides reasonable results compared to experimental observations and a cohesive phase field model by Geelen et al [3].

SOME ADVANCES ON THE FAST BEM FOR ACOUSTIC PROBLEMS

Yijun Liu[*1], Ruoyan Li[1], Zonglin Li[1] and Zhenyu Gao[1]*

[1]*Southern University of Science and Technology*

ABSTRACT

Some progresses on the boundary element method (BEM) for solving acoustic wave problems will be reported in this talk. For the frequency-domain acoustic wave problems, a new fast direct solver is proposed to improve the computational efficiencies in the solutions of the BEM equations. New enriched boundary elements based on the traditional constant elements and using plane wave expansions are also proposed to improve the representation of the variables on the boundary in the discretization of the boundary integral equations. For the 3-D time-domain acoustic wave problems, a new solution strategy based on the concept of a kernel-function library is developed in order to save the computer memory consumption in the solution of the time-domain BEM. Various examples using the above proposed new methods in the acoustic BEM are presented in this talk to show their accuracies and efficiencies in solving acoustic problems in both frequency and time domains.

NEURAL NETWORKS WITH LOCAL CONVERGING INPUTS (NNLCI) FOR SOLVING CONSERVATION LAWS AND MAXWELL'S EQUATIONS IN VARYING DOMAINS WITH GREATLY REDUCED COMPLEXITY AND TRAINING COSTS

Harris Cobb[1], Haoxiang Huang[1], Hwi Lee[1], Yingjie Liu[1] and Vigor Yang[1]*

[1]Georgia Institute of Technology

ABSTRACT

This talk is based on a series of joint works (arXiv:2109.09316 and 2204.10424). With Haoxiang Huang and Vigor Yang, we are able to predict discontinuities and smooth parts of solutions of the Euler equations in 1D and 2D by a neural network accurately. For example, in order to predict the solution of the 1D Euler equations at a space-time location, one can design the output of a neural network to be the solution value at the location. If one tries to design the input as the low-cost numerical solution patch in a local domain of dependence of the location (where the information comes from), can the neural network tell if the input is across a shock or in a smooth region ? The answer is no! Our approach uses two numerical solutions of a conservation law from a converging sequence, computed from low-cost numerical schemes, and in a local domain of dependence of a space-time location as the input for a neural network to predict its high-fidelity solution at the location. Despite smeared input solutions, the output provides sharp approximations to solutions containing shocks and contact discontinuities. The method reduces the complexity by several orders of magnitude compared to a fine grid numerical simulation, has much lower cost to train, and can be used naturally in varying computational domains through training and prediction because it's a local method. It can be applied to other differential equations, e.g., the Maxwell's equations for solving electromagnetic waves scattered around complicated PECs (Cobb, Lee and Liu, arXiv:2302.02860).

GENERATIVE MODEL TO PREDICT THE DEFORMATION FIELD OF CFRP LAMINATES WITH GEOMETRIC DEVIATIONS IN WING ASSEMBLY

Yuming Liu[*1], Yong Zhao[1], Qingyuan Lin[1], Wei Pan[1], Yu Ren[1] and Wencai Yu[1]*

[1]Shanghai Jiaotong University

ABSTRACT

Thin-walled structure of CFRP laminates is widely utilized in the assembly of aircraft wings. The deformation field generated during the assembly process can impact the assembly performance of the structure, thereby influencing the product quality and operational performance of the wings. The geometric deviations on the critical mating surfaces of the laminate are key factors influencing the deformation fields during the assembly process. Analyzing the mapping relationship between geometric deviations and assembly deformation field plays a crucial role for assessing the assembly results. The traditional analysis methods only consider the impact of simple directional deviations on assembly results and do not comprehensively account for the part geometric deviations. This paper proposes a deviation- deformation analysis framework for CFRP laminates in aircraft wing assembly. The framework introduces a multi-scale geometric deviations modelling method based on the statistical parameters for critical assembly features. Subsequently, it integrates heterogeneous data characterizing shape deviations by employing the encoders. Finite element analysis is then conducted to calculate the assembly deformation field considering the constitutive relationships and damage mechanisms. Taking the parameters representing the geometric deviations as input and deformation field as output, a conditional generative model is employed to learn the influence pattern of the geometric deviations on the deformation field. The framework establishes a prediction model from the deviation field to the deformation field and introduces specific accuracy metrics. Corresponding simulations and experiments demonstrate that the proposed method can predict assembly deformation field more efficiently than traditional numerical methods. It exhibits excellent performance on the accuracy metrics, enabling accurate and efficient field-to-field predictions. This method, by learning expert knowledge such as damage mechanisms and mechanical characteristics during the assembly process, constructs an end-to-end deformation prediction for the CFRP laminates. The predicted results can serve as a research framework for predicting other physical fields.

ANISOTROPIC TAILORED SPINODOID MECHANICAL METAMATERIALS: CONSTITUTIVE MODEL-GUIDED RAPID INVERSE DESIGN AND APPLICATION IN ARTIFICIAL BONE IMPLANTS

Zhanli Liu[*1], Ziming Yan[1] and Zhuo Zhuang[1]*

[1]*Tsinghua University*

ABSTRACT

Spinodoid mechanical metamaterials have garnered significant attention in designing lightweight, high-strength engineering structures and medical implants due to its tunable extreme anisotropic behavior. However, the lack of explicit relationship between complex topology and anisotropic mechanical properties severely restricts rapid inverse design and metal additive manufacturing for spinodoid materials with desired mechanical response. In this study, an integrated methodology leveraging constitutive model-guided rapid inverse design and additive manufacturing for spinodoid metamaterials is developed. First, the volume-fraction- and fabric-tensor-based orthotropic constitutive model for spinodoid materials is developed to describe how topological parameters determine effective mechanical properties. Guided by the parametric constitutive model, representative spinodoid structures are efficiently selected to characterize the mechanical property variation in the whole material space. Next, a deep learning-based model trained by 256 representative spinodoid samples is proposed to inversely design tailored spinodoid materials, which substantially reduces the training sample demand and promotes the pretraining efficiency of design model. Furthermore, by representing the complex 3D spinodoid structure as a two-dimensional topological parameter via dimension reduction method, the explicit structure-property relationship for arbitrary topological parameters is built and the target structure can be efficiently searched by a global optimization strategy. At last, the approach is successfully applied in metal additive manufacturing for tailored spinodoid materials with Ti6Al4V that matches the orthotropic mechanical properties of cancellous bones. The new approach paves an efficient way to build the property-structure-process relationship for precision-engineered spinodoid mechanical metamaterials with tailored mechanical performance in various applications.

STABILIZED UNFITTED FINITE ELEMENT METHOD FOR HYDRO-MECHANICAL COUPLING WITH WEAK DISCONTINUITY

Yimin Zhang[1], Yuxin Tong[1], Fanke Wu[1], Yongliang Wang[1] and Zhijun Liu[*1]*

[1]Lanzhou University

ABSTRACT

The traditional finite element method requires that the mesh must match with various discontinuous, which can significantly increase the difficulty of preprocessing for hydrodynamic coupling problems with complex boundaries and material interfaces. In such case, the finite element method using unfitted mesh is obviously more advantageous, however, this method also has certain problems, for example, irregular mesh cutting may lead to ill-conditioned coefficient matrix to appear, which in turn affects the accuracy and stability of the algorithm. The ghost penalty technique was proposed to overcome the ill-conditioning issue. Recently, an unfitted finite element was proposed for two-field poroelasticity problem, where stabilization terms based on the ghost penalty were developed. Material interfaces are even more difficult to deal with than the boundary as they require careful treatment of the weak discontinuity conditions as well as the mesh cutting stabilization. In this paper, we formulate an unfitted finite element for the poroelastic problem with both material interfaces and complex boundaries. A weak formulation based on the Nitsche's method was developed. Ghost penalty stabilization terms are designed for both sides of the elements intersected by the material interface. The performance of the proposed methodology is tested by several benchmark and practical hydraulic problems of complicated rock-soil mixtures. The numerical results demonstrate optimal convergence rates and low-level condition numbers independent of the mesh cutting.

DIMENSION-REDUCTION REPRESENTATION FOR STOCHASTIC GROUND MOTIONS AND ENGINEERING APPLICATIONS

Zixin Liu[1] and Zhangjun Liu*[2]

[1]*Institute of Disaster Prevention*
[2]*Wuhan Institute of Technology*

ABSTRACT

When using frequency domain analysis methods to simulate random seismic actions, both traditional spectral representation and proper orthogonal decomposition belong to the conventional Monte Carlo simulation method. Currently, the conventional Monte Carlo simulation method still face difficulties such as large random variable dimensions, low accuracy of finite simulation samples, and random convergence. To solve these difficulties, this study first derives the original spectral representation (decomposition) of non-stationary random (vector) processes, The sources and significance of classical random amplitude method and random phase method are provided. On this basis, a dimension-reduction representation based on random orthogonal functions is further proposed, which introduces the constraint form of random orthogonal functions to accurately express the full probability information of the random (vector) processes of seismic ground motions with merely several elementary random variables. This dimension-reduction representation has achieved simulation of non-stationary ground motion processes, multi-point and multi-dimensional ground motion vector processes, and continuous ground motion fields. Benefitting from the dimension-reduction representation, each representative sample has assigned probability and all the probabilities constitute a complete set, which lays a solid foundation for the refined analysis of non-linear seismic response and dynamic reliability of engineering structures within the third structural design theory. By far, the dimension-reduction simulation method has been successfully applied to the stochastic dynamic response and overall reliability refinement evaluation of complex engineering structures such as high-rise buildings, large-span bridges, and dams under earthquake action.

DEVELOPMENT AND ANALYSIS OF THE THEORY OF COMPOSITE EXPANSION RING UNDER ELECTROMAGNETIC LOADING

Zongxing Liu[*1] and Jun Liu*[1]

[1]*Northwestern Polytechnical University*

ABSTRACT

High-speed impact collisions are common mechanical problems in engineering and life. Researchers have recognized that the response of objects under impact loads significantly differs from that under static loads. The dynamic mechanical parameters of materials are crucial for predicting their mechanical response under dynamic loads. Electromagnetic loading expansion ring test technology is essential to achieving a high strain rate tensile loading of materials. The intense pulse Lorentz force is sufficient for low resistivity specimens to achieve the desired strain rate. However, for high resistivity specimens, the induced current is relatively small under achievable loading voltages, making it challenging to obtain satisfactory loading results. Using a low resistivity pusher, the composite expansion ring loading scheme promotes specimen expansion and enables electromagnetic loading expansion ring tests to achieve dynamic tensile loading on most materials. Nevertheless, since this proposed test method, the theory of electromagnetic loading composite expansion rings has yet to develop fully.

This paper comprehensively analyzes the dynamic induction of coil, pusher, and specimen during the process where the pusher promotes the specimen's expansion. It considers the influence of electromagnetic-thermal-mechanical coupling on load results during electromagnetic loading processes and proposes a compound theory capable of accurately predicting composite expansion ring load processes. The simplified compound theory is also presented when dealing with specimens with relatively large resistivities.

The proposed theories in this paper are validated through numerical simulation methods. Furthermore, this paper analyzes the impact of driving ring materials on electromagnetic loading results and investigates how parameters such as coil and capacitance affect electromagnetic loading outcomes. Finally, the applicability of the simplified compound theory is discussed. This paper provides theoretical support for the design of the composite expansion ring under electromagnetic loading.

VARIATIONAL SYSTEM INFERENCE OF PHASE FIELD FRACTURE MODELS

Elizabeth Livingston[*1], Siddhartha Srivastava[2], Jamie Holber[1] and Krishna Garikipati[2]*

[1]University of Michigan
[2]University of Southern California

ABSTRACT

The mechanical behavior of biological materials is systematically studied in the paradigm of continuum mechanics. Complex phenomena, such as damage and fracture, have been modeled using the phase-field framework in which the total energy functional is minimized with respect to the deformation fields and internal variables (i.e. phase fields) to determine the material's mechanical response [1]. This approach is popular since it can model crack nucleation, propagation, branching, and merging without the need for distinct methods or additional discontinuities in the solution fields. In this work, we present a data-driven inverse method to infer the parameters of a phase-field model of fracture for materials exhibiting complex mechanical responses.

The phase-field fracture formulation has been applied in challenging biological applications such as angioplasty, aneurysm, and ligament tears [2]. This model utilizes hyperelastic free energy that degrades with evolving phase field to model damage and fracture in biological tissues. This general framework takes a modular approach to select a nonlinear stress-strain response and fracture dynamics from a set of hyperelastic models and fracture growth laws, respectively. In our data-driven approach, we identify the best hyperelastic free energy form and damage growth laws from a set of admissible candidates.

We formulate an algebraic optimization problem by considering the weak form of the momentum balance equation with different constitutive models and apply it to the deformation fields. We infer the parameters in the constitutive model and sequentially drop the non-contributing terms to infer the best-suited parsimonious model. This approach is referred to as Variational System Identification [3]. We demonstrate the performance of our methods in the face of noisy data that challenges the identification of mathematical models while attaining high accuracy in the predicted response of the inferred models.

COMPUTATIONAL MODELING OF MULTILAYERED BENDING PLATES (A 2D+ MULTISCALE APPROACH)

Pablo Wierna[1], Daniel Yago[1], Oriol Lloberas-Valls[1], Alfredo Huespe[2] and Javier Oliver[1]*

[1]Universitat Politècnica de Catalunya
[2]Centro de Investigación de Métodos Computacionales

ABSTRACT

This study introduces a novel 2D multiscale strategy, referred to as the 2D+ approach, employing a computational homogenization formalism tailored for modeling multilayered plates in situations dominated by bending. Such structural elements often involve advanced materials like laminated composites, characterized by a heterogeneous distribution of low-aspect-ratio layers exhibiting substantial nonlinear mechanical behavior across their thickness.

In this methodology, the macroscopic scale is represented by the 2D plate mid-plane, while the mesoscopic scale employs a 1D filament-like Representative Volume Element (RVE) orthogonal to the plate mid-plane, spanning the plate thickness. This RVE captures nonlinear mechanical behavior across the plate thickness at each integration point of the 2D plate discretization. The selected kinematics and discretization at these scales are chosen to effectively capture nonlinear mechanical behavior, achieve computational efficiency, and provide accurate stress distributions compared to high-fidelity 3D simulations.

The proposed strategy aligns with the standard first-order hierarchical multiscale framework, involving the linearization of the macro-scale displacement field along the thickness. It incorporates an additional fluctuating displacement field in the RVE to capture higher-order behavior, computed through a local 1D finite element solution of a Boundary Value Problem (BVP) at the RVE.
A notable feature of the 2D+ approach is the application of the Hill-Mandel principle, establishing mechanical energy equivalence in both macro and meso scales. This weakly couples the 2D macroscopic plate and the set of 1D mesoscopic filaments, resulting in significant computational savings compared to standard 3D modeling. Solving the resulting RVE problem in terms of the fluctuating displacement field enables the enforcement of an additional condition: the fulfillment of linear momentum balance (equilibrium equations). This yields a physically meaningful 2D-like computational setting for the considered structural object (multilayered plates under bending), providing accurate stress distributions typical of full 3D models at the computational cost of 2D models.

DEVELOPMENT, VERIFICATION AND VALIDATION OF 3D FEA-BASED SURROGATE MODELS FOR DAMAGE TOLERANCE APPLICATIONS

Adrian Loghin[1] and Shakhrukh Ismonov*[2]

[2]*Jacobs Technologies Inc.*

ABSTRACT

The two requirements for a cost-effective modeling procedure in probabilistic fatigue crack growth life assessment are solution accuracy and runtime speed. Quite often, solution accuracy is sacrificed for computational cost using reduced-order models, which can carry some level of solution uncertainty. To overcome such shortcomings, a 3D Finite Element (FE) modeling procedure capable of inserting, analyzing and propagating arbitrary-shaped cracks is employed to generate accurate solutions without the simplifications of geometry, crack shape/path and loading which are associated with reduced-order models.

Since 3D FEM solutions tend to be computationally expensive, machine learning algorithms (surrogate modeling) are used here to leverage the accuracy of the 3D FEM and reduce runtime. Depending on the type of the life assessment requirements, the deterministic solutions consisting of stress intensity factor values, remaining useful life or a 3D crack propagation path, are used for calibrating the surrogate models. The 3D FEA-based surrogate modeling allows for the parametrization of the geometry of interest, loading conditions, crack location, and can be further utilized in probabilistic life assessments. For instance, it can account for intrinsic fatigue crack growth rate scatter as a source of material behavior uncertainty.

Two types of surrogate models suitable for use in probabilistic fatigue crack growth life assessment are developed. For mode I applications, Gaussian Process Regression (GPR) is employed, while for mixed-mode loading cases, where the out-of-plane crack path is a critical output, Radial Basis Function (RBF)-based response surface modeling is utilized. A 3D finite element modeling procedure is used to generate accurate solutions to train the surrogate models, and verification is performed on both types of calibrated surrogate models. Experimental measurements are used to provide validation references for deterministic as well as surrogate modeling solutions.

It was demonstrated that the two surrogate modeling types (GPR and RBF response surface) significantly reduce the solution runtime compared to their deterministic counterparts, making them suitable for probabilistic damage tolerance assessments.

ABSTRACT

Multilayered aluminum components are of great interest in the aerospace industry due to their high strength-to-weight ratio and corrosion resistance. One of the common production methods of such layered components is diffusion bonding of similar and dissimilar metals. For load bearing applications the bond strength between the different layers is critical. Alongside experimental techniques for assessing bond strength in layered components, a computationally efficient method to model interface failure is the cohesive zone approach (CZM). In this framework the mechanical response of the interface is governed by a traction-separation law (TSL). The TSL represents the relation between the stresses across the interface and the relative displacement between layers, capturing the loss of load-bearing capacity before the final layer separation.

The TSL parameters are commonly determined by fitting of experimental load displacement data and numerical simulations (FEM). In such an approach, micromechanical aspects such as bonding defects (micro-voids) due to oxide layer fracture along the interface, which are known to greatly influence the bond strength, cannot be directly taken into consideration. The goal of the current study is to utilize a micromechanical based FE approach in conjunction with a Continuum Damage Model (CDM) approach to determine the TSL parameters, of diffusively bonded aluminum 7075 specimens, solely based on the defects pattern observed at the interface and a ductile failure law for Al 7075. First the flow-stress of Al7075 at temperatures of 400-500C was determined by cylindrical compression experiments and finite element modelling. Next, Al7075-Al7075 specimen pairs underwent diffusion bonding at 400-500C and thermo-mechanical finite element modelling was used to compute the time dependent thermo-mechanical fields at the specimen interface. Following the bonding experiments, small tensile specimens were cut from the bonded pairs and underwent characterization of the interface using a Scanning Electron Microscope (SEM) and subsequent mechanical testing. The, interfacial morphology observed from the SEM imaging was used to construct microstructural based Representative Area Elements (RAE) of the interface area. To model intact bond failure of the Al7075 in the RAE, a continuum damage approach for Al7075 previously published by the authors was utilized [1]. It is demonstrated that effective TSL can be obtained from the micromechanical models which explicitly take micro-structural parameters of the interface into consideration.

AN EXTENDED PHASE-FIELD METHOD FOR FRACTURE SIMULATIONS

Verena Curosu[1], Christian Krüger[1] and Stefan Löhnert[1]*

[1]Dresden University of Technology

ABSTRACT

The extended phase-field method (XPFM) combines the phase-field method for fracture with concepts from the extended/generalized finite element method. The approach aims at a significant reduction of the computational effort in comparison to the standard phase-field method while keeping the advantages of not having to explicitly track the crack geometry and to introduce additional crack propagation criteria.

The XPFM is based on a transformed phase-field ansatz and an enrichment of the displacement field. This allows for much coarser meshes, and it leads to truely mesh independent crack geometries including cracks that run through elements. The transformed phase-field ansatz incorporates knowledge about the analytical solution of the phase-field equation in 1D. The displacement enrichment is entirely based on the phase-field solution, and in contrast to the initial XPFM approach [1], in the present, refined version of the XPFM the necessity to calculate the direction perpendicular to the crack can be avoided completely. This allows for more general applications and the extension of the XPFM to 3D. The displacement enrichment is computed in a discrete way on a subgrid within each enriched finite element on which a phase-field dependent Laplacian problem needs to be solved for each direction. The respective scalar solution fields for the discrete displacement enrichment functions can be obtained in a very efficient way.

In this contribution, the latest developments for the XPFM including the algorithmic treatment will be presented, and applications to common academic examples for the simulation of fracture processes will be shown.

A NOVEL VARIATIONAL AUTOENCODER ARCHITECTURE FOR TEMPERATURE-ADAPTIVE ULTRASONIC GUIDED WAVE GENERATION

Rafael Junges[1], Luca Lomazzi[1], Lorenzo Miele[1], Marco Giglio[1] and Francesco Cadini[1]*

[1]Politecnico di Milano

ABSTRACT

Ultrasonic guided waves (UGWs) have recently captured the attention of the structural health monitoring (SHM) community. This heightened interest primarily stems from the remarkable sensitivity of UGWs to alterations in the properties of the medium through which they propagate. This makes such waves an interesting diagnostic tool to identify and describe damage affecting thin-walled structures. Among the results of damage diagnosis procedures, anomaly localization is fundamental to drive maintenance actions and restore the health state of the structure. To date, localization has predominantly relied on tomographic algorithms. Despite being widely adopted, they come with unsolved issues, including the generation of artifacts in damage probability maps and the bad performance under varying environmental and operational conditions (EOCs). Consequently, supervised data-driven approaches for UGW-based damage diagnosis have been proposed in the literature. Although such methods are characterized by satisfactory performance, a notable constraint is the requirement for large high-fidelity datasets for training the algorithms, which are typically unavailable for real-life structures. Furthermore, such methods still cannot deal with varying EOCs. A potential remedy lies in unsupervised machine learning methods. These methods have already found application in damage detection within the SHM field, but unsupervised approaches that can localize damage under varying EOCs still have to be investigated in detail. This work aims to overcome the limitations mentioned above by proposing a novel unsupervised network architecture based on variational autoencoders (VAEs). The algorithm was trained over an experimental dataset of UGWs acquired under varying temperature conditions. Testing was performed against experimental signals acquired at temperatures not seen during training to verify that the generative artificial intelligence tool is able to capture the influence of temperature on UGWs.

ABSTRACT

Numerical simulation aided design of large-scale metal and alloy structures under extreme conditions, such as accidental mechanical overloads that may lead to failure, remains a major concern of various industrial sectors such as transportation, energy, and defense.

In this work, we present a three-dimensional numerical approach able to macroscopically account for various dissipative mechanisms (e.g., plasticity and ductile damage) leading to failure. The methodology is developed within the finite strain framework and is implemented into ABAQUS-std finite element computational code as a user finite element (UEL), in view of ensuring mesh-objective results.

Key features of the methodology include its treatment of both geometric and material nonlinearities using an updated Lagrangian formulation (ULF) [1]. The phase of more or less diffuse damage is reproduced by using Gurson-Tvergaard-Needleman (GTN) microporous plasticity model [2] employing standard finite element methods (FEM). Furthermore, the micro-void coalescence phase-induced dilation/shear band is modeled using an innovative extended cohesive finite element approach (XFEM-CZM) [3]. The progressive loss of cohesion culminating in ultimate cracking is addressed with the extended finite elements method (XFEM). A particular attention is paid to transition criteria (damage to localization, localization to cracking), the orientation of the localization plane (especially in Mode II), the cohesive zone model (empirical vs. inspired by the micromechanics of micro-void coalescence), and techniques for overcoming numerical challenges (e.g., volumetric locking [4], numerical integration [5]).

The unified methodology is shown to be able to replicate the degradation process until fracture (progressive drop in resistance, fracture surface orientation) in large elastoplastic deformation of structures used in laboratory tests, even with relatively coarse meshes.

MODELING SOLID-SOLID CONTACT IN A FULLY EULERIAN PHASE-FIELD FRAMEWORK

Flavio Lorez[1], Mohit Pundir[1] and David Kammer[1]*

[1]*ETH Zürich*

ABSTRACT

This work introduces a novel Eulerian finite element framework based on a phase-field representation of solids to model mechanical contact between elastic solids, with a particular focus on systems involving evolving and intricate surfaces [1]. Traditionally, Lagrangian frameworks dominate in modeling such interactions, yet they often demand sophisticated algorithms for contact detection and resolution. Furthermore, they face difficulties when dealing with solids undergoing dynamic boundary changes, such as crystals growing within confined spaces. Because the physical or chemical evolution demands an Eulerian framework, it is desirable to phrase the mechanical solid boundary value problem in such a framework as well, requiring novel approaches to contact modeling.

Our approach employs the phase-field method that includes a diffuse representation of geometries on a spatial mesh, streamlining the modeling of evolving surfaces. To model elasticity, we make use of the reference map technique [2]. A distinctive feature of our methodology is the introduction of volumetric penalty forces that weakly enforce the contact constraint. Capitalizing on the single reference system, the traction force is defined as a simple function of the phase-fields of the two bodies in contact, which renders contact search obsolete. We demonstrate the validity and versatility of our method through numerical examples, showcasing its capability to accurately capture complex solid-solid interactions.

The Eulerian phase-field formulation significantly simplifies the complexities associated with contact detection and resolution in traditional Lagrangian contact models. Additionally, our framework can be used to seamlessly integrate with other physical phenomena by incorporating multiple energy terms in the evolution of the phase-field. This enables the modeling of multiphysics scenarios, presenting a valuable tool for a broad spectrum of applications involving chemically or physically evolving deformable solids in contact. Such scenarios are, for example, prevalent in deterioration processes of porous media.

In conclusion, our Eulerian finite element framework provides an innovative and promising alternative solution for modeling contact between elastic solids, particularly in scenarios with evolving and intricate surfaces. The methodology's adaptability and capability for multiphysics modeling makes it a promising tool for addressing a wide range of applications, offering insights into the mechanical interactions of deformable solids in contact during processes like growing corrosion precipitates in porous media.

REDUCED ORDER MODELLING OF EXACT PERIODIC FLOWS USING A SPACE-TIME DISCRETISATION

Jacob Lotz[*1] and Ido Akkerman[1]*

[1]*Delft University of Technology*

ABSTRACT

Periodic flows are omnipresent in a large number of industrial applications. Examples include the flow past wind turbines, rotating flows in turbomachines and the pulsatile flow of blood. Simulation of periodic flows is computationally demanding for design and control applications as they need a long time domain for periodicity in the flow to develop. We circumvent the problem by using a parametric POD-Galerkin reduced order model, which exploits the nature of the problem.

In the full-order model, we apply the framework of residual-based variational-multiscale turbulence modelling and space-time iso-geometric analysis to solve the incompressible Navier-Stokes equations [1]. We convert the initial value problem to a boundary value problem by applying a periodic boundary condition in time to compute the time-periodic states directly. We use the Proper Orthogonal Decomposition (POD) to create a basis using parameter-dependent solutions from the full-order model. The time-periodic basis contains information on space and time, allowing for a dimension reduction in both. We create the reduced-order model using the POD basis and the same stabilisation as the full-order model [2,3]. The reduced-order model can use the DEIM, Q-DEIM and the S-OPT hyper-reduction techniques.

We apply the reduced-order model to flow past periodically heaving and pitching hydrofoils at a Reynolds number of O (103). Parameters include heave amplitude and motion period. The numerical experiments show a fast decay in singular values, allowing for small basis sizes. The results are in agreement with the results of the full-order model.

[1]*Indiana University*
[2]*Memorial Sloan Kettering Cancer Center*
[3]*Johns Hopkins University*

ABSTRACT

In recent years, transformative technological advancements have markedly enhanced our ability to detect individual cancer cells and clusters within patients' blood, lymph nodes, and bone marrow. Despite these groundbreaking developments, the clinical significance of these detected cells remains elusive. This study addresses this uncertainty by introducing a systematic framework designed to select hypotheses that elucidate the population-level dynamics of non- and post-hypoxic cells during breast cancer metastasis to lung tissue. This framework leverages rich data obtained from meticulously conducted ex vivo experiments. Additionally, our approach employs an agent-based model, strategically translating macroscopic information into a microscopic perspective. This enables a comprehensive exploration of dynamic processes and facilitates the generation of novel hypotheses regarding breast cancer metastasis. The efficacy of our framework is demonstrated through the rigorous testing of 1152 candidate models at the population level, resulting in the efficient elimination of unlikely hypotheses and the revelation of valuable insights into the intricate metastatic process. Our multiscale model intricately unravels the proliferative advantage held by non-hypoxic cells within the lung tissue microenvironment. These findings contribute significantly to a deeper understanding of breast cancer metastasis dynamics and bear implications for the development of future therapeutic interventions. This integrated approach serves as a bridge between recent technological breakthroughs and sophisticated modeling techniques, thereby advancing our collective understanding of the complexities inherent in breast cancer metastasis.

A MULTI-FIDELITY APPROACH TO PREDICTION OF FLUTTER BOUNDARY UNDER UNCERTAINTY

George Lu[*1], Masayuki Yano[1], Amin Fereidooni[2] and Anant Grewal[2]*

[1]*University of Toronto*
[2]*National Research Council Canada*

ABSTRACT

We present a multi-fidelity uncertainty quantification (UQ) approach that leverages multiple computational aeroelasticity (CAE) models of various accuracies and costs to characterize the flutter boundary of a wing under uncertainties. The accurate determination of the flutter boundary, which corresponds to the point where the aeroelastic system exhibits zero damping and indicates the onset catastrophic unbounded oscillation, is crucial to aircraft certification. In the presence of model parameter uncertainties, aircraft may experience flutter far below the predicted flutter speed [1]. Our goal is to quantify this uncertainty and to provide the probability of flutter for a range of flight conditions. The problem can be considered a probabilistic extension of the deterministic flutter prediction using multi-fidelity models considered in [2]. Our multi-fidelity UQ approach builds on the following three ingredients: Gaussian process models, which readily incorporate sampled responses from models of various fidelities and provide probabilistic estimates of the damping coefficient over the parameter space; an input-dependent error estimate throughout the parameter space for each model, which is constructed by appealing to the predicted model discrepancies across levels of model fidelities; and contour-targeting adaptive sampling strategies, guided by the expected improvement in and/or estimates of approximation error, to select a sequence of models and sampling points that best improves the approximation of the flutter boundary while accounting for model evaluation costs. We demonstrate the multi-fidelity method for a transonic flutter problem using the following models: a Reynolds-averaged Navier-Stokes CAE model; a Euler CAE; and a traditional aeroelasticity model based on Theodorsen's aerodynamics. The multi-fidelity method enables efficient characterization of the probabilistic flutter boundary and accurately captures the sharp decrease in flutter velocity in the unsteady transonic flow regime with proper model selection.

EMULATING OCEAN MODELS TO QUANTIFY UNCERTAIN RESPONSES TO CLIMATE CHANGE

Hannah Lu[1], Siddhartha Bishnu[1], Simone Silvestri[1], Raffaele Ferrari[1] and Youssef Marzouk[1]*

[1]*MIT*

ABSTRACT

To better understand the responses of ocean systems to different forcings that represent climate change scenarios, we have explored a wide range of values for the parameters and initial/boundary conditions in an idealized ocean model on a global scale, NeverWorld2, which has intermediate complexity: it incorporates basin-scale geometry for an idealized Atlantic and Southern ocean, with non-uniform ocean depth to allow for mesoscale eddy interactions with topography. The simulation is implemented in Oceananigans.jl, a Julia-based software package for finite volume simulations of the nonhydrostatic Boussinesq equations on CPUs and GPUs. Due to the complexity of global circulation models, however, simulations of ocean processes are prohibitively expensive (even on GPUs), making the tasks of uncertainty quantification for future predictions and sensitivity analysis for model parameters extremely challenging. To address this challenge, we have investigated a wide range of deep learning tools to build dynamical emulators for targeted quantities of interest (QoIs). In addition, we have explored and developed systematic ways of identifying additional informative or dynamically relevant variables from the governing system, to make these QoI emulators more predictive and accurate. The efficient emulators will make it possible to capture interactions between the ocean and other components of climate models (e.g., atmospheric models, land models, human activities). This provides valuable scientific information for stakeholders in fighting climate change.

A GENERALIZED FRAMEWORK SUITABLE FOR DYNAMIC AND ELASTIC-PLASTIC CRACK GROWTH PROBLEMS: THE PRINCIPLE OF LEAST EXTERNAL WORK

Longkun Lu[*1]

[1]*Northwestern Polytechnical University*

ABSTRACT

Starting from the principle of least action, we propose the principle of least external work suitable for dynamic and elastic-plastic crack growth problems. Among those possible crack growth patterns, the principle of least external work indicates that the real one consumes the minimum value of the external work. Like the phase-field method, the proposed principle also converts crack growth problems into an energy minimization value problem, except that the energy term here is the work applied by external loadings. According to the first law of thermodynamics, external work can convert into kinetic energy, elastic and plastic deformation energy, or fracture energy. Therefore, the proposed principle can naturally apply to dynamic and elastoplastic crack growth problems.

Moreover, it can be proved that:
1) For the pure deformation of an elastic solid, the principle of least external work is equivalent to the principle of minimum potential energy;
2) In the case of quasi-static crack growth in elastic solids, the principle of least external work can give the Griffith criterion [1];
3)When a crack grows dynamically in an elastic solid, the principle of least external work can derive the dynamic fracture criterion proposed by Freund [2];
4) When a crack propagates quasi-statically in an elastic-plastic solid, the principle of least external work will give the fracture criterion based on the incremental J-integral [3].

MULTI-PHYSICS SIMULATIONS FOR LI BATTERY

Wei Lu[*1]

[1]*University of Michigan*

ABSTRACT

In this talk, I will present some of our recent work of developing battery simulation tools, and how these tools may help facilitate the battery design and management. The prediction of capacity fade and lifetime of batteries is important for cell design, determination of the optimal operation condition and control, and cell maintenance. Various mechanisms contribute to capacity fade. I will talk about a comprehensive capacity fade model and its experimental validation and application for battery optimization; a multiscale approach that couples mechanics and electrochemistry consistently at both particle and electrode scales which enables simulating various electrode phenomena; and approaches to optimize battery health while fulfilling both energy and power requirements. In simulation-based battery design, a large amount of simulations are required to determine the optimal design variables. The computational cost can be prohibitively expensive. I will introduce a new approach of Self-directed Online Learning Optimization (SOLO), which integrates dynamic deep neural network with finite element calculations. SOLO reduces the computational time by up to 5 orders of magnitude compared with directly using heuristic methods, and outperformed all state-of-the-art algorithms tested in our experiments. I will also show a pruner and sampler approach to determine model parameters or battery design parameters, which can reduce the battery testing time by about 75%. Finally, I will discuss simulations of concurrent dendrite and SEI growth.

REACTIVE DIFFUSION OF LITHIUM IN SILICON – NEW INSIGHT FROM ATOMISTIC SIMULATIONS

Bin Li[*1] and Jun Xu*[2]

[1]*Iowa State University*
[2]*University of Delaware*

ABSTRACT

Atomistic simulations are performed to investigate the insertion of lithium (Li) in crystalline silicon (c-Si) by using a modified embedded atom method potential. The mechanism for the formation of the amorphous a-LixSi was analyzed by conducting novel structural analysis. Diffusion pathways of Li in c-Si and the energy barrier are also analyzed and calculated. The results show that Li atoms diffuse preferably along the 112 directions on the {111} planes, and the energy barrier is too high for thermally activated diffusion around room temperature. The formation mechanism for the amorphous/crystalline interface (ACI) is also analyzed. The diffusivity of Li in Si is calculated based on the simulation results. Our results show that the diffusivity of Li in the a-LixSi is about 50~100 times faster than in the c-Si. Our results also show that the composition of Li in the a-LixSi is non-uniform during lithiation, and the distribution of Li is analyzed. The simulation results are compared with the available experimental results.

The phase field method for fracture: Theory, numerics, and applications

STABILIZED FORMULATION FOR PHASE-FIELD FRACTURE IN NEARLY INCOMPRESSIBLE HYPERELASTICITY

Bin Li[1], Ida Ang[2] and Nikolaos Bouklas[2]*

[1]*Guangdong Technion-Israel Institute of Technology*
[2]*Cornell University*

ABSTRACT

This work presents a stabilized formulation for phase-field fracture of hyperelastic materials near the limit of incompressibility. At this limit, traditional mixed displacement and pressure formulations must satisfy the inf-sup condition for solution stability. The mixed formulation coupled with the damage field can lead to an inhibition of crack opening as volumetric changes are severely penalized effectively creating a pressure-bubble. To overcome this bottleneck, we utilize a mixed formulation with a perturbed Lagrangian formulation which enforces the incompressibility constraint in the undamaged material and reduces the pressure effect in the damaged material. A mesh-dependent stabilization technique based on the residuals of the Euler–Lagrange equations multiplied with a differential operator acting on the weight space is used, allowing for linear interpolation of all field variables of the elastic subproblem. This formulation was validated with three examples at finite deformations: a plane-stress pure-shear test, a two-dimensional geometry in plane-stress, and a three-dimensional notched sample. In the last example, we incorporate a hybrid formulation with an additive strain energy decomposition to account for different behaviors in tension and compression. The results show close agreement with analytical solutions for crack tip opening displacements and performs well at the limit of incompressibility.

NUMERICAL SIMULATION OF MATERIAL STRENGTH OF CMCS BASED ON CT DATA RECONSTRUCTION

Guoqing Chen[1], Leijiang Yao[1] and Bin Li[1]*

[1]Northwestern Polytechnical University

ABSTRACT

Ceramic-Matrix-Composites are an important material candidate for thermal structures in aero engines. To investigate the strength failure of CMC materials occurring at ordinary temperature service, this paper establishes a detailed geometric model of the material by obtaining the material structure and defect distribution characteristics through CT technology and establishes a strength prediction model of ceramic matrix composites at ordinary temperature by writing different material subroutines for the failure modes of different kinds of materials.

First, we carried out the geometric analysis model and FEM model construction for 2D-C/SiC composites containing defects. Using μX-CT technique, we conducted CT scans on four specimens of 2D-C/SiC composites at different locations and sizes, respectively. Based on the CT slice data obtained from the scans, the volume fraction and location distribution of defects were obtained by reconstructing and analyzing the material defects. Meanwhile, by analyzing the CT slice data, we obtained the geometric parameters of fiber bundles in 2D-C/SiC composites, characterized the geometry of fiber bundles more accurately, and placed the hole-type defects completed by the analysis into them, and finally obtained the single-layer finite element analysis model of 2D-C/SiC composites and the structural FEM of 2D-C/SiC composites.

Next, numerical simulations of the strength of 2D-C/SiC composites were performed. Based on FEM, the fiber bundles consisting of fibers and matrix are equated to a homogeneous material by the known use of the equivalent homogenization method. By writing the VUMAT subroutine, we defined the fiber bundle failure criterion and the matrix failure criterion respectively, and simulated the static tensile process of the material. In the simulation, we found that during the static stretching of the material, the damage of the material occurs first below the location of the coating cracks, and the cracks gradually expand downward with the increasing tensile load. After the failure of the first layer, the crack expansion path changed clearly from directly below the coating crack defect to the maximum bending position of the woven structure, which is more in line with the crack expansion law of CMC material in the static tensioning process. Through the numerical simulation analysis of the static tensile strength of the material at room temperature, the tensile strength of the material at room temperature was determined, and the reliability of the finite element model was also verified by combining the test results. This supports the effective data for ceramic matrix composites in material design and engineering applications.

RELIABILITY ANALYSIS OF CABLE-STAYED BRIDGE SYSTEM BASED ON DIRECT PROBABILITY INTEGRAL METHOD

Bingzhu Li[*1], Zhenhao Zhang[1] and Mengmeng Tao[1]*

[1]Changsha University of Science and Technology

ABSTRACT

The system reliability analysis of cable-stayed bridges is an important part of structural safety analysis, and this paper proposes a method to analyze the overall dynamic reliability of prestressed concrete cable-stayed bridges based on the direct probability integral method. Firstly, the limit state equations of the main girder bending strength failure, wind-induced vibration failure and the main tower strength damage failure in the downward direction and the transverse direction buckling failure as well as the strength damage failure of the tie ropes of the cable-stayed bridge are established. Then the reliability analysis of the whole bridge cables is carried out, and the most dangerous three pairs of cables are selected to form a series-parallel system with the failure modes of the main girders and towers of the cable-stayed bridge, and the joint probability density integral equations of the extreme value mapping of multiple performance functions are established. Finally, the equations are solved using the direct probability integration method containing Heaviside function (DPIM-H) to obtain the overall dynamic reliability index of the cable-stayed bridge, and the Monte Carlo method is used to verify the reasonableness of the results. Taking the prestressed concrete cable-stayed bridge as an example, the system degree is analyzed by DPIM-H as well as the reasonableness of the results is verified by Monte Carlo.

PORE-SCALE STUDY OF MULTIPHASE FLOW PATTERNS IN LAYERED POROUS MEDIA WITH FRACTURES

Bo Li[*1], Hao Yu[1] and HengAn Wu[1]*

[1]*University of Science and Technology of China*

ABSTRACT

The presence of fractures increases the difficulty of multiphase flow mechanism analysis, and it remains unclear how fractures affect multiphase flow displacement in the layered rock matrix. Herein, a pore-scale imbibition model considering the layered matrix-fracture system is established using the phase-field method, where oil is displaced by a range of fluids with various properties. Two typical flow modes are carefully analyzed, depending on the locations of the fracture and the interfaces between different layers of the matrix: fracture is parallel to the interface (mode I) and it penetrates through the interface (mode II), which are dominated by the co-current imbibition and counter-current imbibition mechanisms, respectively. Interestingly, the surface tension is found to be negatively correlated with the ultimate oil recovery rate for mode I and plays an opposite effect on that of mode II. For flow mode I, the conditions of lower injection rate, higher viscosity ratio, higher grain diameter ratio, and injection of the invading fluid from the larger pore throat size (positive direction flow) can improve oil recovery. For flow mode II, the fracture bifurcation angle has little effect on the positive direction flow, while it can significantly regulate the phase distribution in the negative direction flow. Based on the scaling analysis of relating pore-filling events to displacement modes and the equilibrium relationship between capillary and viscous forces, two theoretical models are derived to predict the imbibition patterns, and the variation of the flow regime under various parameters in the typical layered matrix-fracture models is systematically concluded.

IMAGE-BASED MESOSCOPIC SIMULATIONS OF ALLOYS

Bingbing Chen[1] and Chenfeng Li[*1]*

[1]Swansea University

ABSTRACT

Polycrystalline materials consist of aggregates of grains with varying lattice orientations and sizes separated by grain boundaries. The random morphological and crystallographic microstructure characteristics are responsible for the anisotropic behavior of polycrystalline microstructures and determine their macroscopic properties and performance. The mechanical properties of alloys, including stress and strain response and elastoplastic anisotropy, are significantly affected by morphological and crystallographic (grain orientation, etc.) features.

The present studies of the microstructure effect on mechanical properties and performance have certain limitations. Research methodologies are mainly limited to representative volume elements (RVEs)-based experimental observations. In practice, the microstructure characterizations exhibit a large degree of randomness during deformation processing, and microstructure randomness reveals polycrystalline materials' probabilistic properties and performance. Consequently, the vast size and number of the microstructure RVE necessary to build the process–structure–properties–performance (PSPP) linkages are computationally prohibitive and challenging to investigate. Meanwhile, the simplified polycrystalline microstructures, such as single crystals, bicrystals, Voronoi, and ellipsoid polycrystals, fail to capture all the statistical microstructure characterizations of the heterogeneous grains. Aa a result, the datasets between microstructural characteristics and mechanical properties and performance are unlikely to be built without sufficient data.

In this work, we propose a patch-based texture synthesis reconstruction algorithm to accurately capture the statistical microstructure characterizations of the heterogeneous grains. Then, the established computational plasticity FEM model combined with explicit characterization algorithms was used to perform quantitative analysis on Inconel 718 superalloy to fully understand the macroscopic properties and performance responses (ultimate tensile strength, Von Mises stress, ductile failure initialization and propagation) in terms of morphological, crystallographic, and boundary characteristics. Finally, the patch-based texture synthesis coupled with explicit characterization algorithms was developed to determine the ductile failure sets using the microstructural parameters, such as grain orientation and boundary characters.

LOAD-AREA RELATION OF RANDOM ROUGH SURFACES FOR LARGE CONTACT FRACTION

Chengya Li[*1], Yue Ding[1], Xuan-ming Liang[1] and Gangfeng Wang[1]*

[1]Xi'an Jiaotong University

ABSTRACT

Establishing the accurate load-area relation is pivotal for comprehending complex phenomena such as friction, wear, and thermal and electrical conduction, particularly for large contact fraction. Unfortunately, prevailing contact models often fall short in capturing behaviors across the entire contact regime due to the oversight of intricate asperity interactions, especially in high load level. In this investigation, we address the challenge by incorporating asperity interactions in both elastic and elastic-plastic contact. The actual random distribution of contacting spots with various sizes is simplified as a hexagonal distribution of identical spots sharing the same quantity and total area. Leveraging the perfect symmetry, a representative asperity is then simulated by finite element method and asperity interaction is incorporated through the periodic boundary condition. The load-area relation is calculated up to almost complete contact. It is interesting to find that surface morphology and material properties predominantly affect the initial linear relation at small contact fraction, and the interactions among asperities are closely related to contact fraction and lead to a larger load than that neglecting asperity interactions. By comparing with the theoretical prediction of an incremental equivalent contact model at initial contact, the load-area relation is extended for general rough surfaces. Direct simulations on typical rough surfaces verify the accuracy of the advanced load-area relation within a large range of contact fraction. This developed model provides an efficient method to predict the overall contact response of rough surfaces, significantly reducing the computational burden. The advancement serves as a robust foundation for in-depth analyses in tribology, laying the groundwork for a nuanced understanding of friction, wear, and sealing behaviors.

BI-MATERIAL TOPOLOGY OPTIMIZATION FOR VIBRO-ACOUSTIC PROBLEMS BASED ON NON-NEGATIVE INTENSITY

Dan Li[*1] and Haibo Chen*[1]

[1]*University of Science and Technology of China*

ABSTRACT

In this work, the non-negative intensity (NNI) method is applied to a large-scale vibro-acoustic interaction system using the fast multipole boundary element method (FMBEM), and a bi-material topology optimization method is constructed to minimize the integration of non-negative intensity on predefined surfaces. The NNI provides a field on the surface of the radiating structure, consisting of positive-only contributions to the radiated sound power, which avoids the near-field cancellation effects that otherwise occur with the sound intensity field [1]. To intuitively characterize the contribution degree of structural surface to far-field radiation and provide a theoretical basis for acoustic radiation analysis and design of large-scale vibro-acoustic interaction systems, the FMBEM is adapted to the NNI by calculating the eigenvalue solution of the symmetric acoustic impedance matrix using a two-stage solution method. The fast multipole algorithm is adapted to accelerate the calculation of matrix vector products of adjoint problems. The topology optimization of a large-scale submerged cylindrical shell model is realized using FMBEM [2]. The vibro-acoustic interaction system is first solved using a FEM–FMBEM model, and the resulting surface fields are then used in the FMBEM calculation of the NNI. The integration of the NNI on the predefined surface is selected as the objective function to design the radiation mode of the structural surface. A structural material interpolation model is established using the solid isotropic material with the penalization method, and the topological sensitivity formulation is derived based on the adjoint variable method. Numerical results confirm the effectiveness of the proposed optimization method in minimizing the integration of the non-negative intensity.

Keywords: FEM-FMBEM coupling analysis; topology optimization; non-negative intensity

MULTI-PHYSICS FRACTURE ANALYSIS OF COMPOSITE LAMINATES BASED ON EXTENDED LAYERWISE METHOD

Dinghe Li[*1]

[1]*Civil Aviation University of China*

ABSTRACT

An extended layerwise method (XLWM) is presented for the composite laminates with multiple delaminations and transverse cracks. The discontinuity of displacements and temperature induced by multiple delaminations is simulated by strong discontinuous function while the discontinuity of strain between dissimilar layers is modeled by a weak discontinuous function. Transverse cracks are modeled using classical Extended Finite Element Method (XFEM). And then, based on the XLWM, some mixed variational principle is employed or presented to derive the Euler equations and the discrete forms for the multi-physics fracture analysis of composite laminates. A fully coupled time integration method is developed based on the Newmark integration algorithm and Crank-Nicolson scheme, the multi-physics fields are solved simultaneously. The thermo-mechanical, thermo-chemo, thermo-chemo-mechanical, piezoelectric-mechanical, thermo-piezoelectric-mechanical and thermo-mechanical-curing-seepage coupling analysis are carried out numerically for the damaged composite laminates. Many numerical examples are studied to demonstrate the capabilities of static response, stress intensity factor and energy release rate for the composite plates, stiffened plates and sandwich plates.

CREEP LIFE MODELLING OF NICKEL-BASED SINGLE CRYSTAL SUPERALLOY DD6 WITH MCRALY COATING

Dongxu Li[1], Chaoji Wang[2], Shengwei Pan[2] and Xueling Fan[1]*

[1]*Xi'an Key Laboratory of Extreme Environmental and Protection Technology, Xi'an Jiaotong University*
[2]*AECC Guiyang Engine Design Research Institute*

ABSTRACT

Single-crystal superalloy is a crucial structural material widely employed in aerospace, energy, and petrochemical industries. High-temperature creep resistance is a critical indicator for evaluating alloys. In this study, a method for predicting the creep behavior of MCrAlY-coated DD6 single crystal alloy was proposed, and the influences of oxide layer thickness and inner wall temperature on the creep strain rate were investigated. The model was validated experimentally. The results indicate that the MCrAlY coating has a minimal impact on the high-temperature creep lifetime of [001]-oriented DD6 single-crystal superalloy. Pre-exposure treatment thickens the initial oxide layer of the coating, effectively extending the creep lifetime of the coated alloy, particularly at higher temperatures and stress levels. This underscores the effectiveness of pre-exposure treatment in increasing the creep lifetime of the MCrAlY-coated DD6 single-crystal superalloy system. The influence of inner wall temperature on creep lifetime follows a parabolic pattern. Excessively low inner wall temperatures reduce creep lifetime due to significant thermal mismatch stresses, while excessively high inner wall temperatures decrease creep lifetime because of changes in material properties at those temperatures.

TYPE Ⅰ TO TYPE Ⅱ TRANSITION IN SWEPT-FORWARD FIN SHOCK INTERACTIONS

Guangli Li[1], Jing Yang[1] and Kai Cui[1]*

[1]*Chinese Academy of Sciences*

ABSTRACT

The transition from Type I to Type II in the swept-forward fin shock interaction is important, as it represents a shift from low to high heat flux interaction types. However, the mechanism for this transition remains unclear. In this study, theoretical and numerical analyses is employed to explore the transition mechanism. A theoretical model is developed to obtain the analytical solution for the transition condition, considering only the interaction of the incident shock and the bow shock of the fin on the symmetry plane. The theoretical solution is compared with numerical results at a freestream Mach number of 6.36. The results suggest that the transition occurs advanced, with three distinct transition mechanisms observed. At small wedge angles, the downstream flow pattern has an influence on the transition. In the downstream flow, the transmitted shock reflects on the wall as a Mach reflection. If the height of the Mach stem approaches the detachment distance of the fin shock, the transition occurs. At larger wedge angles, the transition occurs when the Mach number behind any one of the two transmitted shocks is less than 1. The other transition is observed at a wedge angle of 30°, which occurs accompanied by the disappearance of the supersonic jet.

SHAPE OPTIMIZATION FOR LITHIUM-ION BATTERY WITH POROUS ELECTRODES

Hanyu Li[1], Jorge-Luis Barrera[1] and Thomas Roy[1]*

[1]*Lawrence Livermore National Laboratory*

ABSTRACT

In this presentation, we introduce a gradient-based shape optimization framework to design porous electrodes for maximum energy storage. Lithium-ion batteries are becoming increasingly important energy storage devices. Highly tortuous electrode materials can provide significant surface area per volume, which is required for large energy density. However, such a tortuosity can also deteriorate electrochemical transport, leading to poor material utilization in planar electrodes. Consequently, architecting electrodes that account for both transport and chemical activity is a promising alternative.

We consider a model with two materials: porous electrode and pure electrolyte. Density-based topology optimization has previously been used to design batteries for both half-cell and full-cell models to maximize energy storage. Despite the capability of producing complex interdigitated structures, an appropriate penalization scheme for intermediate materials is required for the optimizer to provide near binary designs. Setting up such a penalization is often time-consuming due to the large number of design-dependent variables that affect the forward model differently. Alternatively, the shape optimization approach used in this work produces binary designs naturally by morphing conformal meshes, circumventing inaccuracies associated with fuzzy interfaces. Shape sensitivities are computed via the adjoint method and leveraging automatic differentiation. The optimization problem is solved using a nonlinear programming technique.

In this presentation, we perform shape optimization on a half-cell model to maximize its energy storage when a fixed charging current is applied. We study multiple arrangements of physical parameters and compare their performance against a monolithic electrode. Both 2D and 3D results are presented.

STUDY OF TIMOSHENKO BEAM-BASES CRANKSHAFT MODEL WITH NON-LINEAR BREATHING CRACKS

Hongliang Li[1]*

[1]*Harbin Engineering University*

ABSTRACT

With the development of the marine industry, marine diesel engines have the characteristics of complex structure and worse operating environment and frequently changing operating conditions, which put forward higher requirements on the index of shaft vibration. In the actual operation of a diesel engine, the crankshaft will generate three forms of vibration: bending, axial and torsion. These three forms of vibration are coupled with each other. Therefore, it is studied of the three-dimensional coupled vibration problems of the crankshaft system in this paper.

Firstly, the single crank is simplified as a five-segment straight beam structure. Based on the continuum vibration theory, the three-dimensional space field transfer matrix of the straight beam is derived. It is established for the point transfer matrices of coordinate transformation by using the conditions of displacement continuity and force equilibrium. The three-dimensional coupled vibration dynamic equation of the crankshaft system is constructed by using the multiplication of the transfer matrices. By taking modalities as generalized coordinates, there are simple representation for kinetic energy and potential energy of the vibration system. Lagrange equation is used to establish the differential equation of forced vibration of Simple crank system. The response of three-dimensional coupled forced vibration can be solved. A Timoshenko beam-based modelling method is proposed in this study, which considered the cross-section shape effect of the beam and non-linear breathing cracks are inserted as a spring potential energy term of the Lagrange equation.

Secondly, the finite element model of the crankshaft system was built by ANSYS WORKBENCH. The free vibration and forced vibration of the crankshaft system are calculated. The coupling vibration characteristics of the crankshaft system with non-linear breathing cracks under the burst force are analyzed. The results verified the correctness of the theoretical method in this paper.

DATA-DRIVEN MODELLING AND OPTIMIZATION METHOD FOR EFFICIENT MODELING OF COMPLEX STIFFENED CURVED SHELLS

Hongqing Li[*1]

[1]*Dalian University of Technology*

ABSTRACT

A data-driven modelling and optimization method is proposed to automatically model and optimize stiffeners on the complex stiffened curved shells. Firstly, a novel mesh-mapping method is developed for the data-driven modelling of complex stiffened curved shells based on radial basis function surrogate model. Secondly, an active learning-driven control point optimization method is proposed, which can improve the efficiency of modeling. Furthermore, a data-driven optimization approach, based on the deep neural network method, is employed to minimize the weight of the complex stiffened curved shells. Finally, two engineering examples are presented to verify the effectiveness of the proposed method, which reduces the modeling time by 84.9% and 66.3%, respectively, compared to using all control points in mesh-mapping. In conclusion, the proposed method has substantial potential in efficient modeling and improving engineering’s optimization efficiency.

INVESTIGATION OF MESOSCALE FRACKING IN HETEROGENEOUS QUASI-BRITTLE MATERIALS USING A HYDROMECHANICAL COHESIVE PHASE-FIELD MODEL

Hui Li[*1] and Zhenjun Yang[1]*

[1]*Wuhan University*

ABSTRACT

This study develops a mesoscale hydraulic fracturing modelling method combining a hydromechanical cohesive phase-field model with random field (RF) models and random aggregate models for simulating complicated 2D/3D mesoscale hydraulic damage and fracture in quasi-brittle materials. In this method, a Weibull RF generation algorithm is used to implicitly represent the material's fracture properties such as tensile strength and fracture energy, and its meso-structures such as aggregate, mortar, and interfaces are explicitly built using a random aggregate generating and packing algorithm and an aggregate scaling algorithm. The hydromechanical cohesive phase-field model is used to automatically model fluid-driven crack initiation and propagation in mesoscale models without remeshing. Monte Carlo simulations and parameter studies are then carried out to investigated the effects of mesoscale properties on fracking. A concrete cube under hydraulic pressures was analysed as an example. It is found that the predicted crack paths and fluid pressure curves both are stochastically affected by random fracture properties. A higher variance of tensile strength leads to a lower mean and larger standard deviation of peak pressures. Due to weaker fracture properties of aggregate-mortar interfaces than mortar, 3D hydrocrack tends to propagate along interfaces, leading to tortuous and non-planar crack paths after fracking.

CONFINEMENT EFFECTS ON THE THERMODYNAMICS AND FLUID FLOW IN POROUS MEDIA

Jiaoyan Li[*1]*

[1]*University at Buffalo*

ABSTRACT

Unconventional shale recovery requires fundamental understandings of confinement effects on fluids flow behavior. Natural shales have complex pore network and chemical compositions, which prevent systematic study to understand the confinement effects. In this talk, we will present results from molecular simulations and provide insights into pressure-driven hydrocarbon fluid flow confined under amorphous silica pores. Coarse grained molecular simulations are performed to elucidate how confinements including the confinement size, shape, surface wettability, influence the thermodynamics and fluid transport in pores of single nanometer size. The force parameters of the adopted coarse grained molecular model are calibrated from the thermodynamic equation of state. Our numerical results demonstrated the importance of fluid-pore interaction, pore size, and pore morphology effects in mediating the pressure-volume-temperature (PVT) properties of hydrocarbons. Also, we found that the saturation pressure predicted from the van der Waals-type adsorption isothermal loop could be elevated or suppressed relative to the bulk phase. Based on the flow simulation results, a detailed analysis regarding the impact of each of these factors will be presented.

APPLICATION OF SOLID SHELL MATERIAL POINT METHOD IN EXTREME DEFORMATION OF THIN STRUCTURES

Jiasheng Li[*1] and Xiong Zhang*[1]

[1]*Tsinghua University*

ABSTRACT

Shell structures play a significant role in large-span situations. For safety and security, large deformation and destruction of shell structures has attracted great attention. With the large span of shell structures and inhomogeneous in material distribution, experiments of equal proportion are ordinarily expensive, while the corresponding results of the same experiment conditions may vary from each other. Therefore, the development of efficient and powerful algorithms to simulate complicated responses of shell structures remains an active field of research.

The standard material point method (MPM) has been applied to simulate shell structures. Several locking phenomena induced by the linear shape function will result in an overestimation of stress state and an underestimation of deformation when adopting a coarse background grid in the standard MPM. And thus, the discretization size of background grid should be small enough for shell simulations with the standard MPM, usually smaller than 1/5 of the shell thickness, which would lead to prohibitive computational cost.

A novel solid-shell material point method (SSMPM) is proposed in this work by introducing shell particles and locking treatments. The SSMPM adopts the shell particles to define the geometry of shell structures. A shell particle consists of a hexahedral particle domain, eight corners and Gauss quadrature points. Its deformation is obtained by solving the momentum equations on the background grid. For each shell particle, the assumed natural strain (ANS) method is adopted to eliminate shear locking and trapezoidal locking, and the enhanced assumed strain (EAS) method is employed to eliminate thickness locking. With the accurate description of bending modes, a single layer of shell particles and a coarse background grid are sufficient for shell structure simulations, which dramatically increase the computational efficiency. A local multi-mesh contact method is presented for contact situations. The advantages of MPM particles to simulate fragmentation and shell particles to simulate bending deformation are combined for extreme deformation of thin structures.

DEVELOPING AND ANALYZING A NOVEL UNCONDITIONALLY STABLE EXPLICIT FINITE ELEMENT METHOD FOR THE ELECTROMAGNETIC ROTATION CLOAK MODEL

Yunqing Huang[1], Jichun Li[2] and Bin He[3]*

[1]Xiangtan University
[2]University of Nevada Las Vegas
[3]Lanzhou Jiaotong University

ABSTRACT

One potential application of metamaterials is for designing invisibility cloaks. In this talk, I'll talk about a rotation cloak model. Here we carry out the mathematical analysis of this model for the first time. Through a careful analysis, we reformulate a new system of governing partial differential equations by reducing one unknown variable from the originally developed modeling equations in our previpous work [1]. Then a novel unconditionally stable explicit finite element scheme is proposed and its stability and optimal error estimate are proved. Numerical simulations are presented to demonstrate that the new scheme for the reduced modeling equations can effectively reproduce the rotation cloaking phenomenon. The talk is based on [2].

RESEARCH ON THE DYNAMIC RESPONSE OF OIL STORAGE TANK PLATFORM STRUCTURE UNDER THE EARTHQUAKE ACTION IN ICE REGIONS

Liang Li[*1]*

[1]*Harbin Institute of Technology*

ABSTRACT

In recent years, with the rapid development of China's economy, the importance of marine resources has become increasingly prominent. Oil storage tank platform structures play a fundamental role in the development of offshore oil and gas resources. These structures often face complex and harsh environments in ice-prone regions, including the threat of seismic excitation and seasonal sea ice. To ensure the safe operation of offshore platform structures, it is necessary to conduct research on the dynamic response of oil storage tank platforms in ice zones under seismic excitation. In addressing this issue, this study developed a non-freezing model ice that is representative of the Bohai Sea ice environment. Subsequently, underwater vibration table tests were conducted on the oil storage tank platform structure using the model ice in a model ice pool. A numerical model was also established to simulate the dynamic response of the oil storage tank platform structure under seismic excitation. The seismic response analysis of the oil storage tank platform structure in ice zones was conducted by combining the numerical model and experimental data.

SELECTIN AND INTEGRIN COOPERATIVELY REGULATE ROLLING ADHESION OF LEUKOCYTE UNDER SHEAR FLOW

Long Li[1] and Jizeng Wang*[1]

[1]*Lanzhou University*

ABSTRACT

Cell interacting with its extracellular matrix involves complex structures formation consisting of a multitude of proteins and often takes place in a hydrodynamic environment, e.g., leukocyte locomotion inside blood vessel in the process of inflammation. Despite the omnipresence of rolling adhesion of cell mediated by multiple type of proteins under hydrodynamic impact, the mechanisms underlying how the mechanics of multiple proteins cooperatively may govern the dynamics of cell rolling is not yet fully resolved. Here we present a mechanical model on rolling adhesion of cell mediated two distinct adhesive proteins in shear flow, corresponding to selectin- and integrin- jointly regulating leukocyte adhesion. Considering two pairs' binding/unbinding events as Markov processes and describing kinetics of leukocyte by the approach of continuum mechanics approach give rise to the mechanical description of rolling adhesion process. Through examining the dynamics of leukocyte rolling as a function of relative fraction of selectin and integrin pairs, we show that, during recruitment, the elongation of intermittent weak selectin bonds consuming the kinetic energy of rolling leukocyte decelerates the rolling speed and enables the integrin pairs to form strong bonds, therefore achieving the arrestment of leukocyte (firm adhesion). The coexistence of selectins and integrins may also be required for effective phase transition from firm adhesion to rolling adhesion, due to dynamic competition in pairs' formation and elongation.

[4]*University of Chinese Academy of Sciences*

ABSTRACT

The inner wetting characteristics in the catalyst particles have a significant impact on the activity and selectivity of catalysts[1]. Due to the complexity of the internal geometry structure of particles and the limitations of experimental conditions, the wetting condition inside particles remains unknown and assumed. Therefore, the paper numerically explored the wetting state and mechanism for hydrogen-oil flow in a catalyst particle by phase field lattice Boltzmann method (pf-LBM) developed by our team[2]. First, we randomly constructed irregular pore structures and reproduced the cross-sectional morphology of the catalyst particles. Combining the uniform distribution and Gaussian distribution, using the Voronoi edge topology to take the midpoint, doing spline interpolation to satisfy the random channel, and then verifying through tortuosity. There were 36 interpolation schemes dealing with the complex inner wall boundary condition. And the wettability condition was set at the inclinded planes which hydrogen, oil and inner wall contacted. After validating the pf-LBM, we simulated the oil wetting process in the porous media with different catalyst shape under different conditions. According to the numerical results, this work mainly focused on the effect of the catalyst geometry construct, fluid physical properties and operation conditions on the wetting area and efficiency. We studied the laws how the porosity, average pore diameter, tortuosity, catalyst shape, hydrogen/ oil physical properties, hydrogen/ oil ratio and driving force decided the oil distribution. A correlation about the inner wetting efficiency for the catalyst particles was presented. Thus the results are helpful to quantitatively master the inner wetting state and optimize catalyst geometry.

Key words: inner wetting efficiency; phase-field lattice Boltzmann method; geometric construct; porous media; two phase flow

WRINKLED AND WRINKLE-FREE MEMBRANES

Heng Gao[1], Qinglin Duan[1] and Ming Li[1]*

[1]Dalian University of Technology

ABSTRACT

Membranes are easy to buckle and wrinkle due to their extreme flexibilities, leading to the performance degradation and hampering the engineering applications. Here we propose a wrinkle-free approach through optimizing the shape and distribution of interior irregular holes in the membrane. A theoretical model with Marguerre function and complex analysis is performed to accurately estimate the stress distribution and wrinkling capability of the non-uniform membrane. The non-gradient particle swarm optimization (PSO) algorithm is implemented to determine the optimized holes to achieve wrinkle-free performance with ignorable area loss, the computational efficiency has been significantly enhanced through the superposition method. Both post-buckling analyses and physical experiments are carried out to verify wrinkle-free performance of membranes with optimized holes. In addition, an easy-to-implement empirical method is provided to guide the design of wrinkle-free membranes with arbitrary aspect ratio.

MULTI-PHYSICS HIGH-FIDELITY NUMERICAL SIMULATION METHODS FOR METAL ADDITIVE MANUFACTURING PROCESSES

Ming-Jian Li[1] and Yanping Lian*[1]

[1]*Beijing Institute of Technology*

ABSTRACT

Metal additive manufacturing processes involve multi-physics interaction problems, including heat transfer, fluid dynamics, and solid mechanics. Such complexities challenge conventional numerical methods. This study introduces two novel numerical methods specifically designed to address the multi-physics problems in metal additive manufacturing processes. The first method, called the local multi-mesh finite volume method, efficiently handles heat transfer and melt pool dynamics. It utilizes a dual-mesh system to solve macroscopic temperature across the entire domain and mesoscopic heat and fluid dynamics within the melt pool vicinity. By employing a refinement-by-superposition paradigm, this method enables efficient simulations at the powder scale. The second method, known as the multi-physics material point method, effectively addresses thermo-fluid-solid interactions. It discretizes the material domain using a structured grid and a group of particles for heat transfer, fluid dynamics, and thermal stress solution under both Eulerian and Lagrangian frameworks. This method incorporates a semi-implicit local iteration for phase-changing heat transfer, a modified Chorin's projection method for Darcy's damping, and a staggered derivation scheme for Marangoni forces.

Numerical cases were conducted to validate these methods, and the results were compared with analytical, numerical, and experimental benchmarks. Notably, the local multi-mesh finite volume method demonstrated significantly improved computational efficiency, outperforming the traditional finite volume method by factors of 16 to 50. Furthermore, the multi-physics material point method achieved faster convergence in managing phase transitions, requiring 75% fewer iterations than the traditional bisection and Newton methods. The two methods present promising solutions for addressing the challenges of multi-physics phenomena in metal additive manufacturing.

A PYTHON TOOLBOX FOR BAYESIAN LEARNING OF PORT-HAMILTONIAN SYSTEMS

Peilun Li[1], Kaiyuan Tan[1] and Thomas Beckers[1]*

[1]*Vanderbilt University*

ABSTRACT

Machine learning has emerged as a powerful tool for modeling and control of dynamical systems across various scientific and engineering domains. Dynamical systems, characterized by their evolution over time, can exhibit intricate behaviors that are challenging to capture using first principal methods alone. Hence, utilizing data driven approaches to model complex dynamical systems can offer high accuracy and emerges as a generalizable method. However, for creating robust modeling and safe control of dynamical systems, machine learning approaches has often been hindered by their inherent limitation: a lack of consideration for the underlying physical laws and constraints that govern the behavior of any real-world dynamical system. As a result, the models often lack trustworthiness and generalizability.

In contrast, physics-informed machine learning leverages the inherent knowledge and understanding of the physical world to inform the learning process of machine learning algorithms. By explicitly integrating physical laws, domain expertise, and prior knowledge into the learning framework, physics-informed learning empowers control systems to leverage the flexibility and adaptability of machine learning while remaining grounded in a solid understanding of the underlying dynamics.

In the talk, we will introduce PyGpPhs – an easy-to-use toolbox for physics-informed learning of electromechanical systems. The toolbox is built on our recently introduced Gaussian Process Port-Hamiltonian systems (GP-PHS) which is a physics-constrained, nonparametric Bayesian learning approach with uncertainty quantification. In contrast to many other physics-informed techniques that impose physics by penalty, the proposed data-driven model is physically correct by design. The Bayesian nature of GP-PHS uses collected data to form a distribution over all possible Port-Hamiltonian systems instead of a single point estimate. Thus, the GP-PHS model i) generalizes well, ii) is highly interpretable and iii) the inherent uncertainty quantification enables future safe model-based control approaches. To further demonstrate theory and usages of the toolbox, we will present the learning of the dynamics of a non-harmonic oscillator in detail. The toolbox is easy to use and demonstrate high accuracy in modeling.

PHASE FIELD FRACTURE MODEL AND TOPOLOGY OPTIMIZATION FOR ADDITIVE MANUFACTURING

Qing Li[1], Chi Wu[1], Cuiyi Li[2], Jianguang Fang[2] and Grant Steven[1]*

[1]*University of Sydney*
[2]*University of Technology, Sydney*

ABSTRACT

Phase field models have been extensively studied in the analysis of brittle and ductile fracture. However, few have been explored to simulate additively manufactured materials and validated by experimental data so far. This study develops a phase field framework for modelling complex mechanical behaviours of 3D printed metallic and ceramic materials [1]. To consider the 3D printing induced microstructural orientation, transversely isotropic Hill48 and modified Mohr-Coulomb constitutive models are incorporated here to depict the plastic and fracture behaviours, respectively. The numerical results divulge that, by considering the stress state-dependent crack initiation, the proposed phase field model can better simulate the force-displacement responses [1]. Remarkably, the complex fracture sequences, including crack initiation, propagation, and final rupture, can be properly simulated by the proposed phase field model. Importantly, it is necessary to apply a transversely isotropic fracture model to characterise the orientation-dependent fracture behaviour.
Further, the phase-field damage model established is incorporated into the topology optimization framework to consider crack initiation and propagation in a path-dependent fashion [2,3]. The topological design enables to enhance fracture resistance of structures made of additive manufacturing components. A path-dependent shape derivative is developed in a step-wise manner during the nonlinear fracture analysis, which enables to drive the topology optimization properly [3]. To measure the fracture resistance of structure, a p-norm function is formulated to aggregate the phase-field variables into a single constraint. The numerical examples demonstrated that the proposed phase field based topology optimization method can significantly improve the fracture resistance of additively manufactured structures [2]. The proposed method is anticipated to provide an effective approach for sophisticated path-dependent topological design of structures reducing severe stress concentration and high risks of fracture failure.

RECENT PROGRESS IN REACTIVE DIFFUSION MODELLING FOR FLEXIBLE BIOELECTRONIC SYSTEMS

Rui Li[*1]*

[1]*Dalian University of Technology*

ABSTRACT

Flexible bioelectronics is a class of technology that involves components which physically disappear, in whole or in part, at prescribed rates and at programmed times. Enabled devices include medical monitors that fully resorb when implanted into the human body (“bio-resorbable”) to avoid long-term adverse effects, or environmental monitors that dissolve when exposed to water (“eco-resorbable”) to eliminate the need for collection and recovery. Theoretical modeling of the behaviors of the constituent materials represents important design tools for flexible bioelectronic systems. In this talk, a class of reactive diffusion models for the analyses and designs of flexible bioelectronic systems are reported, by which the key quantities such as the distribution of water concentration, thickness change, and lifetime predictions are obtained analytically. These models are well validated by the experiments and provide effective approaches to innovative designs of related devices.

DEVELOPMENT OF VARIATIONAL BAYESIAN LEARNING NEURAL NETWORK FOR SOLUTIONS OF INVERSE PROBLEMS: FROM FORENSIC ANALYSIS OF TRAFFIC ACCIDENTS TO THERMAL DISTORTION CONTROL IN 3D PRINTING

Shaofan Li[*1]

[1]*University of California, Berkeley*

ABSTRACT

We have developed a class of variational Bayesian learning neural networks-based machine learning algorithms, including a mixed Bayesian variational finite element method, to solve various inverse problems, such as reconstruction of car crash accidents, thermal distortion control in 3D printing, and general structural forensic analysis on fracture and crack propagation. In this work, powerful variational Bayesian learning-based computation algorithms have been developed to “inversely” identify the deformation maps in the sense of continuum mechanics as well as the loading conditions while the only information given is the deformed material shape or geometry.

We developed several novel techniques, such as (1) Variational Bayesian Learning formulation coupled with a Feed-forward architecture, and (2) a mixed Galerkin variational Bayesian learning finite element method and its inverse solution for deformation mappings in any dimension. We have then applied these computational algorithms to several important real engineering applications. We have demonstrated that the developed machine-learning algorithm can practically identify the deformation field of a real crashed car and recover its initial pre-crash state based on residual damaged geometric configuration, and the Bayesian regularization network can provide a powerful geometric deviation control (BRN-GDC) algorithm that has the capability to control the thermal distortion in 3D printing that is parameter- and location-dependent.

In this talk, we present an overview of the theory and computational algorithms of Variational Bayesian learning neural network methods and their applications.

THERMOELASTIC DAMPING OF FGM MICRO BEAMS BASED ON THE HIGHER-ORDER SHEAR DEFORMATION THEORY

Shirong Li[1] and Zeqing Wan*[1]

[1]*Yangzhou University*

ABSTRACT

Thermoelastic damping (TED) in free vibration of a simply supported functionally graded material (FGM) micro beam with rectangular cross section is investigated based on the classical thermoelasticity. Material properties of the FGM micro beam are assumed to be continuously vary along the beam thickness. Governing equations for the structural vibration coupled with the temperature field are formulated by using Levinson higher-order shear deformation beam theory. Heat conduction equation coupled with the bulk strain is derived on the basis of Fourier model. For small amplitude transverse vibration, we assume that heat conduction effect is dominant in the thickness direction so that the heat conduction equation is simplified as a quasi-one-dimensional differential equation with variable coefficients which are functions of the coordinate in the beam thickness direction due to the transverse inhomogeneity of the materials. A layer-wise homogenization approach is employed to approximately solve the heat conduction equation with variable coefficients, where the FGM beam is divided into numerous uniform layers where the thermal and mechanical properties in each layer are considered to be constant and evaluated at the mid-surface of the divided layer. Consequently, the heat conduction equation possessing variable coefficients is discretized into a series of differential equations with constant coefficients in each layer. Analytical solutions for these equations with the adiabat boundary conditions at the beam top and bottom surfaces and the continuation conditions at the interfaces are obtained in terms of the kinematic quantities. Afterwards, the TED in the FGM Levinson beam is determined by the complex frequency approach in terms of the isothermal frequency of the homogenous Euler-Bernoulli beam by using mathematical similarity between the eigenvalue problems for the two types of beams. Considering an FGM beam with the material properties varying as power functions from full silver (Ag) at the top surface to full silicon (Si) at the bottom one, numerical results are presented to quantitively analyze the effects of the material gradient, the geometry and the shear deformation on the TED and the frequency shift of the micro beams in detail. The numerical results show that the TED evaluated by the Levinson beam theory (LBT) is smaller than that by the Euler-Bernoulli beam theory (EBBT) and the difference becomes significant along with the increase in the value of the thickness-to-length ratio. Therefore, for a thick or moderately thick micro beam the LBT can provide a more accurate prediction for the TED than the EBBT.

A DATA-DRIVEN MULTISCALE SURROGATE MODEL FOR CFD–DEM SIMULATIONS

Shuo Li[1] and Mikio Sakai*[1]

[1]*The University of Tokyo*

ABSTRACT

Gas–solid flows are commonly investigated in industries. The CFD–DEM method is an established method for simulating the gas–solid interactions. However, the CFD–DEM simulation of industrial gas–solid flows often requires substantial computational resources. To address this issue, in this study, a novel data-driven multiscale surrogate model, referred to as a reduced-order model coupled with a signed distance function-based graph network (ROM–SGN), is proposed to accelerate the simulation of gas-solid flows. Validation studies are conducted in a fluidized bed. Macroscopic properties such as particle distribution, pressure drop, and bubble distribution are compared between the CFD–DEM and ROM–SGN simulations. The results demonstrate that the ROM–SGN accurately simulates the gas–solid dynamics and significantly reduces calculation time by several orders of magnitude compared to CFD–DEM simulation. This work will contribute significantly to the advancement of simulation and modeling for industrial multiphase flows.

Keywords: CFD–DEM; Surrogate model; ROM–SGN; data-driven coupling.

A SIMPLE MODEL FOR SIMULATING VESICLE EXPANDING AND SHRINKAGE

Shuwang Li[*1], Steve Wise[2] and Xiaoxia Tang[1]*

[1]*Illinois Institute of Technology*
[2]*University of Tennessee*

ABSTRACT

In this talk, we present a diffuse interface model for vesicle expanding (growth) or shrinkage induced by an osmotic pressure. The model consists of an Allen-Cahn equation describing the evolution of the phase field and a Cahn-Hilliard equation describing the evolution of the concentration field. We establish control conditions for expanding or shrinking vesicles using the concept of common tangent construction in materials science, allowing the exchange of materials between the interior and exterior domains. Numerical experiments reveal that the model can capture the main feature of dynamics: formation of circle-like (expanding) and finger-like (shrinking) vesicles.

CURVATURE-CONTROLLED BAND ALIGNMENT TRANSITION IN 1D VAN DER WAALS HETEROSTRUCTURES

*Wenbin Li**[1]

[1]*Westlake University*

ABSTRACT

One-dimensional (1D) van der Waals (vdW) heterostructures of coaxial inorganic nanotubes, such as carbon nanotubes and transition metal dichalcogenide (TMDC) nanotubes, have recently emerged as a new area of endeavor in materials science. A key prerequisite for designing the properties of 1D vdW heterostructures is to understand the band alignment of the coaxial nanotubes in these novel heterostructures. In this talk, I will present our recent first-principles study of the effect of curvature on the electronic structure and band alignment in 1D vdW heterostructures of TMDC nanotubes. We find that, as the diameter of an individual TMDC nanotube decreases, the combined effect of curvature-induced flexoelectricity and circumferential tensile strain causes a rapid lowering of its conduction band minimum, while the valence band maximum exhibits an initial lowering before rising. As individual TMDC nanotubes form coaxial heterostructures, the concerted effect of diameter-dependent band-edge levels and intertube coupling via flexovoltage can lead to a Type II to Type I transition in intertube band alignment in several 1D TMDC heterostructure systems, including large-diameter MoSe2@WS2, MoTe2@MoSe2, and MoTe2@WS2 heterostructures. The results lay down a foundation for the rational design of 1D vdW heterostructures.

BIOMIMETIC CELLULAR MATERIAL UNIT CELL REPRESENTATION AND ON-DEMAND DESIGN BASED ON A TRANSPARENT NEURAL NETWORK AND A NEURAL OPERATOR

Xiang Li[1], Ziming Yan[2], Zhanli Liu[2] and Zhuo Zhuang[2]*

[1]*Hainan Normal University*
[2]*Tsinghua University*

ABSTRACT

Cancellous bone is a natural cellular material that is able to proactively change its microstructure to adapt to the surrounding loading conditions. This adaptability gives the bone anisotropic mechanical properties and the ability to absorb energy. Inspired by the topological and mechanical properties of cancellous bone, this research proposes a framework to represent and design biomimetic cellular materials based on a transparent neural network and a neural operator. In this research, a transparent neural network is used to compute the Gaussian random field and generate the topology of the spinodoid, a biomimetic cellular material. Furthermore, a novel homogenization method accelerated by neural operators is presented to efficiently compute the anisotropic elastic matrices of the spinodoid unit cells, combining improved computational speed with precision. Finally, a data-driven workflow is introduced to inversely determine the topological parameters of the spinodoid unit cell based on the given anisotropic elastic matrix. Numerical examples show that the proposed framework is capable of efficiently and correctly designing spinodoid unit cells with given design goals and can be extended to the design applications of other biomimetic cellular materials.

FRONT TRACKING AND APPLICATION TO PARTACHUTE SIMULATION

*Xiaolin Li**[1]

[1]*Stony Brook University*

ABSTRACT

We introduce an integrated computational method for the simulation of the parachute system using the front tracking methodology. A dual-stress spring-mass model based on the front tracking method is used to study the dynamics of fabric surfaces in air. The numerical algorithms for this complex physics system includes fabric model and its coupling with the fluid solvers, both incompressible and compressible. The fabric porosity is modeled by the ghost cell method. The collisions, including fabric-fabric, fabric-rigid, rigid-rigid and string collisions with fabric and rigid are implemented. This presentation will introduce on the algorithms and simulation of the
supersonic parachute simulation. We will also present other applications, including fluid interface instabilities, phase transition and particle tracking with the front tracking software library.

ANALYSIS ON NONLINEAR WHEEL-HOLDING CONTACT ON NOSE LANDING GEAR DYNAMICS CHARACTERISTICS DURING NEW TOWING-OUT MODE OF AIRCRAFT

Xiaoyun Li[*1], Yijun Chai[1], Xiongwei Yang[1] and Yueming Li[1]*

[1]Xi'an Jiaotong University

ABSTRACT

The safety and efficiency of airports are compromised due to civil aircraft commonly using their own engines for taxiing in the current era. A new generation of towing-out mode has been introduced, which utilizes the external power supplied by a towbarless tractor. A complex constraint relationship exists between the nose landing gear's wheel and the wheel-holding mechanism of the tractor during this towing process. The nose landing gear, a crucial component for ground taxiing, possesses dynamic characteristics that directly influence the safety of high-speed taxiing and the service life of the structure. Given the constraint relationship of wheel-holding contact force, it is imperative that a study be conducted on the vibration characteristics of the nose landing gear, which is subjected to both heavy load and towing load. A specific type of civil aircraft front landing gear is selected as the research subject, and a mathematical model is derived to describe the constrain between the nose landing gear's wheel and the wheel-holding mechanism. This derivation is based on the wheel-holding contact geometric relationship and the Winkler contact model. The static and dynamic characteristics of the nose landing gear under heavy load are investigated. Considerations are given to the wheel-holding contact interaction during towbarless towing, the nonlinear axial force of the shock absorber, and the buffering effect of the tractor tire. The influence of wheel-holding contact stiffness and nonlinearity on the vibration characteristics of the structure is also examined. A nonlinear relationship between the radial force and radial deformation of the wheel is revealed by the results, with the degree of nonlinearity inversely proportional to the radius of the clamping rod. As the wheel-holding contact stiffness increases, frequency veering and mode conversion are gradually experienced by the first and second modes of the nose landing gear under full-load towing conditions. The occurrence of frequency steering is observed when a specific nonlinear function relationship is exhibited between the clamping contact force and the stiffness of the tractor tire. Moreover, the nonlinearity of wheel-holding contact stiffness exerts a more pronounced impact on the first-order natural frequency of nose landing gear. The findings of this study can serve as a valuable reference for optimizing the nose landing gear under the new towing-out mode and designing the wheel-holding mechanism.

[4]*State University of New York at Albany*

ABSTRACT

Efficient simulation of SDEs is essential in many applications, particularly for ergodic systems that demand efficient simulation of both short-time dynamics and large-time statistics. However, locally Lipschitz SDEs often require special treatments such as implicit schemes with small time-steps to accurately simulate the ergodic measure. We introduce a framework to construct inference-based schemes adaptive to large time-steps (ISALT) from data, achieving a reduction in time by several orders of magnitudes. The key is the statistical learning of an approximation to the infinite-dimensional discrete-time flow map.

We use the classical numerical schemes to derive informed basis functions, leading to a parameter inference problem. We introduce a scalable algorithm to estimate the parameters by least squares, and we prove the convergence of the estimators as data size increases. The numerical tests confirm that ISALT can tolerate time-step magnitudes larger than plain numerical schemes.

NUMERICAL SIMULATION METHOD FOR FATIGUE CRACK PROPAGATION IN CLADDED C(T) TEST SPECIMEN

Yanlong Li[*1] and Toshio Nagashima*[1]

[1]*Sophia University*

ABSTRACT

To improve the corrosion resistance and rust prevention properties of nuclear reactor pressure vessel (RPV) in nuclear power plants, stainless steel is welded on the inner surface of vessel as cladding. In such cladded structure, due to the dissimilar material interface, fatigue crack propagation behavior is complex and further researches are required.

In this study, a numerical simulation method based on extended finite element method (XFEM) for fatigue crack propagation in cladded structure is proposed. This method employs 8-node hexahedral continuum elements enriched with only Heaviside step function, which can model planar crack independently of finite elements. For the crack across dissimilar material interface in cladded structure, first, the stress intensity factors along the crack front are evaluated by domain integral method, and then crack front shapes are updated by using Paris' law and then smoothed by the cubic Bezier curves in each region. The crack propagation analysis is performed by repeating this series of processes mentioned above.

In this presentation, fatigue crack propagation analyses for cladded C(T) test specimens are performed. The obtained relationships between crack length and load cycle as well as transition of propagating crack front shapes are compared with those of experiment and validated. It was shown that the proposed method appropriately simulated the fatigue crack growth behaviours in cladded C(T) test specimens.

NUMERICAL SIMULATION OF THE COMPRESSIBLE STABLE RAYLEIGH-TAYLOR-KELVIN-HELMHOLTZ INSTABILITY WITH DISCRETE BOLTZMANN METHOD

Yaofeng Li[1] and Chuandong Lin*[12]

[1]*Sun Yat-sen University*

[2]*Key Laboratory for Thermal Science and Power Engineering of Ministry of Education, Tsinghua University*

ABSTRACT

The Rayleigh-Taylor (RT) and Kelvin-Helmholtz (KH) instabilities are typical fluid instability phenomena that often occur in conjunction. The coupled RTKH system can be categorized as stable or unstable, depending on whether the heavier fluid lies beneath or above the lighter one. In stable RTKH systems, the evolution of physical fields is often accompanied by complex phenomena such as nonlinearity, multiscale effects, and nonequilibrium behavior. These complexities pose challenges for traditional methods. As a mesoscopic method, the discrete Boltzmann method (DBM) is capable of describing both hydrodynamic and thermodynamic behaviors and has recently been applied to study the RTKH instability[1-2]. In this study, we utilize the DBM to investigate the competition mechanism between the suppression and promotion of interface evolution, where stable RT inhibits interface evolution, while KH promotes it. This work aims to enhance our understanding of the nonequilibrium evolution of compressible stable RTKH instability and contribute to the theoretical framework of fluid instability.

ANALYZING THE LONG TERM BIOMECHANICAL RESPONSE OF ORTHOKERATOLOGY BY CONSIDERING THE ANISOTROPIC VISCOELASTIC BEHAVIOR OF THE CORNEA

Yifeng Li[*1], Zhuoran Yang[1], Ziming Yan[1], Huibin Shi[1] and Zhanli Liu[1]*

[1]Tsinghua University

ABSTRACT

Orthokeratology, an effective myopia correction and control technique widely adopted among adolescents, is increasingly gaining scientific attention. Most existing research focused on analyzing patient corneal morphology data to discern deformation patterns but often fell short in understanding the underlying biomechanical mechanisms. This limitation resulted in the fitting of orthokeratology lenses heavily relying on clinicians' judgment, posing a significant challenge for accurately predicting orthokeratology outcomes, i.e., corneal deformation. This study aims to reveal the mechanisms of orthokeratology by establishing a biomechanical model, facilitating the prediction of corneal deformation. We began by collecting extensive corneal morphological data from clinical myopia patients, based on which we constructed a geometrically personalized finite element model. This model considers the anisotropic, visco-hyperelastic mechanical properties of the cornea. It was validated by simulating the long-term response in central corneal thickness over an 8-day orthokeratology period and comparing these results with experimental data. Furthermore, the study explored the effects of corneal anisotropic characteristics and posterior surface boundary conditions on the shaping process. Corneal shear dominated by indentation was revealed as the key deformation mechanism in orthokeratology. Using this model, we analyzed the effects of lens-wearing time and cycle duration of orthokeratology lenses on myopia correction and proposed appropriate lens-wearing strategies for various degrees of myopia. The biomechanical model established in this research successfully captured the long-term viscoelastic response of central corneal thickness, laying a solid foundation for the quantitative prediction of orthokeratology outcomes.

HIGH-THROUGHPUT SCREENING AND PREDICTION OF HIGH MODULUS OF RESILIENCE POLYMERS USING EXPLAINABLE MACHINE LEARNING

Ying Li[1]*

[1]*University of Wisconsin-Madison*

ABSTRACT

The ability to store and release elastic strain energy, as well as mechanical strength, are crucial factors in both natural and man-made mechanical systems. The modulus of resilience (R) indicates a material's capacity to absorb and release elastic strain energy, with the yield strength (σy) and Young's modulus (E) as R = σy2/(2E) for linear elastic solids. To improve the R in linear elastic solids, a high σy and low E combination in materials is sought after. However, achieving this combination is a significant challenge as both properties typically increase together. To address this challenge, we propose a computational method to quickly identify polymers with a high modulus of resilience using machine learning (ML) and validate the predictions through high-fidelity molecular dynamics (MD) simulations. Our approach commences by training single-task ML models, multitask ML models, and Evidential Deep Learning models to forecast the mechanical properties of polymers based on experimentally reported values. Utilizing explainable ML models, we were able to determine the critical substructures that significantly impact the mechanical properties of polymers, such as E and σy. This information can be utilized to create and develop new polymers with improved mechanical characteristics. Our single-task and multitask ML models can predict the properties of 12 854 real polymers and 8 million hypothetical polyimides and uncover 10 new real polymers and 10 hypothetical polyimides with exceptional modulus of resilience. The improved modulus of resilience of these novel polymers was validated through MD simulations. Our method efficiently speeds up the discovery of high-performing polymers using ML predictions and MD validation and can be applied to other polymer material discovery challenges, such as polymer membranes, dielectric polymers, and more.

CHARACTERIZING CYCLIC INELASTIC BEHAVIOR OF ANGLE MEMBERS: A MODIFIED HYSTERETIC MODEL

Yiwen Li[*12] and Songye Zhu*[1]

[1]*The Hong Kong Polytechnic University*
[2]*Tongji University*

ABSTRACT

Predicated on the Dicleli physical model [1], a modified hysteretic model tailored for displacement-controlled cyclic loading is devised. Comparative analysis through a finite element model indicates that the interrelation between normalized axial and lateral displacements solely depends on slenderness, ensuring the physical interpretation of the equation's parameters. Additionally, the study also explores the way local buckling alters cross-section shape and macroscopic component behavior. The new model reduces this impact with effective width. Given that the residual lateral displacement of each loading cycle may transform a straight rod into a bow-shaped rod, aggravating second-order effects and triggering early buckling. The improved model integrates geometric nonlinearity by updating the tangent modulus after each cycle, except initial imperfection, which is already included in the derivation of physical model. Since subsequent simulations demonstrate that low cycle fatigue damage and fracture propagation minimally affect the component's hysteresis curve, these factors are excluded from the model. The modified hysteretic model, validated by experimental tests and finite element simulations, effectively captures the key numerical values of the hysteresis curve, enabling a smooth transition from regular to random loading. This study offers a promising methodology for representing the cyclic inelastic behavior of angle members in various structures.

AI-ENABLED RAPID IMAGE-BASED HEMODYNAMIC MODELING AND SIMULATION

Pan Du[1], Delin An[1], Yongqi Li[1], Chaoli Wang[1] and Jianxun Wang[1]*

[1]University of Notre Dame

ABSTRACT

Cardiovascular disease (CVD) has persisted as a leading global cause of mortality for decades. While image-assisted computational fluid dynamics (CFD) simulation has proven invaluable in offering comprehensive hemodynamic insights for non-invasive diagnosis and clinical treatment planning for CVD, the conventional approach faces significant challenges hindering its widespread application. Firstly, the manual extraction of geometries from medical images is time-consuming, inconsistent among different operators, and may introduce human artifacts during geometry reconstruction. Secondly, the meshing, case setup, and execution of CFD simulation under realistic settings (e.g., high spatial and temporal resolution, fluid-solid interaction (FSI), Wind-Kessel boundary conditions) can be time-demanding, limiting its applicability in clinical scenarios requiring timely feedback or iterative model queries for device implant design. Thirdly, uncertainties in boundary conditions or model parameters during CFD simulation can compromise result credibility, reducing its effectiveness in clinical diagnosis.

In response to these challenges, we introduce a novel AI-enabled image-based computational modeling framework for automatic patient-specific image segmentation and rapid hemodynamic simulations, which harnesses the potency of deep learning to enable fast prediction of 3D blood flow patterns from raw image scans. Firstly, we automate vessel segmentation in medical imaging by developing a Laplacian-of-Gaussian (LoG) based Bayesian network, enhancing segmentation accuracy across diverse vascular structures. Subsequently, a shape deformation model using graph neural network (GNN) with residual connection reconstructs high-quality patient-specific simulation-ready meshes from segmented voxel images. Surface smoothness on the reconstructed geometry is ensured through the use of a large deformation diffeomorphic metric mapping (LDDMM) method. Finally, a GNN-based CFD surrogate model is established for rapid prediction of simulation results, handling unstructured meshes and featuring full gradient tracking and backpropagation for swift model adjustments and parameter optimization across complex vascular structures. The proposed models are demonstrated on a main aorta with upper branches (brachiocephalic trunk, left common carotid artery, and left subclavian artery), showcasing its merit and effectiveness. This study serves as a compelling indication that the integrated machine learning technologies hold substantial promise and have the potential to revolutionize CVD diagnosis, offering a more effective and efficient tools for cardiovascular healthcare.

MULTIPHYSICS-INFORMED MACHINE LEARNING FOR ARCHITECTED BATTERY DESIGN

Parth Bansal[1] *and Yumeng Li**[1]

[1]*University of Illinois Urbana-Champaign*

ABSTRACT

Li-ion batteries (LIBs) are critical for electrification in a wide range of applications to reach zero-net emission goal. These increasingly widespread applications warrant an improvement in the existing battery designs so as to meet this increasing demand. One such possible improvement is the use of Si anode instead of the traditionally used graphite electrode as this change allows for increased battery life, increased capacity, increased safety and better performance. The unique intercalation mechanism of Li ions into the Si anode Si anode results in a better specific capacity of the battery. In this mechanism Si atoms react with lithium, which leads to the bonds between the Si atoms giving way for the formation of the LixSi alloy. However, there is a cost associated with this design improvement. Volumetric changes of upto 300% are observed in the Si anode during the lithiation/delithiation cycles which results in the development of large internal stresses in the anode. Delamination of the Si anode from the current collector substrate and the cracking in the Si anode material itself are the consequences of this volumetric stresses, which causes a reduction in the capacity of the battery. The growth of the solid electrolyte interface (SEI) layer is another capacity fade mechanism that is coupled with mechanically induced damage in the LIBs. SEI layer growth in LIBs can lead to the increase in the internal resistance of the cell and the removal of the active Li material from the cycling process. The growth of the SEI layer on the surface of the anode mainly occur during the battery cycling phase. The continued growth of this layer increases the overall resistance and removes the active Li from the cycling system, thereby reducing the overall capacity of the battery. Hence, to be able to truly utilize Si as the active material for the LIBs, there is a tremendous need to understand these three coupled failure modes in the battery and identify electrode design that can mitigate the mechanically induced capacity degradation. One potential solution is architected electrode. In this study, multiphysics-informed machine learning has been developed to investigate the capacity degradation of architected electrodes with various designs under different operating conditions. This is the first work that can consider all major coupled failure models of Si-based electrodes in the performance analysis, which can facilitate the design of high efficiency battery with architected electrodes.

SYNERGISTIC EFFECTS OF ENVIRONMENTAL DETERIORATION ON FATIGUE AND FLEXURE PROPERTIES OF GLASS FIBER REINFORCED POLYMERIC (GFRP) COMPOSITES : A MULTISCALE AND MULTIPHYSICS MODEL.

Zhiye Li[*1] and Michael Lepech*[1]

[1]*Stanford University*

ABSTRACT

This study aims to simulate synergistic UV & moisture deterioration and demonstrate its role in changing the residual fatigue and flexure performance in architectural GFRP composites. This study develops an experimentally validated 3D Multiphysics model at structural level and gets this homogenization-based model to identify each of the degradation mechanisms observed in the experimental data and to analyze the differences that the various degradation mechanisms might make to the properties and durability of the environmental aged composite materials. Sensitivity analyses are conducted to investigate the effect of mesh density on the accuracy of functions homogenized from micromechanical models. The aging-fatigue-bend model with respect to two different deterioration mechanism assumptions is developed and analyzed. Research shows that models with homogeneous damage assumptions allow higher feasibility and convergence when aging concurrently with complicated mechanical loading, while models with surface erosion assumptions describe the actual deterioration mechanism more precisely and offer more freedom, especially when the environmental aging condition is more complicated.

This model can be incorporated into many commercial finite element codes for a sustainability study of composite structures/systems. In future work, the models developed in this study will be combined with life cycle assessment (LCA) tools to support better sustainability-focused new material design, thus reducing costs and environmental impacts in the built environment.

NUMERICAL SIMULATION METHODS AND DATA-DRIVEN MODELS FOR METAL ADDITIVE MANUFACTURING

Yanping Lian[*1], Ming-jian Li[1], Wenze Zou[1], Jiawei Chen[1], Shi Dai[1] and Zhidong Wang[1]*

[1]*Beijing Institute of Technology*

ABSTRACT

Metal additive manufacturing (AM) technologies have found the potential to revolutionize the global part manufacturing landscape for their tremendous advantages in building geometrically complex parts with tailorable microstructures and properties. However, they still suffer from unexpected formation defects of the as-built geometry, dimension, and material properties, which require a complete understanding of the process-structure-property relationship. Because the process of metal AM involves extremely multi-physical phenomena taking place at a variety of temporal and spatial scales, high-fidelity numerical simulations are preferred to the costly trial-and-error experiments to address the process-microstructure-property relationship of AM and to aid the process parameters optimization for reducing the final product defects such as surface roughness, void formation, heterogeneous grain structures, etc. In this study, we proposed multi-scale and multi-physics numerical simulation methods, including the proposed multi-physics material point method, extended cellular automaton method, crystal plasticity finite cell self-clustering analysis method, for the powder melting-solidification process, grain structure evolution, and mechanical properties for different as-built alloys with different metal AM processes. The predictions from the proposed computational methods are in good agreement with the experimental data available in the literature for both powder bed fusion and wire-based directed energy deposition processes. Furthermore, data-driven models based on deep learning algorithms for the process-structure-property problems are developed based on the dataset by the proposed numerical simulation methods. The high efficiency and accuracy of these models are demonstrated. It is shown that the proposed methods and models can shed light on the process-microstructure-property relationships and can be further applied to optimizing process parameters.

A UNIFIED THEORY FOR SHEAR DEFORMABLE COMPOSITE PLATES

Chen Liang[*1] and C.W. Lim[1]*

[1]*City University of Hong Kong*

ABSTRACT

A shear deformation-based unified theory for composite plates is established. The theory contains four unknowns which are explicit to interpret the physical response. Apart from the three common displacement components for a point on the midplane, a remaining higher-order displacement component is exclusively attributed to transverse bending and shear deformation. The transverse shear deformation of the function distribution can be represented by general shape functions. The elucidation of the thickness locking mechanism relies on the innovative displacement component introduced in this study, which improves the kinematic assumptions inherent in conventional plate/shell theories. Further, the present theory explicates the explicit physical terms associated with transverse normal stress and strain. In addition, the present unified theoretical framework, along with the corresponding assumptions, induces further simplification and transition into the conventional plate theories, namely, first-order shear deformation theory (FSDT), higher-order shear deformation theory (HSDT), and others. Exact analytical solutions of composite plates are obtained. A comprehensive numerical investigation has been performed, encompassing diverse plate theories and various composite structures, including functionally graded material (FGM) plate structures, FGM sandwich plate structures, etc. The clarity and unity in the present theory and the physical meanings can be elaborated by integrating the conventional theories under certain assumptions.

SPECTRAL DIFFERENCE SOLUTIONS OF TWO THREE-DIMENSIONAL KINEMATIC DYNAMO PROBLEMS

Russell Hankey[1], *Maxwell Stephan*[1] *and Chunlei Liang**[1]

[1]*Clarkson University*

ABSTRACT

We report a recent development of the high-order spectral difference method with divergence cleaning (SDDC) for accurate simulations of two 3D kinematic dynamo benchmark problems on unstructured grids consisting of high-order iso-parametric hexahedral elements. The divergence cleaning approach is based on the improved generalized Lagrange multiplier (GLM), which is thermodynamically consistent and Galilean invariant. The Spectral Difference with Divergence Cleaning (SDDC) method has been used to successfully model a number of nonlinear MHD problems. The spectral difference method is a versatile high order method that can be used for unstructured grids and can be massively parallelized. The first kinematic dynamo problem was solved in a cubic box with all periodic boundary conditions. The SDDC method will be verified to capture the “Cigar” structures published in the literature. The second kinematic dynamo problem adopts a spherical shell geometry and non-penetrative and stress-free boundary conditions. The SDDC method will be employed to predict Sunspot cycles.

A REDUCED-ORDER METHOD WITH MIXED NONLINEAR KINEMATICS FOR GEOMETRICALLY NONLINEAR AND BUCKLING ANALYSIS OF THIN-WALLED STRUCTURES

Ke Liang[*1] and Zheng Li*[1]

[1]*Northwestern Polytechnical University*

ABSTRACT

Thin-walled structures subjected to the in-plane and out-of-plane loads are widely used as load-bearing components in the aircraft, space and various civil engineering fields. The out-of-plane deflection of thin-walled structures is normally much larger than the wall thickness when the external load is applied laterally and/or buckling occurs. In these cases, a geometrically nonlinear analysis is required to achieve a realistic load-displacement response which greatly influences the load-carrying capability of thin-walled structures.

The conventional finite element (FE) method with a Newton-Raphson incremental-iterative technique still has limitations for geometrically nonlinear analysis. The repeated linear solutions of a large full-order FE system are computationally expensive, limiting the step size of the path-following analysis. In addition, a sufficient number of path-following steps must be adopted to achieve a geometrically nonlinear response curve with a favorable smoothness. This further aggravates the computational burden of geometrically nonlinear analysis.

In this work, a novel reduced-order method in the framework of mixed nonlinear kinematics is proposed for the geometrically nonlinear analysis of thin-walled structures with large deflections and/or buckling. The mixed nonlinear kinematics are developed in the combination of co-rotational and updated von Kármán formulations. The co-rotational kinematics are used to calculate the internal force and tangent stiffness of the structure, whereas the third- and fourth-order strain energy derivatives are achieved using the updated von Kármán kinematics. For the geometrically nonlinear problem with large deflection, reduced-order models with one degree of freedom are constructed based on the perturbation theory, otherwise more degrees of freedom are involved in the presence of buckling. The use of mixed nonlinear kinematics can greatly improve the computational efficiency in construction of a reduced-order model. The solutions of reduced-order models can be regarded as nonlinear predictors to the geometrically nonlinear response. Nonlinear predictors are required to be corrected using internal force-based residuals to ensure the accuracy of the geometrically nonlinear analysis. A geometrically nonlinear response with favorable smoothness is efficiently and accurately achieved using large step sizes in the path-following analysis. Various numerical examples are applied to validate the numerical accuracy and efficiency of the proposed method.

HINGE AND SMOOTHED-HINGE MODELS FOR CLOTH SIMULATION

Qixin Liang[*1] and K.Y. Sze*[1]

[1]*The University of Hong Kong*

ABSTRACT

The hinge model commonly used in fabric and cloth simulation quantifies bending energy in terms of the angle between the triangular facets defined by four computational nodes with translational but not rotational dofs. The classical hinge model (CHM) starts with the angle between two vectors normal to the triangular facets and derives the first and second order derivatives of the angle for the subsequently nonlinear solution process. In this study, an alternate but an equivalent angle or hinge angle is employed. It leads to the same set of derivatives, but the derivation process appears to be simpler. The torsional stiffness of the hinge is often calculated from the bending energy in one-third or the total area of the two triangular facets which are assumed to be under the cylindrical bending curvature fitting the hinge and the two computational nodes away from the hinge. In this submission, a smoothed-hinge model (SHM) is proposed in which a smooth cylindrical surface is first defined by interpolation at the four computational nodes of the hinge. Under the small curvature and small strain assumptions, the curvatures along the perpendicular directions to the three edges of a triangular facet can be expressed as linear functions of the nodal displacement. The three normal curvatures are transformed into the three curvature components defined in two orthogonal axes on the tangential plane of plate/shell and the conventional bending stiffness matrix used in the plate/shell is used to compute the bending energy. By incorporating the corotational concept, the bending energy can be approximated as a quadratic function of the nodal displacement. As a result, the Hessian of the bending energy is a constant matrix and does not require to be updated in the iterative solution procedure. For the membrane energy, a six-node interpolation instead of the three-node interpolation is employed. The former, when combined with either CHM or SHM, effectively mitigates the occurrence of sharp crease artifacts. To model contact and friction conditions, the incremental potential contact (IPC) is employed. Quasi-static and elasto-dynamic problems are both examined. Through quantitative and qualitative numerical experiments, the results demonstrate that our computational models exhibit stability with large time steps and convincingly simulate a variety of draping and garment scenarios.

A GENERAL CONTACT MODEL FOR ROUGH SURFACES BASED ON THE INCREMENTAL CONCEPT

Xuan-Ming Liang[*1], Shiwen Chen[1], Chengya Li[1] and Gangfeng Wang[1]*

[1]*Xi'an Jiaotong University*

ABSTRACT

It is now widely accepted that the real contact area between rough solids rises linearly with increasing normal loads. However, the coefficient of proportionality varies among different theoretical models and simulation results. This study advances a model for analyzing the elastic contact of rough solids. By taking into account the specific shape of contacting asperities, the connection between the real contact area and geometric truncation area is established in priority. Furthermore, the relationship between geometric truncation area and normal load is addressed by adopting the incremental concept. For surfaces covered with spherical asperities, the model could reproduce the predictions provided by the celebrated GW model [Greenwood, J. A., and Williamson, J. B. P., 1966, Proc. Roy. Soc. A., 295(1442), 300-319]. Avoiding prescribing the asperity geometries, the model tends to be more robust when surfaces are random and fractal. For general fractal Gaussian random rough surfaces, the model suggests that the coefficient of proportionality lies between 1.67 and 2.56. The upper and lower limits are close to the predictions of the BGT model [Bush, A. W., Gibson, R. D., and Thomas, T. R., 1975, Wear, 35(1), 87-111] and Persson's theory [Persson, B. N. J., 2001, J. Chem. Phys., 115(8), 3840-3861], respectively. In the thermodynamic limit, the potential varying scope for the coefficient of proportionality is further narrowed ranging from 1.92 to 2.22. The resultant predictions are in accord with numerical results presented in literature. The current study might provide profound insights into understanding the role of surface morphologies in elastic rough contact.

NUMERICAL SIMULATION INVESTIGATION ON NONLINEAR FLOW CHARACTERISTICS OF ROUGH SINGLE FRACTURES WITH DIFFERENT CONTACT AREAS

Yanbo Liang[*1], Yuanfang Cheng[1], Zhongying Han[1] and Chuanliang Yan[1]*

[1]China University of Petroleum (East China)

ABSTRACT

Abstract: To comprehensively understand the influence of the contact area on the flow characteristics of rough single fractures, a rough fracture surface is initially constructed using a spatial frequency domain approach. Subsequently, rough single fractures with varying contact ratios are derived by translating and displacing the fracture surface. The Navier-Stokes equation and Mass-conservation equation are solved by utilizing the laminar flow module integrated within the COMSOL software. The simulation results show that the nonlinear correlation between fluid flow velocity and pressure gradient can be described by using Forchheimer equation. Under the same flow velocity, a higher contact rate will exacerbate the nonlinear characteristics of fluid flow. In contrast to non-contact fractures, the streamlines within contact fractures exhibit increased tortuosity, accompanied by an elongation of flow pathways. Furthermore, with an expanding contact area, the complexity of the streamline pattern amplifies. The overall pressure field distinctly exhibits non-uniform characteristics, with larger pressure gradient observed within localized contact regions, consequently facilitating an increase in flow velocity.

Keywords: Rough fractures; Contact area; Nonlinear flow characteristics; Numerical simulation.

MULTISCALE MODEL REDUCTION FOR INVERSE HEAT CONDUCTION IN HIGH-CONTRAST MULTISCALE MEDIA

Ying Liang[*1] and Siu Wun Cheung*[2]

[1]*Purdue University*
[2]*Lawrence Livermore National Laboratory*

ABSTRACT

Efficient numerical simulations for forward problems are crucial for decision-making applications like inverse problems and optimal design. However, when dealing with multiscale medium properties, direct numerical simulation of the forward problem becomes computationally expensive, requiring a fine grid to capture variations in highly oscillating material properties. To address this, model reduction techniques are necessary. In this presentation, we introduce a novel multiscale model reduction method for inverse heat conduction in high-contrast multiscale media, significant in various engineering and industrial applications. Our method, grounded in recent advances in multiscale finite element methods, computes multiple localized multiscale basis functions per coarse region using local spectral problems and the localized energy minimization principle. We provide a theoretical analysis of the proposed method and present several numerical tests to verify its performance.

THE EXTENDED MATERIAL POINT METHOD FOR MODELLING EVOLUTION AND INTERACTION OF MULTIPLE DISCONTINUITIES

ABSTRACT

The Extended Material Point Method (XMPM) has demonstrated efficacy in numerically simulating shear band evolution and post-failure behavior during large deformations. However, the current formulation of XMPM is inherently limited to representing a single discontinuity, constraining its application in modeling intricate scenarios involving multiple discontinuities. This paper introduces a comprehensive extension to the XMPM framework to overcome this limitation, enabling the simulation of realistic problems characterized by the presence of multiple discontinuities.

Our enhanced method incorporates modifications to the original particle displacement approximation, empowering the XMPM to effectively handle multiple discontinuities within the material domain. Additionally, a dedicated contact strategy is developed to deal with the interaction between these multiple discontinuities within the XMPM framework. Several numerical case studies demonstrate the proposed extension's efficacy in simulating scenarios with multiple discontinuities, which is expected to contribute significantly to the understanding and prediction of material failure in various engineering and scientific applications.

ABSTRACT

This study investigates dynamic mesh adaptation (DMA) for hybrid RANS/LES (HRLES) simulations of compressible turbulent flow. HRLES models, which blend Reynolds-Averaged Navier-Stokes (RANS) and Large Eddy Simulation (LES), are by their nature very sensitive to the computational mesh, because of the very different resolution requirements in the RANS and LES regions. The proposed DMA strategy relies on a high-order k-exact finite volume spatial discretization [1] designed to ensure robust, accurate and conservative solutions for compressible flows with strong discontinuities while limiting the numerical dissipation of vortical structures. A mesh refinement criterion related to the truncation error of the k-exact reconstruction scheme is introduced, and compared with several heuristic refinement criteria from the literature [2]. To limit the computational burden of frequent re-meshing for unsteady flow simulations, the adaptation is performed only at certain time steps, and the error criterion is averaged over the chosen adaptation period [3]. A simple and effective criterion is then introduced to automatically control the averaging and adaptation period. The proposed DMA strategy is evaluated against a series of test cases of increasing complexity, ranging from inviscid vortex advection to turbulent transonic flow past an axisymmetric backward-facing step, representative of the base flow behind a space launcher.

ANALYTICAL DESIGN SENSITIVITY INFORMATION OF COMPOSITE LAMINATE SHELLS

Jan Liedmann[*1], Franz-Joseph Barthold[1] and Nikolai Gerzen[2]*

[1]*TU Dortmund*

[2]*The Technische Hochschule Ostwestfalen-Lippe*

ABSTRACT

Fiber-reinforced composites represent a class of materials celebrated for their exceptional strength, lightweight nature, and versatility. These advanced materials are composed of a matrix, often a polymer, reinforced with fibers such as glass, carbon, or aramid. The strategic integration of these fibers provides unique mechanical properties to the composite, combining the high strength of the reinforcing fibers with the flexibility and formability of the matrix material. This synergy results in materials that are widely employed across various industries, ranging from aerospace and automotive engineering to construction and sports equipment manufacturing. The tailored design possibilities and superior performance characteristics of fiber-reinforced composites make them a focal point of research and innovation in materials science and engineering.

In the optimization of laminated composite shells, diverse objective functions are sought depending on the intended use of the structure. This also applies to the selection of design parameters, where, in some cases, alterations in fiber orientations are desired without affecting the thickness of the structure, while in other instances, only specific layer thicknesses, and possibly their fiber orientations, may be subject to variation. This study explores fundamental types of design parameters for composite laminates, including total thickness, specific layer thicknesses, and fiber orientations, with the derivation of sensitivity relations.

Based on the solid shell formulation described in [1], investigations have been conducted for the extension to anisotropic material behavior, cf. [2], and exploring sensitivity relations concerning the shell geometry, cf. [3]. In this work, these methodologies have been used to formulate efficient sensitivity relations of composite shell structures. Employing a variational approach that embeds sensitivity analysis into the continuum mechanical framework, sensitivity relations for layer thicknesses and fiber orientations are established. These continuously derived quantities can be readily discretized and incorporated into a finite element environment.

Numerical examples are referenced to discuss various aspects, such as computational performance, numerical accuracy, and algorithmic treatment.

A HYBRID VIRTUAL ELEMENT FORMULATION FOR PLANE ELASTICITY

Francesco Salvatore Liguori[1], Antonio Madeo*[1], Sonia Marfia[2] and Elio Sacco[3]*

[1]*University of Calabria*
[2]*Roma Tre University*
[3]*University of Naples Federico II*

ABSTRACT

The enhanced Virtual Element Method (VEM) formulation, recently proposed by D'Altri et al. [1] for plane elasticity, provides numerous advantages over the classic VEM. The main innovation resides in the expression of the projection condition through an energy norm in which a divergence-free interpolation is assumed. This leads to the absence of stabilisation terms and a considerable accuracy improvement.
This work shows how the minimisation of Total Potential Energy and the projection operation typical of enhanced VEM can be obtained from the stationarity condition of the Hellinger-Reissner mixed functional. Starting from this theoretical result, a family of polygonal elements for plane elasticity is proposed, named as Hybrid Virtual Element Method (HVEM). The primary unknowns are the displacements along the element contour, as usual in classic VEM, and the stress field. The latter is assumed to within a polynomial basis that a-priori satisfies the equilibrium equations expressed on a Cartesian frame and corresponds to the divergence-free assumption in the projector term in enhanced VEM formulations. Then, all the discrete operators can be evaluated through line integrals, facilitating the formulation for polygonal elements with a generic number of edges [2].
The HVEM not only provides a wider theoretical background, but also reveals a close relationship with mixed hybrid-stress Finite Elements (FEs) [3], traditionally limited to triangular or quadrilateral geometries. Then, leveraging the broad literature on the hybrid-stress FEs behaviour, we discuss the critical role of selecting appropriate stress interpolation functions, not only for the element stability, but also for the accuracy improvement. In particular, a so-called iso-stable interpolation, that adopts the minimum number of stress parameters to ensure the element stability, turns out to be the optimal choice for achieving accurate solutions also for coarse meshes.

INVESTIGATING EVOLUTION OF VOIDS IN AL2219 USING 3D CHARACTERIZATION AND CRYSTAL PLASTICITY SIMULATIONS

Hojun Lim[1], Philip Noell[1], Matthew Vaughan[2], Andrew Polonsky[1], John Emery[1] and Kyle Johnson[1]*

[1]*Sandia National Laboratories*
[2]*Texas A&M University*

ABSTRACT

In this work, emerging high-resolution computed tomography (CT) and crystal plasticity (CP) simulations are used to understand void growth mechanisms in aluminum alloy 2219. By combining experimental and computational results, we investigate how microstructural features such as grain boundaries, triple junctions and particles influence void growth. Both DCT (Diffraction Contrasted tomography) and XCT (X-ray Computed Tomography) techniques are used to characterize initial crystal orientations, voids and phases, and their evolution at various applied strains. On the modeling side, high-fidelity crystal plasticity simulations are performed at the same resolution as CT measurements to obtain local stress/strain fields, stress triaxiality and Lode parameter that are frequently used to understand the void growth. Developed framework enables direct and quantitative comparisons between experimental and computational results for understanding void growth mechanisms in metal alloys.

IDENTIFYING CRACKED/DAMAGED STRUCTURES AND THEIR LOCATIONS USING PHYSICS-INFORMED MACHINE LEARNING WITH SPARSE MEASUREMENTS

Jae Hyuk Lim[*1], Myeong-Seok Go[1], Hong-Kyun Noh[1] and Seungchul Lee[2]*

[1]Jeonbuk National University
[2]Korea Advanced Institute of Science and Technology

ABSTRACT

In this paper, we introduce a novel method for identifying cracked or damaged structures and precisely locating these flaws by integrating physics-informed machine-learning techniques. Our approach combines principles from physics with advanced machine learning algorithms to address longstanding challenges in structural damage detection. By analyzing the vibrational, acoustic, and quasi-static properties of structures, we extract valuable insights from sparse measurement data to detect subtle indicators of structural degradation. Through rigorous experimentation, we validate the effectiveness and precision of our method in detecting structural damage, highlighting its potential to revolutionize current practices in structural health monitoring and maintenance. To demonstrate the performance of the proposed work, several practical examples, such as cracked and damaged structures, were treated. Finally, it was found that the proposed approach is sufficiently accurate despite a few sensor measurement data. It means that it has great potential to evaluate the anomaly detection of large engineering structures.

HYBRID SURROGATE MODELING FRAMEWORK AND REINFORCEMENT LEARNING FOR DIGITAL TWIN APPLICATIONS

Jasmin Lim[*1], Dimitrios Pylorof[2], Humberto Garcia[2] and Karthik Duraisamy[1]*

[1]*University of Michigan*
[2]*Idaho National Laboratory*

ABSTRACT

Nuclear energy has high operational risks that a digital twin (DT) can aid in the areas of operations & management (O&M); reactor safety analysis and improvement of plant efficiency. A system surrogate model is developed to predict physical asset quantities (e.g. reactor, heat exchanger, pumps) and computational assets responses (e.g. control system). The system surrogate model is labeled hybrid because it leverages the accuracy of physical models for robustness while also integrating low-fidelity models for speed and predictive capabilities. The framework is applied to a Pebble-Bed Fluoride-Salt-Cooled Reactor (PB-FHR), a new-generation reactor that has drawn interest from both research institutes and commercial companies. The physics-based models are used to compute the relative xenon concentrations and pump degradation, both essential quantities that determine the current reactor conditions. The remaining quantities are predicted using a Vector Autoregressive Moving Average with Exogenous term (VARMAX) model trained with data generated from the System Analysis Module (SAM); a transient system analysis tool for advanced reactor concepts. This model can also update itself by assimilating online measurements. The system state awareness provided by the surrogate model is utilized for the reinforcement learning (RL) of weighing plant operations, predictive maintenance and market performance.

TOPOLOGY OPTIMIZATION IN MAGNETIC FIELD USING HIGH-FREQUENCY HOMOGENIZATION METHOD

Sunghoon Lim[*1], Kazuhiro Izui[1], Seungjae Min[2] and Shinji Nishiwaki[1]*

[1]*Kyoto University*
[2]*Hanyang University*

ABSTRACT

Since the driving performance of a magneto-mechanical system is dominated by the magnetic flux distribution, optimizing the shape of the ferromagnetic material (FM), which determines the path and intensity of the magnetic flux, is the most important design process for improving system performance. The important properties of FMs considered here are the magnetic permeability, which describes the amount of magnetic flux generated due to the magnetic field intensity, as well as the energy loss characteristics due to magnetic hysteresis and eddy currents. In particular, since most magneto-mechanical systems currently under development for industrial devices use alternating electric fields, energy loss occurring within FMs is a critical factor that increases the operating temperature of the system and impairs performances. Therefore, in order to design a high-performance system, it is necessary to use a FM that simultaneously satisfies high permeability, low hysteresis, and low eddy current loss, however it is difficult to develop a new material with these properties.
This study aims to optimize both the microstructure of the FM composite and the shape of the magnetic core using the topology optimization method with a large degree of design freedom [1], and apply the optimized magnetic core with high magnetic permeability and low loss coefficient to a magnetic actuator. To do this, a high-frequency homogenization method, which uses a complex permeability tensor to consider the frequency of the applied magnetic field and predict the eddy current loss density of FMs [2], is applied to magnetic field analysis and design. The optimization problem is formulated to optimize the element density and orientation of the core for achieving the target force and flux distribution, while optimizing the microstructure of the FM that can reduce loss even at high frequency of the applied magnetic field. To verify the effectiveness of the proposed design method, optimized results of a linear oscillatory actuator with high operating frequency are introduced.

PATIENT-SPECIFIC OPTIMIZATION OF THERAPEUTIC REGIMENS VIA DIGITAL TWINS TO IMPROVE TRIPLE NEGATIVE BREAST CANCER RESPONSE TO NEOADJUVANT THERAPY

ABSTRACT

Neoadjuvant therapy (NAT) is the standard of care for locally advanced triple-negative breast cancer (TNBC). However, pathological complete response (pCR) rate in TNBC patients to current NAT regimens is 50-60% [1]. Aside from the need to develop new therapies with higher efficacy and lower toxicity, a critical barrier to improving TNBC response is the lack of rigorous ways to personally tailor therapeutic regimens. We seek to address this challenge by employing digital twins (i.e., mathematical models that provide a virtual representation of individual patients to predict changes in tumor status) to systematically evaluate TNBC patient's response to different NAT regimens, thereby patient-specifically optimizing treatments.

A cohort of TNBC patients (n = 37) from the ARTEMIS trial (NCT02276433) [2] was used for this study. For each patient, standard-of-care NAT chemotherapy was administered (i.e., 4 cycles of Adriamycin/Cytoxan (A/C) every 2-3 weeks, followed by 12 cycles of weekly Taxol (T)) and longitudinal MRIs were collected before and during NAT. Post-surgical pathology was performed to assess final response status. A digital twin framework has been developed by integrating longitudinal MRIs with a mechanism-based model to predict the treatment response [3]. The model was based on a reaction-diffusion equation that describes the change in tumor cellularity due to migration, proliferation, and drug-induced death. With parameters personalized using the MRIs, the patient-specific model (i.e., digital twin) was used to estimate individual patient's response to 128 simulated but clinically feasible schedules of A/C/T. The predicted response (pCR or non-pCR) from each alternative schedule was compared to the patient response from their actual treatment to evaluate the effect of altering treatment regimens.

We observed that, without changing the total dose, shortening the duration of A/C/T administration increased the treatment efficacy. The effectiveness of altering the schedules varied substantially in different patients. In particular, 8 out of 18 patients who had non-pCR responses to their actual treatment were predicted to achieve pCR with the dense-dose Taxol (i.e., 4 cycles of biweekly Taxol), indicating a 21.62% improvement of pCR rate in the study cohort. We are currently applying the optimization to a larger cohort (n > 130).

The preliminary results of our approach provided a unique opportunity of improving TNBC response to NAT through patient-specific optimization of therapeutic schedules. Ongoing efforts focus on accounting for toxicity and investigating the effects of altering therapy type, dose, and schedule on patient response.

A SIMPLIFIED FLUID STRUCTURE ANALYSIS OF AN ELASTOMERIC SINGLE-LOBE PROGRESSIVE CAVITY PUMP

Diego Peña[1] and João Lima[1]*

[1]Federal University of Paraiba

ABSTRACT

Widely used in the petroleum industry, progressive/progressing cavity pumps (PCPs) were conceived by René Moineau in the 30s and are in continuous design and efficiency improvement. Notwithstanding, PCPs with an elastomeric stator suffer an efficiency decrease due to elastic deformation provided by the fluid pressure rise along the rotor: in cases with interference, the pressure can cause a clearance, and in cases with clearance, the gap expands. To simulate this phenomenon, the present work improves the model proposed by [1] for the analysis of two-way fluid-structure interaction (FSI) in PCPs, by coupling the element-based finite volume method (EbFVM) for the fluid flow field with more general analytical models for the structural deformation field. The previous simplified structural model was implemented as a FORTRAN subroutine accounting for the local fluid pressure as the structural load in a Hookean linear model for radial deformations only [1]. Although the proposed model can still be considered simplified, it extends the previous one-dimensional structural model to a linear plane stress state considering the Poisson effect, thus making it more realistic. The main goal is to establish a reliable procedure for the development of a three-dimensional structural model for analysis of two-way FSI in PCPs that does not require expensive computational costs, as it is currently required in this type of analysis. The EbFVM was implemented in ANSYS/CFX with a developed FORTRAN code (a DLL routine) for structured mesh generation for each time step analysis accounting for the PCP rotor/stator relative motion [1,2,3]. The results were compared with those obtained with the ANSYS/CFX native mesh deformation algorithm, and with those obtained with the previous one-dimensional approach, showing better accuracy, since the first method causes mesh distortions and hysteresis, whereas the second method does not capture the deformations developed in the angular directions of the stator cross-section.

AN EFFICIENT SEMI-ANALYTICAL APPROACH FOR THE STOCHASTIC ANALYSIS OF SOFT BIOLOGICAL STRUCTURES

Georges Limbert[1,2], Teja Melink[3] and Joze Korelc[3]*

[1]*University of Southampton*
[2]*University of Cape Town*
[3]*University of Ljubljana*

ABSTRACT

Introduction: Integration of variability and stochasticity in predictive finite element models of biological systems is of critical importance, particularly in the context of diverse populations, whereby, besides intra-individual variability, there are statistically significant differences in biophysical and microstructural properties across ancestry and age groups. In a mechanobiological context other sources of variability include boundary and loading conditions as well as biochemical factors and their driving forces [1]. Stochastic finite element (SFE) analyses aim to propagate stochastic properties of a system directly through the governing partial differential equations but are more complex to implement and computationally expensive than their deterministic counterparts [2]. It is therefore advantageous to develop general and efficient methodologies to conduct such analyses, especially those that can capture spatial variations of random variables (i.e. stochastic fields).

Method: Here, it is proposed to represent stochastic fields using the Karhunen-Loève (KL) decomposition and calculate the stochastic response of the system using a second-order sensitivity analysis [2, 3]. The numerical implementation, based on automatic differentiation, is general and modular, valid for arbitrary kinematics and constitutive laws, making it particularly attractive to model biological soft tissues and their inherent heterogeneities. KL decomposition is computed via the formulation of a macro-element associated with a Fredholm integral equation of the second kind involving the covariance kernel of the stochastic field, and whose solution is obtained via standard Galerkin procedure.

Results: The SFE framework was assessed on various examples by accounting for geometric and material stochastic fields on 2D geometries, and solutions compared to Monte-Carlo simulations. A path-following method was used to solve the geometrically and materially non-linear problems. The gain in computational speed afforded by the semi-analytical approach could reach four orders of magnitude.

Discussion and Conclusion: The ability of a perturbation approach to capture propagation of uncertainties in highly non-linear systems is inherently limited by the expansion order (here, second order). However, the use of automatic differentiation combined with optimisation of computer code means that extension of the SFE framework to higher orders is possible and should be explored in the future. The numerical framework presented here provides an attractive platform to rapidly and statistically explore the influence of multiple factors on the physics of biological tissues and structures.

QUANTITATIVE NUMERICAL STUDIES OF LITHIUM ELECTROPLATING: VISCOPLASTIC INFILTRATION AND CRACKING IN A SOLID ELECTROLYTE

Chen Lin[*1]*

[1]*Sun Yat-sen University*

ABSTRACT

This talk proposes a mechano–electrochemical multi-phase field (MPF) model to study electroplating in ASSLB, which induces cracking and short–circuiting. Different from previous models [1 - 4], in this model, large viscoplastic deformation is involved to account for huge eigenstrain induced by electroplating; The plating reaction is described by generalized BV equation involving Eshelby stress tensor, which introduces effects of conformational volume change and deformation energy on overpotential; Contact between solid phases is considered to simulate different modes of Li growth associated with mechanical constraint; MPF framework incorporated fracture–PF model to describe cracking and viscoplastic infiltration of Li. Accuracy of proposed model is validated by quantitatively comparing simulated and experimental findings [5].

This model provides a comprehensive depiction of the transition from vertical elongation to shank–expansion of Li whisker for low–voltage plating scenario with variable constraints. It indicates a transition from reaction–controlled root–growth of Li whisker to viscoplastic flow of Li in gaps or cracks. Critical time for transition, depending on bias voltage and stack pressure is quantitatively predicted.

In high–voltage plating with rigid constraints, simulation shows that cracking is caused by wedge-opening mechanism. Specially, if LLZO particle is tightly constrained, Li can only fill in narrow crack via viscoplastic flow rather than pushing sidewalls apart to increase deposition space, quickly resulting in a short circuit. If the LLZO particle is not constrained, the growth of Li changes from the fissure eruption to root–growth that widens the crack and considerably extends short–circuit time. It indicates that reducing mechanical constraints of electrolyte particles instead of increasing their mechanical strength or decreasing defect size can improve cyclability of solid–state battery or mitigate short–circuit.

INTEGRATING DEEP ENERGY METHODS IN THERMOELASTICITY AND PIEZOELECTRICITY

Kuan-Chung Lin[*1], Kuo-Chou Wang[1] and Cheng-Hung Hu[1]*

[1]*National Chen Kung University*

ABSTRACT

This comprehensive study combines two pioneering research works that investigate the use of the deep energy technique for difficult multi-physics issues, especially in thermoelasticity and piezoelectricity. The deep energy approach, which is well-known for its resilience in dealing with nonlinearities and producing exact findings, has been intensively investigated for its efficiency and accuracy in these sectors. The first section of the research looks at its use in thermoelasticity [1], examining how network parameters such as layers, neurons, and activation functions affect result accuracy. Successfully resolving 1D and 2D thermoelasticity issues, which compare favorably with analytical solutions and empirical data, has confirmed this technique. The second portion applies this concept to piezoelectricity [2], solving complex 2D piezoelectric issues as well as piezoelectric composite plate actuators. The tanh activation function emerges as a really useful tool, considerably improving accuracy. This two-part study not only proves that the deep energy method can be used instead of traditional numerical methods to solve multi-physics problems, but it also shows how to set up neural networks in the best way to make them work better and more accurately. This will help both computational physics and engineering.

STABILITY AND ERROR ANALYSIS OF GENERALISED SAV SCHEMES FOR A DIFFUSE-INTERFACE TUMOUR GROWTH MODEL

*Ping Lin**[1]

[1]*University of Dundee*

ABSTRACT

In this talk we consider a diffuse-interface (phase-field) model for tumour growth that takes into account nutrient consumption and chemotaxis. The model is described by a nonlinear system consisting of a Cahn-Hilliard-type equation coupled with a reaction-diffusion equation. We first prove the existence of its weak solutions. Efficient schemes are then constructed based on the idea of scalar auxiliary variable (SAV), which we show are not only decoupled and easy to implement, but also have the properties of mass conservation and unconditional energy stability. Furthermore, we derive rigorous error estimates of one of the schemes. Several numerical examples are presented to validate the accuracy and stability of the proposed schemes. It is worth noting that when the scheme is equipped with an adaptive time-stepping strategy, it effciently simulates the typical phenomena of aggregation of multiple tumours with different shapes and tumour chemotactic growth. This is a joint work with Zhaoyang Wang and Junxiang Yang.

[3]National Taiwan University

ABSTRACT

Recently, Autonomous Mobile Robots (AMRs) have become promising solutions for the tasks of picking, transporting and placing objects within dynamic environments in smart factories. AMRs are required to position and navigate themselves within an indoor space that is filled with stationary obstacles such as walls, shelves, tables, machines, etc. as well as moving personnel. Ensuring high precision in the positions and configurations of AMRs is difficult due to factors such as wheel slippage, mechanical part backlash, unstable vibrations, sensor inaccuracies and environmental changes. In this paper, the uncertain motions of a 9-degree-of-freedom AMR (i.e., 3 for the ground vehicle and 6 for the robot arm) have been studied and a probabilistic approach for path and motion planning of AMR has been proposed. The probability that the shortest distance between the AMR and the nearby obstacles exceeds the allowable limit was consistently kept at a safe level. In the optimization process of AMR path and motion planning with obstacle avoidance, a linear probabilistic constraint with respect to the AMR control parameters was utilized to maintain the desired reliability level. In this approach, a Most Probable Target Point (MPTP) was found at the tail of the random distribution of the AMR configuration, which has a shortest distance to a Most Probable Failure Point (MPFP) on the nearby obstacle. Both MPTP and MPFP, which were simultaneously determined by a sub-optimization process, were essential for the formulation of the linear probabilistic constraint. Various numerical examples were utilized to show the performance of the proposed Probabilistic Indoor Navigation and Object Manipulation (PINOM) of AMR.

A FAST PREDICTION METHOD FOR BEARING STRENGTH OF AIRCRAFT COMPOSITE BOLTED STRUCTURES CONSIDERING INITIAL ASSEMBLY DEVIATION

Qingyuan Lin[*1], Yong Zhao[1], Yuming Liu[1], Wei Pan[1], Wencai Yu[1] and Yu Ren[1]*

[1]Shanghai Jiaotong University

ABSTRACT

The application of advanced composite materials is currently a key approach to improving the performance of high-end equipment such as aerospace. Joints are the weak points of composite structures. More than 60% of the failure of composite structures occurs in the connection position. Mechanical behavior analysis and joint performance prediction of the assembly and loading process of the composite structure is the key guarantee to realize its expected performance. Bolted joins are the most important form of assembly for composite structures. In the assembly process of composite bolted structures such as airplane wings, due to the influence of the complex multi-source uncertainty factors such as the manufacturing errors of the parts, the accumulation of errors in the pre-procedure assembly process, and the deviation of the assembly tooling, composite laminates always have initial assembly deviations, which are mainly manifested in the shape deviation of the parts and the relative position deviation between the parts. The above shape-position deviations will have a significant impact on the assembly state of the composite bolted joint and result in the joint strength deviating from the design value. This is a key bottleneck in improving the performance of composite bolted structures. Existing related studies have given less consideration to initial assembly deviations, usually focusing on the effect of a single deviation when it acts alone. In fact, there is a significant coupling effect of multi-source shape-position deviations on the assembly results and joint strength. In this study, a fast prediction method for the strength of the composite bolted joints considering the effects of initial shape-position deviation is proposed. This method firstly quantitatively expresses, and data fuses the multi-source initial assembly deviation information of the composite bolted joint. Using the fused deviation information as input, the joint strength is obtained through the virtual assembly-loading analysis. Prepare datasets by parametric sampling and batch simulation. Construct a neural network model and train it using this dataset. Finally, the fast model for the strength prediction considering the initial shape-position deviation of composite bolted joints is established. This model can provide assistance in performance evaluation and calibration of composite bolted joints.

INVESTIGATING THE EFFECTS OF THE MECHANICAL VENTILATION STRATEGIES ON PULMONARY MECHANICS PROPERTIES FOR CHILDREN WITH ACUTE RESPIRATORY DISTRESS SYNDROME

Siang-Rong Lin[*1], Jeng-Hung Wu[2], En-Ting Wu[2] and Chia-Ching Chou[1]*

[1]National Taiwan University
[2]National Taiwan University Hospital

ABSTRACT

This study aims to investigate the mechanical ventilator support management and pulmonary physiological characteristics of pediatric patients with Acute Respiratory Distress Syndrome (ARDS) in the Pediatric Intensive Care Unit (PICU).

The lung parenchyma of patients with ARDS often exhibits inhomogeneity, leading to local stress concentration and causing local lung injury, triggering a local inflammatory response. Pulmonary recruitment maneuvers, such as the application of positive end expiratory pressure (PEEP), are common treatments for patients with ARDS. Pulmonary recruitment involves the sustained application of pressure in the airways, allowing collapsed alveoli to reopen. This not only improves oxygenation in patients with ARDS but also helps prevent shear injuries caused by the repetitive opening and closing of alveoli. However, excessive PEEP can also cause lung damage, leading to Ventilator-Induced Lung Injury. At present, the optimal PEEP setting strategy remains unclear and has not yet been determined.

Therefore, we collect ventilator settings records and pulmonary compliance and inflammation evaluation data from patients with ARDS in the PICU. Through data processing and machine learning (including supervised learning and reinforcement learning), we evaluate the impact of different ventilator settings on lung compliance. Additionally, we apply the Ontology Web Language to encode the structural information of respiratory system anatomy and pulmonary mechanics, integrating this information into the machine learning models to enable them to learn from these data. This analysis enhances our understanding of how strategies of mechanical ventilator influence the physiological status of patients, providing more concrete guidance for clinical practices.

UPPER AND LOWER BOUNDS CONFIDENCE BAND COMPUTING FOR ACCURACY AND ERROR ESTIMATION USING SEFEA (STRAIN-ENRICHED FINITE ELEMENT ANALYSIS) FORMULATION

Theodore Lin[1] and Yu Hou*[2]

[1]*AMPS Technologies Company*
[2]*HuaXi Technology Innovation LLC*

ABSTRACT

Sefea (Strain-Enriched Finite Element Analysis) formulation[1] has been incorporated into several Industrial CAE products for design analysis for over a decade now. In the latest update, Sefea further refines the enrichment method by incorporating the nodal/element cluster density into the heterogeneous enrichment process. Additional convergence in accuracy is observed even with extremely coarse meshes.

Sefea technology allows general users with minimum or no FEA experience to perform routine design analysis with ease and achieve accurate and robust results. Experienced analysts can leverage speed, accuracy, convenience, and robustness to achieve superior outcomes. As CAD design analysis becomes more prevalent, users are increasingly seeking more guidance on the accuracy and reliability of the analysis results. This is the motivation for the ongoing research.

We first review the Sefea formulation and the critical nature of the zero integral-sum of the enriched strain. The method preserves the constant stress state required for convergence while elevating the low-order constant strain tetrahedron and triangle elements to the 2nd-order element accuracy without additional equations.

We observed that the lower and upper bounds of a given mesh can be derived from the enrichment process in the optimal strain enrichment development[2]. Without any enrichment, the method effectively degenerates into a constant strain low-order element with over-conservative results. Conversely, when uniformly enriched, it exhibits a softened behavior similar to the nodal integration method[3]. In comparison, the proposed enrichment formulation selectively enriches the strain during the integration process based on nodal density, element clustering, and strain variations and produces optimal results within the upper and lower bounds for the given discretization.

The implementation offers a quick feedback on the solution bounds and accuracy with small computational costs by adjusting only the enrichment component without the need for a costly element integral loop. It greatly improves the usability and accuracy projection for general CAE design analysis.

We will present the comparison with the analytical and other numerical methods, evaluating the accuracy, computational efficiency, and general usability. Comparison with traditional error evaluation techniques such as the energy error method is also reviewed. Finally, we highlight the potential areas for future research and development.

DISTRIBUTIONAL COMPLEXES AND THEIR COHOMOLOGY: HESSIAN, DIVDIV, AND ELASTICITY

Ting Lin[*1], Kaibo Hu[2], Qian Zhang[3] and Snorre Christiansen[4]*

[1]*Peking University*
[2]*University of Edinburgh*
[3]*Michigan Technological University*
[4]*University of Oslo*

ABSTRACT

Recently, there has been a growing interest in discretizing differential complexes beyond the de Rham case, including the Hessian, divdiv, and elasticity complexes. A conforming finite element discretization may involve high polynomial degrees. In contrast, using distributional spaces is much more computationally efficient. Moreover, distributional spaces can be categorized as elements from the dual mesh, which formally establishes a connection between finite element exterior calculus and discrete exterior calculus.

In this talk, I will discuss the distributional Hessian, divdiv, and elasticity complexes and their cohomologies in both 2D and 3D settings. We will prove that the cohomologies are isomorphic to their continuum counterparts. For the Hessian and divdiv complexes, we will first construct the discretization. As for the elasticity complex, we will delve into the Regge complex. Additionally, we will explore the twisted complex of the Regge complex, which can be seen as a differential complex perspective of the microstructure elasticity model.

A HIGHLY PARALLEL SIMULATION OF PATIENT-SPECIFIC HEPATIC FLOWS

Zeng Lin[*1]*

[1]*Chinese Academy of Sciences*

ABSTRACT

Computational hemodynamics is being developed as an alternative approach for assisting clinical diagnosis and treatment planning for liver diseases. The technology is non-invasive, but the computational time could be high when the full geometry of the blood vessels is taken into account. Existing approaches use either one-dimensional model of the artery or simplified three-dimensional tubular geometry in order to reduce the computational time, but the accuracy is sometime compromised, for example, when simulating blood flows in arteries with plaque. In this work, we study a highly parallel method for the transient incompressible Navier-Stokes equations for the simulation of the blood flows in the full three-dimensional patient-specific hepatic artery, portal vein and hepatic vein. As applications, we also simulate the flow in a patient with hepatectomy and calculate the portal pressure gradient. One of the advantages of simulating blood flows in all hepatic vessels is that it provides a direct estimate of the portal pressure gradient, which is a gold standard value to assess the portal hypertension. Moreover, the robustness and scalability of the algorithm are also investigated. A 83% parallel efficiency is achieved for solving a problem with 7 million elements on a supercomputer with more than 1000 processor cores.

A TWO-STEP CONSTITUTIVE MODELING FRAMEWORK BASED ON DATA-DRIVEN IDENTIFICATON AND PHYSICS-AUGMENTED NEURAL NETWORKS

Lennart Linden[*1], Karl Kalina[1], Jörg Brummund[1] and Markus Kästner[1]*

[1]TU Dresden

ABSTRACT

The formulation and calibration of constitutive models remain a difficult task for materials that exhibit complex nonlinear elastic or inelastic behavior. Therefore, new approaches, generally referred to as data-based or data-driven methods, have become increasingly popular in the computational mechanics community in recent years. However, these approaches require a large amount of data, usually stresses and strains for problems in solid mechanics. In this contribution, we present a consistent two-step approach for the automated calibration of hyperelastic constitutive models which only requires experimentally measurable data.

In the first step of our approach, data-driven identification (DDI) is applied to determine tuples consisting of stress and strain states [1]. This method enables to identify these data by only prescribing the applied boundary conditions and the displacement field which can be determined from full-field measurement methods such as digital image correlation (DIC). In the second step of the proposed framework, the data are used to calibrate a physics-augmented neural network (PANN) [2]. This model fulfills all common conditions of hyperelasticity by construction and is very flexible at the same time. The implementation of the PANN model into a finite element (FE) code is straightforward.

We demonstrate the applicability of our approach by several descriptive examples. Therefore, two-dimensional synthetic data are exemplarily generated by using a reference constitutive model. The calibrated PANN is then applied in three-dimensional FE simulations, where the solution is compared to the reference model.

BAYESIAN MULTIMODEL INFERENCE IN SYSTEMS BIOLOGY AND MEDICINE

Nathaniel Linden[*1], Padmini Rangamani[1] and Boris Kramer[1]*

[1]*University of California, San Diego*

ABSTRACT

When modeling biological systems, one must often choose from several possible models based on different sets of simplifying assumptions and theories. However, conditioning predictions on a specific model formulation can introduce uncertainty and bias due to the selection of one particular model. Thus, to ensure accurate prediction and uncertainty quantification, we must account for uncertainty in the model formulation in the resulting predictions.

Model selection and discrepancy modeling approaches allow one to choose the “best” model and directly account for model uncertainty. However, given the limited data in many biological applications, these approaches may lead to biases due to the selection of a single model. In this talk, we highlight several methods for multimodel inference that leverage the entire set of available models to avoid selection biases and account for model uncertainty by incorporating contributions from all models. Methods including Bayesian model averaging, pseudo-Bayesian model averaging, and stacking of predictive densities construct robust predictors using the entire model family and avoid conditioning predictions on one model.

In this talk, we characterize multimodel inference with several examples from systems biology, including mitogen-activated protein kinase (MAPK) signaling and prediction of pancreatic function for diabetes diagnosis. Our results show how multimodel inference accounts for model uncertainty and, thus, improves predictive certainty and reduces model selection bias. Furthermore, we demonstrate how multimodel inference yields models that better agree with experimental data and provide more reliable predictions.

A MULTISCALE ANISOTROPIC POLYMER NETWORK MODEL WITH PHASE FIELD FRACTURE AT FINITE STRAINS

Christian Linder[1] and Prajwal Kammardi Arunachala*[1]

[1]*Stanford University*

ABSTRACT

This presentation focuses on modeling fracture in rubber-like materials. Our study proposes a multiscale fracture model for elastomers, considering isotropic and anisotropic network responses, using the non-affine microsphere model and the maximal advance path constraint network model, respectively [1,2]. For the latter, macroscale fracture is driven by micromorphic regularization, introducing local-global damage variables. The model is validated using double-edge notched tensile tests and compared with experimental data. Uniaxial tensile experiments on PDMS rubber films with notches are conducted, and simulations are compared with experimental observations. Visualization of stretch and damage evolution in chains oriented differently assesses predictive capacity. Results are compared with alternative models, demonstrating the utility of our approach in accurately simulating rubber-like material fracture behavior.

SOME STRUCTURES PRESERVING KERNEL-BASED METHODS

Leevan Ling[*1] *and Sun Zhengjie*[2]

[1]*Hong Kong Baptist University*
[2]*Nanjing University of Science and Technology*

ABSTRACT

In this talk, we present innovative kernel-based meshless methods devised to preserve critical structures when solving Hamiltonian and dissipative PDEs. Our first method introduces a conservative Galerkin approach with radial basis functions for Hamiltonian wave equations, ensuring energy conservation through projection operators and a second-order average vector field scheme. The second method details a meshless Galerkin technique for dissipative PDEs on surfaces, which upholds energy dissipation inherently. Both methods are supported by rigorous error and convergence analyses, and their effectiveness is demonstrated with numerical experiments, confirming their theoretical properties.

ABSTRACT

The classical, theory-driven approach to describe the deformation of a material body relies on the formulation of constitutive equations relating strains and stresses. A drawback of this approach are the efforts typically required to develop appropriate functional relations and identify material parameters .

These efforts are not required in data-driven approaches to constitutive modeling. To combine the advantages and overcome the disadvantages of both theory- and data-driven constitutive modeling, we have developed the novel concept of Constitutive Artificial Neural Networks (CANNs). This machine learning approach to data-driven constitutive modeling does not require any major a priori assumptions about the constitutive law but yet incorporates substantial theoretical knowledge about continuum mechanics and constitutive theory. This way, CANNs are able to learn the constitutive law of a material from relatively small amounts of stress-strain data. Moreover, our results suggest that CANNs can robustly discover various flavors of material models from data and by design have clear physical interpretation. These abilities will be illustrated using various data collected from arterial and brain tissue.

TOPOLOGY OPTIMIZATION APPLIED TO PROBLEMS WITH LOCAL FATIGUE CONSTRAINTS BASED ON AUGMENTED LAGRANGIAN METHOD

Carlos Eduardo Lino[*1], Emilio Carlos Nelli Silva*[1] *and André Luis Ferreira da Silva*[1]

[1]*University of São Paulo*

ABSTRACT

Authors:Carlos Eduardo Lino, André Luis Ferreira da Silva, Emilio Carlos Nelli Silva

Fatigue is the most usual failure mode of any mechanical structure subject to loading. There are several methods to predict the structure life, and different approaches can be applied to extend this life. From the point of view of materials engineering, new materials can be proposed to deal with this issue. However, developing and producing these materials can be expensive. A different approach consists of optimizing the design using some optimization algorithm, determining the optimized material distribution that ensures a higher fatigue life. This work proposes to use topology optimization to design structures subjected to permanent loads to increase the component life. The objective is to minimize the volume, considering fatigue constraints. The works in the literature deal with fatigue constraints using aggregate methods, which are common in problems considering stress constraints. Our proposed approach uses a norm of the stress field to represent the stress constraint. However, stress and fatigue are local phenomena. Thus, in this work, the Augmented Lagrangian method is used to deal with the large number of constraints in the problem. This approach, previously used in stress-constraints problems, makes treating fatigue as a local phenomenon. The Modified Goodman method is used to measure local fatigue. This method considers a sensitivity factor that accurately estimates fatigue life. Numerical examples show the efficiency of the proposed method.

RESIDUAL STRESSES COMPUTATION AND OPTIMIZATION FOR DIRECTED ENERGY DEPOSITION PROCESSES

Usman Tariq[1], Sung-Heng Wu[1], Ranjit Joy[1] and Frank Liou[*1]*

[1]Missouri University of Science and Technology

ABSTRACT

The adoption of metal additive manufacturing by various industries is being hindered by the presence of residual stresses and distortion in the deposited parts. One of the important challenges that hinder the adoption of metal AM parts is the formation of residual stresses. Layer-by-layer deposition during metal AM causes cyclical heating and cooling of the metal deposit, resulting in the formation of residual stresses [1]. The presence of residual stresses is often undesirable as it could lead to delamination and cracking of deposited parts. Parameter optimization is predominantly used for residual stress mitigation. Finite Element Analysis (FEA) is a valuable tool for predicting residual stresses, but it requires substantial computational power. Direct energy deposition (DED) is a promising additive manufacturing technique that enables the fabrication of complex structures with excellent mechanical properties. This study aims to reduce computational time by incorporating a thermo-mechanical model specifically designed for the DED processes. This model predicts the thermal history and subsequent residual stresses in the deposited material. Various FEA methods are examined to provide a comparative analysis of computational cost and numerical accuracy. These findings contribute towards the realization of a faster modeling approach, where the incorporation of efficient and accurate FEA models can optimize part quality and strength while reducing computational time.

ELASTIC-PLASTIC SEMI-ANALYTICAL METHOD AND OPTIMIZATION FOR CURVED SCARF BONDING REPAIRS OF COMPOSITE STRUCTURES

Bin Liu[1] and Yancheng Liu*[1]

[1]*Northwestern Polytechnical University*

ABSTRACT

For the semi-analytical method, Hart-Smith[1] first derived a two-dimensional analysis model for scarf repaired and step repaired isotropic materials. Basing on this method, Harman and Wang[2] introduced average reduction method of composite section elastic modulus, and derived a method for calculating stress distribution of two-dimensional scarf repaired composites. Additionally, they proposed an optimization method to minimize the peak shear stress of adhesive layer by optimizing the bonding angle distribution controlled by first order equation. To restore the stress concentration caused by the change of angles of fiber orientation accurately, Liu[3] improved the method with stiffness-distribution principle and provided a modified analytical method(MAM), which has achieved a more precise and believable result in calculating stress distribution on flat adhesive surfaces. MAM and the application of stiffness-distribution principle has been proven concise effective by Yan[4] with experiments.

In this paper, a semi-analytical stress distribution calculating method that is applicable to arbitrary shape surfaces of scarf repaired composites are proposed. To take not only the cohesive failure caused by shear stress, but also the yield of adhesive under consideration, the adhesive is regarded as an elastic-plastic material. Furthermore, an optimization algorithm basing on this method which could significantly improve the carrying capability of scarf repaired composite laminates is developed. Several examples have revealed high universality and accuracy of this method, and the optimization algorithm developed from which has achieved an excellent effect on reducing peak shear stress. Although it would be difficult to manufacture the optimized surface, this paper still provides a simple but efficient way to evaluate designs of scarf repair and reliable schemes for advancing carrying capacity of scarf repaired composites.

A HIERARCHICAL QUADRATURE ELEMENT METHOD FOR FRACTURE PARAMETERS CALCULATION AND CRACK PROPAGATION SIMULATION

Bo Liu[*1], Pai Xu[1], Siqi Jia[1] and Wei Xiang[2]*

[1]*The Solid Mechanics Research Center, Beihang University*
[2]*Southwest Jiaotong University*

ABSTRACT

This paper presents a hierarchical quadrature element method (HQEM) with p-convergence for the calculation of fracture mechanical parameters and the simulation of crack propagation with very coarse meshes and high accuracy and efficiency. The stress intensity factor (SIF), strain energy release rate (SERR), J-integral and weight function are computed using minimum mesh refinement and high accuracy. The SERR is directly computed though virtual crack closure method (VCCM) with high accuracy. Although extrapolation is needed in computing SIF and J-integral, they can also be automatically obtained by choosing a certain local mesh size. The computed fracture mechanical parameters are then used to simulate crack propagation using minimum number of elements. The number of elements is significantly reduced through interpolating the crack trajectory as a single curve and modelling the opened crack as two elements only. Thus, the number of elements is unchanged in the whole simulation process, which greatly improves the computational efficiency. The feasibility of applying the HQEM to fracture mechanical parameters computation and crack propagation simulation is demonstrated through several benchmark examples of mode I and mode II fractures (or mixed mode) with homogeneous materials as well as bimaterials. Numerical comparisons with available results in literatures validated the high accuracy and efficiency of the HQEM, which indicates it has promising potential for complex large-scale fracture problems.

SIGNED DISTANCE FIELD ENHANCED VIRTUAL ELEMENT METHOD FOR LARGE DEFORMATION FRICTIONAL CONTACTS IN FLEXIBLE MULTI-BODY SYSTEMS

Chuanqi Liu[*1]

[1]*Chinese Academy of Sciences*

ABSTRACT

We propose the signed distance field virtual element method (SDF-VEM), which is a virtual element method variant able to model large deformation frictional contact problems in flexible multi-body systems with signed distance field assisted as a geometrical tool. Leveraging the geometrical versatility inherent in the virtual element method, we could represent each flexible body with either a single-element or a multi-element polygonal mesh of arbitrary shape. This enables node-to-node contact enforcement through adaptive mesh insertion and adjustment. Addressing the complexity of contact detection scenarios in multi-body models, arising from the irregular shapes and numerous bodies involved, we introduce an SDF-assisted unified and automatic contact detection framework. Numerical examples in 2D, including Hertzian contact, spur gears engagements, and granular particles contacts, demonstrate the accuracy and effectiveness of our method.

GRADIENT-ENHANCED MODELING OF PORO-VISCO-HYPERELASTICITY-INDUCED TIME-DEPENDENT FRACTURE OF BLOOD CLOTS

Dongxu Liu[*1], Nhung Nguyen[1] and Luka Pocivavsek[1]*

[1]*University of Chicago*

ABSTRACT

A blood clot is a natural soft tissue composed of fibrin networks, red blood cells, and platelets. It contributes to hemostasis when it forms on wounded blood vessel walls, while intravascular clots can cause pathological thrombosis. Due to complex physiological loading, their fracture resistance is crucial for physiological hemostasis and pathological thrombosis. However, the mechanism of blood clot fracture is still not well understood. Quantifying blood clots' deformation and fracture is essential for diagnosing and treating bleeding disorders and thrombotic diseases. This work aims to formulate a thermodynamically consistent, multi-physics theoretical framework for describing blood clots' time-dependent deformation and fracture. This theory concurrently incorporates fluid transport through porous fibrin networks, non-linear visco-hyperelastic deformation of the solid skeleton, solid/fluid interactions, mechanical degradation of tissues, gradient enhancement of energy, and protein unfolding of fibrin molecules. The constitutive relations of tissue constituents and the governing equation of fluid transport are derived within the framework of porous media theory by extending non-linear continuum thermodynamics at large strains. A physics-based, compressible network model is developed to describe the mechanical response of the fibrin network of blood clots. The kinetic equations of the internal variables, introduced for describing the non-linear viscoelastic deformation, non-local damage driving force, and protein unfolding, are formulated according to the thermodynamics principles by incorporating a non-equilibrium energy of fibrin networks, a gradient-enhanced energy, and a stretch-induced internal energy of fibrin molecules, respectively, into the total free energy density function. An energy-based damage model is developed to predict the damage and fracture of blood clots. The proposed model is implemented into finite element code by writing subroutines and is experimentally validated using single-edge cracked clot specimens with different constituents. Computational results show that this model can accurately capture the experimentally measured deformation and fracture. The fracture of blood clots subjected to multiple loading conditions is simulated, and the results demonstrate that the deformation and fracture are sensitive to loading rate. The tissue subject to a higher loading rate is stiffer. The damage at the crack tip initiates earlier and propagates faster when the loading time approaches the characteristic time of intrinsic viscoelastic. The fluid transport influences the fracture by tissue swelling. The mechanisms of blood clots fracture are analyzed systematically. The results hypothesize the importance of fibrin network viscoelasticity and fluid transport in the stability of blood clots.

CORRELATION-BASED LIKELIHOOD-FREE CALIBRATION FOR REALISTIC INVERSION OF MODEL UNCERTAINTY PARAMETERS

Shaojun Feng[1], Hao Liu[1] and Peng Hao[1]*

[1]Dalian University of Technology

ABSTRACT

The Computational model is widely used to represent physical process property, but the prevalence of uncertainty leads to a failure to match the two. Calibration is often used to tune unknown calibration parameters of a computational model. However, model discrepancy can exist even if all calibration parameters are known. One of the main challenges in model calibration is the difficulty in distinguishing between the effects of calibration parameters versus model discrepancy. Thus, the paper illustrates in detail the reason for the identifiability problem of existing methods, and based on this, we propose a new concept that the computational model and the real physical process should be “the most similar” rather than “the closest”. Further, we propose the correlation-based likelihood-free calibration, which avoids the difficulty of solving the maximum likelihood function while obtaining the most realistic calibration parameters. By comparing all the basic function cases and one common engineering case with the existing methods, the results show that our proposed method can obtain a realistic inversion of the model parameters, and the consistency of the parameters will also significantly improve the prediction accuracy of the model.

A NOVEL DUCTILE FRACTURE PREDICTION OF ADDITIVE MANUFACTURED TI6AL4V ALLOY

Hui Liu[*1], Xuan Yang[1], Biao Li[1] and Yazhi Li[1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

Selective Laser Melting (SLM) is one of the revolutionary additive manufacturing (AM) technologies to produce metallic mechanical parts. To thoroughly understand the damage and fracture behavior of SLM-fabricated Ti6Al4V alloy under complex stress states, the article conducted experimental and simulation studies on various types of Ti6Al4V alloy specimens. By incorporating a novel stress state function into an enhanced GTN (Gurson-Tvergaard-Needleman) model, the study successfully predicted the ductile fracture behavior of the Ti6Al4V alloy.

(1) A number of tensile, compressive and torsional experiments covering various stress states were conducted with different types of the specimens, the study has clearly identified the failure modes under different stress states.

(2) A modified GTN model developed by the Authors' team was adopted in the ductile fracture analysis of SLM-fabricated Ti6Al4V alloy. The introduction of a shear damage variable and a stress state-dependent function extends the application of GTN model to a broader range of stress states.

(3) A parameter calibration strategy of the dual damage variable GTN model was proposed, based on the finite element inverse analysis and referring to a group of experimental results. These parameters encompass quenching parameters and damage parameters, with the latter consisting of 6 parameters related to void volume fraction, 4 parameters related to shear damage, as well as 1 parameter within the stress state function. The applicability of the parameters was well validated via the simulation of another group of experiments.

(4) The morphologies of the fracture surfaces were successfully predicted by using the developed damage constitutive model, and the results demonstrated that the deformation, strength and fracture modes of SLM-fabricated Ti6Al4V alloy can be well described by the developed dual damage variable GTN model. Both damage variables contribute to the different failure mechanisms. The variable of void fraction controls fibrous zone failure based on the void growth mechanism, and the shear damage variable facilitates shear fracture based on the void shear mechanism.

INCREASED POWER OF HEMODYNAMIC LOW-FREQUENCY OSCILLATIONS CAN IMPROVE CEREBRAL OXYGENATION

Shilin Yang[1], Pandeng Zhang[1], Zhixian Zhang[1], Xinyu Chen[2], Xia Long[2], Yanxia Zhou[2] and Jia Liu[1]*

[1]Shenzhen Institute of Advanced Technology, Chinese Academy of Sciences
[2]Shenzhen Second People's Hospital

ABSTRACT

Cerebral hemorrhage or ischemia can significantly increase the low-frequency oscillations of blood pressure and cerebral blood flow. Recent studies have shown that such low-frequency oscillations can improve the brain's oxygenation even in the context of reduced cerebral blood flow, which necessitates further investigation. However, this type of study requires special devices, and although previous results have suggested an increase in cerebral oxygenation associated with low-frequency oscillations, it is still unclear whether this increased oxygenation requires a certain power of low-frequency oscillations. We therefore designed and carried out this study.

We recruited 11 healthy subjects aged 18-30 years old, and the experiment was carried out at the Second People's Hospital of Shenzhen. Using the routine clinical syncope test procedure, each participant completed four consecutive stages of the test on a tilt table for syncope testing, including: 10 minutes of supine rest, then the tilt table was raised to a 70-degree angle from the ground within 6 seconds, maintained for 20 minutes, followed by oral administration of 0.25 mg of nitroglycerin, continuing for another 20 minutes, and finally returning to the initial supine position. During the test, we continuously collected blood pressure, bilateral middle cerebral artery blood flow velocity using transcranial Doppler, and near-infrared cerebral blood oxygen signals. Subsequently, we analyzed changes in the power of low-frequency oscillations using power spectral analysis of continuous blood pressure and cerebral blood flow velocity, and calculated changes in the cerebral oxygenation index based on the cerebral oxygen signal.

Our study found that the participants' cerebral blood flow velocity gradually decreased from supine (62.74±1.11 cm/s) to upright (55.65±1.83 cm/s, $P<0.05$) position, and then further after nitroglycerin administration (upright: 55.65±1.83 cm/s vs drug: 43.46±3.93 cm/s, $P<0.05$). At the same time, the power of hemodynamic low-frequency oscillations at approximately 0.1 Hz frequency progressively increased (supine: 45.37±31.38 (cm/s)2Hz-1 vs upright: 133.33±55.71 (cm/s)2Hz-1, $P<0.05$; upright: 133.33±55.71 (cm/s)2Hz-1 vs drug: 243.19±98.82 (cm/s)2Hz-1, $P<0.05$). Interestingly, although the change in cerebral oxygenation index during the upright phase was consistent with the trend of decreasing cerebral blood flow, the cerebral oxygenation index significantly increased when low-frequency oscillations were further enhanced after taking nitroglycerin (upright: 0.0101±0.0008 μM vs drug: 0.0128±0.0008 μM, $P<0.05$).

Therefore, our study suggests that the routine clinical syncope test can effectively induce hemodynamic low-frequency oscillations. We observed for the first time that the increase in cerebral oxygenation index is related to the power of low-frequency oscillations.

ENHANCING PREDICTIVE MODELING IN REACTOR BUILDING DOSE DISTRIBUTION: A NEURAL NETWORK-AIDED APPROACH

Jihong Liu[1], Koji Koyamada[1], Hiroaki Natsukawa[1] and Shuhei Kamioka[1]*

[1]*Osaka Seikei University*

ABSTRACT

Theoretical predictions of dose distribution inside a reactor building using Boltzmann transport equation present a computational challenge due to its substantial resource requirements [1]. To address this issue, we simplify the approach to a diffusion equation in situations where the mean free path of neutrons is relatively short, assuming random scattering [2]. This simplification enhances the manageability of calculations, particularly in scenarios where the scale of computational demands makes Boltzmann equation impractical.

This study involved altering the building shape and radiation source to calculate the Boltzmann transport equation. This methodology enables us to consider various scenarios and conditions influencing neutron transport within the reactor building. The obtained results were then used to derive the diffusion equation through a neural network based on physical information [3]. The incorporation of a neural network introduces computational efficiency and adaptability, thereby improving the practicality of the diffusion equation approach.

The distribution of derivation errors within the building space was visualized, aiding in comprehending the model's accuracy. This visualization highlights areas where the derived diffusion equation may deviate from the more computationally intensive Boltzmann transport equation. The identified regions where the diffusion equation approximation is effective offer valuable insights for practical applications, guiding users on when and where this simplified approach can yield accurate results.

A CONTINUUM AND COMPUTATIONAL FRAMEWORK FOR NONLINEAR VISCOELASTICITY: BEYOND THE HOLZAPFEL-SIMO APPROACH

Ju Liu[1], Jiashen Guan[1], Chongran Zhao[1] and Jiawei Luo[1]*

[1]*Southern University of Science and Technology*

ABSTRACT

Viscoelasticity is a ubiquitous mechanical property in soft matter. The constitutive and computational modeling of nonlinear viscoelasticity is particularly relevant to the understanding and prediction of the performance of various engineering and biomedical materials. There are several desirable features in the design of a model: the soundness in its theoretical root; the potential in accounting for additional materials features (e.g., anisotropy, damage, etc.); the capability to faithfully represent material behavior using as less parameters as possible; the convenience of finite element implementation.

The Holzapfel-Simo model [1] has gained popularity over the past several decades, mainly because it is amenable to finite element implementation and convenient in accounting for material anisotropy. The lack of a thermodynamic foundation has been viewed as a major drawback of this model. In our recent work, we constructed a complete thermomechanical theory for this model and thereby addressed previous concerns [2]. In particular, the study elucidates the origin of the evolution equations of the non-equilibrium stress. It also emphasizes the importance of satisfying the relaxation property for the free energy in the equilibrium limit.

Interestingly, our analysis also reveals that the Holzapfel-Simo model can be regarded as a theory built based on the Green-Naghdi kinematic assumption and the St. Venant-Kirchhoff model for the non-equilibrium elastic behavior. Based on this observation, we extend the Holzapfel-Simo model by incorporating nonlinear effects. A two-parameter strain measure family, which incorporates the well-known Seth-Hill strain family, is introduced. The Green-Naghdi kinematic assumption allows a convenient modular modeling strategy for the inelastic effects using the generalized nonlinear strain measures.

A suite of combined numerical methods is proposed for the computational modeling of the viscoelasticity model. In particular, a smooth generalization of the Taylor-Hood element based on Non-Uniform Rational B-Splines serves as the element technology and is used within a generalized Herrmann mixed variational formulation. A class of strain-drive constitutive integration schemes is discussed, which allows the energy-consistent integration of the overall system. Analysis results and numerical examples will be provided to justify the effectiveness of the proposed methodology.

RELIABILITY DESIGN OF MONOPILE FOUNDATIONS IN SPATIALLY VARIABLE SOIL CONSIDERING RANDOM LOADS

Jun Liu[1], Xinshuai Guo[1] and Ping Yi[1]*

[1]*Dalian University of Technology*

ABSTRACT

Due to the spatial variability of soil properties and the uncertainty of marine environmental loads caused by wind, waves and currents, it is indispensable to perform reliability-based design of monopiles that are extensively utilized in the offshore wind industry. In this study, the random individual capacities and probabilistic VHM failure envelopes of monopiles in spatially variable undrained soil are first obtained using the random finite element method combined with Kriging meta-modelling technique and Monte Carlo simulation. Then, the relationship between the appropriate design (characteristic) quantile of soil shear strength and normalized scale of fluctuation and coefficient of variation of soil strength is investigated when considering the spatial variability of soil as well as the uncertainty of loads. Finally, a design framework of monopiles using appropriate design quantile of soil strength is proposed and verified via an example. The results show that the designed monopile can not only meet the two reliability design requirements set in DNV (2013), but also significantly save costs. The study could be helpful to the design of monopile foundations in practical engineering.

MATHEMATICAL MODELING AND NUMERICAL SIMULATION OF MECHANICAL-THERMAL-CHEMICAL MULTI-FIELD PROCESS

Ke Liu[1], Yazhi Li[1] and Biao Li[1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

Solid materials are subjected to the interactions of multiple physical and chemical fields when they serve in extreme environments. Their response, such as deformation, mass transfer, heat transfer, and chemical reactions, is intimately related to the failure of structures. Multi-field coupling problems implicate interactions among different physical and chemical fields. Considering the multi-field coupling problem which were affected by the force, heat and chemistry, involves complex dynamic process of multi-component substance in an open system, this work chosen a macroscopically homogeneous body composed of a chemically active medium as the research object. And the force balance, mass balance, and internal energy balance equations were provided based on the fundamental laws of thermodynamics. A fully coupled constitutive model that combines mechanical, thermal, diffusion, and chemical reaction effects was then developed to describe the intricate interplay between these effects. The inertial effects of force, entropy and chemical potential were introduced into a macroscopic uniform body by considering the propagations of elastic waves, temperature waves and diffusion waves. Considering the various influential mechanisms, the contributions of mass diffusion and chemical reaction were separated. The evolution equations of heat conduction, diffusion, and chemical reaction were constructed according to the energy dissipation inequality. This coupling model can effectively describe the transient evolution and quasi-static response of multi-field coupled system. Furthermore, the weak form of governing equations were derived by applying the chemical Gibbs function variational principle, which is based on the universal variational principle of thermodynamics. In particular, the model has the ability in predicting the concentration and entropy jump conditions on the moving interface.
In order to verify the proposed model, the oxidation process of silicon nitride was numerically calculated, and the evolutions of oxide thickness and stress were presented. The results agree with the reference results, indicating that the mechanical-thermal-chemical multi-field coupled model is able to reflect the evolution laws of the stress field, concentration field, temperature field and displacement field of silicon nitride under the coupling effect of multi-physical fields.

A NOVEL GPU IMPLEMENTATION OF NONLINEAR EXPLICIT DYNAMIC ANALYSIS FOR COMPLEX CIVIL STRUCTURES

Lanqi Liu[*1], Pu Chen[1], Xianlei Wang[2] and Zhongliang Su[2]*

[1]*Peking University*
[2]*YJK Building Software*

ABSTRACT

The explicit integration method is recognized as the main approach for solving nonlinear transient dynamic responses involving material failure and large deformation. Since computation of the explicit integration is intrinsically decoupled, an efficient implement should consider parallel acceleration, especially GPU acceleration. However, there are still some challenges using GPU as the accelerators when large structures contain multiple element types or complex material constitutive models. To this end, this work presents a novel GPU acceleration strategy for explicit integration method for complex structures.

A basic parallelized computational framework is established using the Compute Unified Device Architecture (CUDA). All stages of the explicit dynamic analysis are ported to GPU, including calculating element strains, stresses and internal forces, assembling the nodal effective force and solving the kinetic equations for nodes at every time step. CPU is responsible for data output. Data transfer between the CPU and GPU is necessary only at the output time step. A concurrent execution strategy is designed to solve problems with non-uniformity of element and material types. The FE model is decomposed into a few domains depending on element or material types as well available memory. The aforementioned parallel computing processes for each domain are performed concurrently on GPU. Once the computation of nodal effective forces at each time step of all domains finishes, data communication between different domains is achieved using MPI. Different data for computation mainly reside in global memory, which is the largest memory available on GPU. These data have to be organized in optimal layouts to allow the coalesced memory access. In our data structure, data for elements and nodes are organized in structure-of-arrays. Element matrices with identified size and sparsity in one domain are rearranged as a collection of arrays with each array corresponding to the values at the same matrix position. Additionally, loop unrolling strategy are employed to reduce instruction latency on GPU. Data in one domain are divided into sets with each set of the same size as the thread block. A block with n threads treats p data sets with n entries, each thread handles entries in the same position in p data sets within one execute iteration.
Performance tests from engineering designs show that a speedup of more than 40 is achieved compared to the CPU serial code computing by commercial YJK building software with validated accuracy of the results.

MICROSTRUCTURAL CONTROL AND DEFECT ANALYSIS FOR FLOW-MEDIATED CRYSTALLIZATION USING PHYSICS-INFORMED DEEP LEARNING

Larry Willis[1], Rekha Rao[2] and Leo Liu[*1]*

[1]FAMU-FSU College of Engineering
[2]Sandia National Laboratories

ABSTRACT

Crystallization, more generally, liquid-solid phase transitions, is a ubiquitous process of significance for industries ranging from manufacturing to pharmaceuticals. Defect analysis and quality control of crystal microstructure are most important in those processes. To that end, reliable and efficient techniques that can give insight into controlling parameters for achieving desired crystal microstructures are critical. Recently, physics-informed neural networks (PINNs) have shifted the paradigm for scientific computing as a data-efficient computational tool for solving scientific inverse problems.

Based on a novel phase field crystal (PFC) formalism, we will discuss how we construct PINNs to identify key parameters controlling crystallization for systems such as CsPbI_3 perovskites. We will also demonstrate the validation and capability of the inverse problem solver for identifying crystal-level controlling strategies for defect mitigation based on first-principle synthetic data and real experimental data.

DEVELOPMENT AND EVALUATION OF MG-CA DEEP LEARNING INTERATOMIC POTENTIALS WITH AID OF AB-INITIO CALCULATIONS

Lijun Liu[1] and Yoji Shibutani*[1]

[1]*Osaka University*

ABSTRACT

Key Words: Interatomic Potential, Mg-Ca alloys, First-principles calculations, Molecular dynamics, Deep learning.

Ab initio molecular dynamics (AIMD) has become a significant tool for microscopic understanding of a wide range of problems. However, the spatial and temporal scales that AIMD can access are limited. Most AIMD calculations can only handle systems containing hundreds of atoms on picosecond timescales. On the other hand, conventional molecular dynamics (MD) can be computed efficiently, but its accuracy is limited to empirically determined atomic interaction potentials.

Nanocrystalline structures of metals, which are real-world applications, are composed of tens to hundreds of millions of atoms, which is far beyond the capabilities of ab-initio calculations. However, the main problem with empirical potentials is the need for more accuracy for structures with defects, such as point defects, dislocations, nanoclusters, etc. Therefore, the development of interatomic potentials with high accuracy is crucial.

Recently, some experimental [1] and molecular dynamic results [2] have reported that the ductility of Mg alloys is improved by the solid solution of Ca. In the design of high-performance Mg-Ca alloys, besides the solid solution effect of Ca atoms, the interactions of dislocations, twins, and grain boundaries with microstructures such as Ca solid solution clusters and precipitates are also essential factors to be considered [3]. Most developed Mg-Ca potentials can reproduce some basic properties under an equilibrium state. However, these potentials are not able to give accurate predictions when the state is unstable or defects are included. The present study used datasets from ab-initio calculations to develop Mg-Ca interatomic potentials by deep learning. Our developed Mg-Ca deep potentials can accurately predict not only basic physical, mechanical, and thermal properties but also phase transition under high temperatures and pressures, which is not able to be done by empirical potential.

CREEP LIFE PREDICTION OF COATED TURBINE BLADES CONSIDERING THE INFLUENCE OF FILM COOLING HOLE BLOCKAGE

Linchuan Liu[1], Chaoji Wang[2], Shengwei Pan[2] and Xueling Fan[1]*

[1]*Xi'an Jiaotong University*
[2]*AECC Guiyang Engine Design Research Institute*

ABSTRACT

Blockage of film cooling holes significantly impacts the operational life of coated turbine blades in harsh environments. Understanding the thermo-mechanical behavior of blades under actual film cooling hole blockage conditions is crucial for predicting failure and enhancing reliability. In this study, firstly, blockage morphologies and ratios of all film cooling holes on a full-scale turbine blade were statistically analyzed, leading to the development of a blade model incorporating blockage characteristics. Subsequently, the thermo-mechanical loads of cross-scale membrane-based structures on blades were explored using the shell conduction model and the Chaboche constitutive model. Finally, the Larson-Miller Parameter (LMP) method was adopted as the creep life evaluation criteria, considering both blocked and unblocked scenarios. The results revealed that the blockage degree of film cooling holes was lowest near the leading edge of the blade and gradually increased towards the trailing edge. Additionally, the highest temperature on the blade was located near the blade tip, with the most dangerous zone situated at the root position on the pressure surface. Blockage reduced the surface cooling efficiency and diminished the creep life, increasing the risk of blade failure. In this paper, a calculation method of cross-scale structural life model is proposed to reveal the effect of hole blockage on the creep life of turbine blades, providing valuable insights for durability assessment of coated high-temperature components.

AN EXPLORATION FOR VISCOELASTIC AND DYNAMIC PROPERTY OF 2D CELLULAR MATERIALS

Li-Wei Liu[1] and Zhen-En Jian*[1]

[1]*National Taiwan University*

ABSTRACT

Cellular materials, mimicking natural architectures inside the wood and honeybee’s honeycomb, exhibit a unique combination of high stiffness and low weight. Bridging the gap in prior research on the rate-dependent and the dynamical performance of 2D cellular materials, this study proposes models and explores the viscoelastic behavior and wave propagation of 2D cellular materials. For the viscoelastic property of the material, our study finds that an increase in energy dissipation with rising relative density under strain control but a decrease under stress input. On the other hand, when the angle of cell wall increases, the strong axis of energy dissipation shifts under strain-controlled conditions. Furthermore, the anisotropic feature of energy absorption for auxetic cellular materials is observed. These results highlight the significant effects of microstructure on the viscoelastic performance of 2D cellular materials. In addition, the exploration of dynamical property of the material reveals a remarkable increase in effective Young's modulus and a significant increase in effective natural frequency when the width of cell wall approaches the characteristic material length. This enhancement is pronounced and points out the critical role of size effect in predicting dynamic responses. Moreover, our study indicates that the existence of band gaps in plane wave propagation within 2D cellular materials signifies its inherent ability to suppress energy at specific frequencies. In essence, our exploration offers insights into the intricate relationship between viscoelasticity and dynamic performance in cellular materials, emphasizing the significant influence of microstructure and size effect.

DIGITAL DESIGN OF GRINDING WHEEL FRAME OF GRINDING MACHINE

Mingshuo Liu[*1] and Dongyan Shi*[1]

[1]*Harbin Engineering University*

ABSTRACT

This research paper explores the grinding wheel holder and feed mechanism to automate the grinding wheel holder. The specific objectives of this research are: (1) Through the determination of the overall programme of the grinding wheel holder of the grinding machine, the disadvantage of low processing efficiency of the ordinary grinding machine is overcome. Through the calculation and verification of the structure, including the lifting beam, serving grinding wheel spindle of the grinder, etc., the design and strength of the parts are verified to be safe and reliable through calculation and verification, and meet the design requirements. Completed the design and selection of the parts, thus improving the machining efficiency and quality of the workpiece. The grinding wheel holder structure is designed to improve the grinding efficiency of the grinding wheel, so that the grinding wheel can work smoothly in the grinder. This structural design extends the service life of the grinder and reduces costs. (2) Finite element analysis and simulation of the parts were carried out to make the structural design of the grinding wheel holder more reasonable, and to improve the reasonableness of the material and structure selection of the grinding wheel holder.

ASYMPTOTIC HOMOGENIZATION FRAMEWORK FOR PHASE FIELD FRACTURE OF HETEROGENEOUS MATERIALS AND APPLICATION TO TOUGHENING

Sen Liu[*1] and Yongxing Shen*[1]

[1]*University of Michigan, Shanghai Jiao Tong University*

ABSTRACT

We propose an asymptotic homogenization framework to account for the fracture of heterogeneous materials. This framework upscales the phase field model for microscale fracture and outputs anisotropic effective properties such as the degraded elasticity tensor and the fracture toughness. Furthermore, it quantitatively accounts for the toughening effect in a succinct way. More specifically, when the critical energy release rate of a heterogeneous material is uniform, the framework reveals that toughening is essentially determined by the disparity of the toughnesses, the energy absorbed by the material before cracking.

AN INTERFACE-ENRICHED TOPOLOGY OPTIMIZATION FOR MITIGATING THE EFFECT OF SURFACE FLAWS IN 3-D BRITTLE SOLIDS

Shangru Liu[*1] and Alejandro M. Aragón*[1]

[1]*Delft University of Technology*

ABSTRACT

We propose a fracture-based topology optimization procedure for tailoring the fracture resistance of 3-D brittle solids. Developing on our previous work [1], topology is described by means of a level set function that is parameterized by radial basis functions, and the structural response is computed via the Interface-enriched Generalized Finite Element Method (IGFEM). Semi-circular cracks are assumed to nucleate at the location of enriched nodes that are crated throughout solid boundaries. Energy release rates (ERRs) for all cracks are evaluated by means of topological derivatives, for which we only require the stress field of a single finite element analysis of the uncracked geometry. To that end, an accurate nodal stress field is obtained by means of a non-local stress improvement procedure. The objective function of the topology optimization aggregates all ERRs using the P-mean function. Two schemes are proposed in relation to the direction of cracks: We first fix the crack opening direction to be parallel to either the xz or yz planes. We then relax this restriction and assume the crack opening direction to be perpendicular to the direction of the first principal stress. 3-D numerical examples, including the commonly studied L-bracket benchmark problem, showcase the capability of the procedure.

TOPOLOGY OPTIMIZATION OF VIBRATING STRUCTURES AND PHONONIC CRYSTALS WITH PRESCRIBED FREQUENCY BANDS

Qiangbo Wu[1], Quhao Li[2] and Shutian Liu[*1]*

[1]Dalian Univerisity of Technology
[2]Shandong University

ABSTRACT

Vibration brings lots of harmful effects for engineering structures in aerospace, high-speed train, and high precision machine, et. al. Thus, how to reduce structural vibration has been a hot topic in engineering and academics. For lots of engineering structures, such as machine tools, vibration isolators, et al., they usually work in some frequency bands[1,2]. When the working or external excitation frequency is equal to or close to the natural frequency of a structure, the resonance phenomenon will happen. Therefore, by reasonably designing the structures and adjusting the natural frequencies to keep away from the common manufacturing or working frequency bands can effectively mitigate the vibration level. In this study, a new continuous and differentiable mathematical formulation of the frequency band constraint[3] based on the modified Heaviside function is proposed to achieve the prescribed frequency bands of vibrating structures. Furthermore, compared to the vibration structural design, the difficulty of phononic crystals' prescribed frequency bands design lies in the correlation between stiffness matrix and wave vector, which is a typical multi-condition eigenvalue problem. Directly utilizing the frequency band constraints may lead to numerical convergence difficulties. Thus the ipsilateral frequency constraint based on a modified Heaviside function is further proposed. Since the developed functions are continuous and differentiable, the sensitivity of the constraint functions can be derived for using the gradient-based optimization solver. The proposed formulation can treat with multi-frequency band constraints and is easily integrated into a topology optimization model. Several numerical examples, including single- frequency band and double-frequency bands problems, are solved by the proposed method. The results validate the effectiveness of the developed method.

DEVELOPMENT AND ANALYSIS IN DATA-DRIVEN SYSTEM IDENTIFICATION METHODS WITH APPLICATIONS IN FLUID DYNAMICS

Xinyang Liu[*1]

[1]*University of Calgary*

ABSTRACT

This work will focus on the development and analysis of data-driven system identification methods and applications in fluid dynamics. The objective is aiming to uncover the underlying pattern of the flow based on model-order reduction methods, in addition to the insights of the flow mechanics. The nature of fluid is very intricate mainly because of being nonlinear, immense in spatial-temporal dimensions, sensitive to the boundary conditions and it's interfered by the noise of irrelevant behaviors during the data measurement. The reduced-order models achieve to identify and reconstruct the principal dynamics indicating the physics of the respective flow. In addition, they filter the noise to prevent from the over-fitting problem. The understanding of the nature of fluid dynamics bridges from the broad existence to the numerous applications in diverse fields, such as performance improvement and energy saving in manufacturing which is a priority area in Canada.

A VISCO-HYPERELASTIC CONSTITUTIVE MODEL OF HYDROGEL BY CONSIDERING CHAIN'S SLIP MECHANISM

Qingsheng Yang[1] and Xinyu Liu[1]*

[1]Beijing University of Technology

ABSTRACT

Polymer is a typical entropic elastic material, and its mechanical response is highly decided by the change of network's conformation. The micro conformation's changing introduces the macro mechanical behavior. For finite deformation, the conformation changes not instantaneously, which leads to visco-hyperelasticity on macro. This process is not only related to loading time but also a multiscale question. In general, the conformation changes in two fields: 1) the single chain's deformation; 2) the relative position's change between chains. To build the bridge from micro to macro, a new transition is put forward in this work. The one-dimensional chain is extended to a three-dimensional cylinder to consider the effect of slippage. Another two free degree is introduced to capture the spatial-temporal characteristic of chain's conformation. The microscopic behavior of chain is then discussed and related to macro behavior of material. The slippage of chain is considered as the main reason leading to the viscosity by this model. This work provides an explanation for the origin of the viscosity in hydrogel by the opinion of chain's motion and gives a new method to build visco-hyperelastic constitutive model.

OPTIMUM DESIGN METHOD FOR ARTIFICIAL EAR OSSICLES BASED ON A HIGH-PRECISION VIBRATION ANALYSIS MODEL

Yang Liu[1]*

[1]*Sojo University*

ABSTRACT

The conductive hearing loss occurs when the middle ear is damaged by various ear diseases, that results in hard sound conduction through the eardrum and three ossicles to the inner ear. The tympanoplasty operation is often carried out to reconstruct the damaged ossicular chain, and to improve the sound conduction efficiency. In the ossicular chain reconstruction, an artificial part called “columella” is produced and used instead of incus which is generally broken. In this operation, the sound conduction efficiency changes by the variations in the shape, material and mounting position of the columella. Currently, the operation is carried out based on the workmanship and experience of the surgeon. In our previous studies, dynamic characteristics of the middle ear in sound conduction have been investigated using three-dimensional finite element method. Based on the analysis results, we have proposed that the hearing restoration effect can be estimated by a comparison of the displacement of the steps footplate between a healthy model and an operation model. Then, designing a reasonable artificial auditory ossicle prior to the operation seems to become possible. However, most of these researches are confined to analytical research dealing with the effect of shapes or mounting positions of the columella, and the optimization based on numerical methods has not been studied.
In the present investigation, an intricate model for the analysis of middle ear vibrations with high precision was formulated, utilizing empirically obtained measurements. A finite element model was also established to simulate the operational dynamics of an impaired ossicular chain induced by chronic otitis media. Subsequently, topology optimization procedures were executed to systematically generate the most optimal configuration for the columella, a pivotal replacement component. The efficacy and soundness of the methodology advanced in this study were substantiated through rigorous verification processes. Notably, the topology optimization of the columella resulted in an augmented vertical displacement of the stapes baseplate, thereby exhibiting potential enhancements in auditory performance post-surgery.

GOAL-ORIENTED ADAPTIVE MULTILEVEL QUASI-MONTE CARLO FOR RANDOM ELLIPTIC PDES

Yang Liu[*1], Joakim Beck[1], Erik von Schwerin[1] and Raul Tempone[12]*

[1]*King Abdullah University of Science and Technology*
[2]*RWTH Aachen University*

ABSTRACT

We present our work titled "Goal-oriented adaptive multilevel quasi-Monte Carlo (MLQMC) for elliptic random PDEs," building upon [Beck, Joakim, et al., "Goal-oriented adaptive finite element multilevel Monte Carlo with convergence rates." Computer Methods in Applied Mechanics and Engineering (2022)] and other ongoing research. Our objective is to solve an elliptic partial differential equation (PDE) with lognormal random input data, when the PDE model faces geometry-induced singularity.

Earlier research [Moon, K-S., et al. "Convergence rates for an adaptive dual weighted residual finite element algorithm." BIT Numerical Mathematics 46.2 (2006)] established convergence rates for a goal-oriented adaptive algorithm. This algorithm utilized isoparametric d-linear quadrilateral finite element approximations and the dual weighted residual error representation in a deterministic context. Notably, this algorithm refines the mesh based on the error's impact on the Quantity of Interest (QoI).

Our current work seeks to merge MLMC/MLQMC with the adaptive finite element solver. Unlike traditional Multilevel Monte Carlo methods, where each sample is determined using a discretization-based numerical method (with resolution tied to the level), our adaptive MLMC (AMLMC) algorithm employs a series of tolerances as its levels. Specifically, for a particular realization of the input coefficient and a set accuracy level, the AMLMC formulates its approximate sample using the initial mesh from the sequence of deterministic, non-uniform meshes. These meshes are produced by the previously mentioned adaptive algorithm and meet the sample-dependent bias constraint. Additionally, the incorporation of QMC enhances the convergence rate.

These meshes are produced by the previously mentioned adaptive algorithm and meet the sample-dependent bias constraint. Additionally, the incorporation of QMC enhances the convergence rate.

A PHASE-FIELD APPROACH FOR THE NUCLEATION AND PROPAGATION OF DYNAMIC CRACKS

Yangyuanchen Liu[1], Oscar Lopez-Pamies[2] and John Dolbow[1]*

[1]*Duke University*
[2]*University of Illinois Urbana-Champaign*

ABSTRACT

Recently, Kumar et al. [1] proposed and revised a phase-field approach for the nucleation and propagation of fracture under arbitrary quasistatic loading conditions. The model accounts for an arbitrary material strength surface through an external driving force in the evolution equation for the phase-field. In this talk, we extend this model through the addition of inertial forces. The dynamic version of the model is then validated against a broad range of benchmark experiments for dynamic brittle fracture, including the experiments by Kalthoff and Winkler, the Brazilian fracture test, and a recent experiment investigating crack initiation, propagation and branching in soda-lime glass specimens [2]. Numerical simulations illustrate the proposed dynamic phase field model provides reasonable results compared to experimental observations and a cohesive phase field model by Geelen et al [3].

SOME ADVANCES ON THE FAST BEM FOR ACOUSTIC PROBLEMS

Yijun Liu[*1], Ruoyan Li[1], Zonglin Li[1] and Zhenyu Gao[1]*

[1]*Southern University of Science and Technology*

ABSTRACT

Some progresses on the boundary element method (BEM) for solving acoustic wave problems will be reported in this talk. For the frequency-domain acoustic wave problems, a new fast direct solver is proposed to improve the computational efficiencies in the solutions of the BEM equations. New enriched boundary elements based on the traditional constant elements and using plane wave expansions are also proposed to improve the representation of the variables on the boundary in the discretization of the boundary integral equations. For the 3-D time-domain acoustic wave problems, a new solution strategy based on the concept of a kernel-function library is developed in order to save the computer memory consumption in the solution of the time-domain BEM. Various examples using the above proposed new methods in the acoustic BEM are presented in this talk to show their accuracies and efficiencies in solving acoustic problems in both frequency and time domains.

NEURAL NETWORKS WITH LOCAL CONVERGING INPUTS (NNLCI) FOR SOLVING CONSERVATION LAWS AND MAXWELL'S EQUATIONS IN VARYING DOMAINS WITH GREATLY REDUCED COMPLEXITY AND TRAINING COSTS

Harris Cobb[1], Haoxiang Huang[1], Hwi Lee[1], Yingjie Liu[1] and Vigor Yang[1]*

[1]Georgia Institute of Technology

ABSTRACT

This talk is based on a series of joint works (arXiv:2109.09316 and 2204.10424). With Haoxiang Huang and Vigor Yang, we are able to predict discontinuities and smooth parts of solutions of the Euler equations in 1D and 2D by a neural network accurately. For example, in order to predict the solution of the 1D Euler equations at a space-time location, one can design the output of a neural network to be the solution value at the location. If one tries to design the input as the low-cost numerical solution patch in a local domain of dependence of the location (where the information comes from), can the neural network tell if the input is across a shock or in a smooth region ? The answer is no! Our approach uses two numerical solutions of a conservation law from a converging sequence, computed from low-cost numerical schemes, and in a local domain of dependence of a space-time location as the input for a neural network to predict its high-fidelity solution at the location. Despite smeared input solutions, the output provides sharp approximations to solutions containing shocks and contact discontinuities. The method reduces the complexity by several orders of magnitude compared to a fine grid numerical simulation, has much lower cost to train, and can be used naturally in varying computational domains through training and prediction because it's a local method. It can be applied to other differential equations, e.g., the Maxwell's equations for solving electromagnetic waves scattered around complicated PECs (Cobb, Lee and Liu, arXiv:2302.02860).

GENERATIVE MODEL TO PREDICT THE DEFORMATION FIELD OF CFRP LAMINATES WITH GEOMETRIC DEVIATIONS IN WING ASSEMBLY

Yuming Liu[*1], Yong Zhao[1], Qingyuan Lin[1], Wei Pan[1], Yu Ren[1] and Wencai Yu[1]*

[1]Shanghai Jiaotong University

ABSTRACT

Thin-walled structure of CFRP laminates is widely utilized in the assembly of aircraft wings. The deformation field generated during the assembly process can impact the assembly performance of the structure, thereby influencing the product quality and operational performance of the wings. The geometric deviations on the critical mating surfaces of the laminate are key factors influencing the deformation fields during the assembly process. Analyzing the mapping relationship between geometric deviations and assembly deformation field plays a crucial role for assessing the assembly results. The traditional analysis methods only consider the impact of simple directional deviations on assembly results and do not comprehensively account for the part geometric deviations. This paper proposes a deviation- deformation analysis framework for CFRP laminates in aircraft wing assembly. The framework introduces a multi-scale geometric deviations modelling method based on the statistical parameters for critical assembly features. Subsequently, it integrates heterogeneous data characterizing shape deviations by employing the encoders. Finite element analysis is then conducted to calculate the assembly deformation field considering the constitutive relationships and damage mechanisms. Taking the parameters representing the geometric deviations as input and deformation field as output, a conditional generative model is employed to learn the influence pattern of the geometric deviations on the deformation field. The framework establishes a prediction model from the deviation field to the deformation field and introduces specific accuracy metrics. Corresponding simulations and experiments demonstrate that the proposed method can predict assembly deformation field more efficiently than traditional numerical methods. It exhibits excellent performance on the accuracy metrics, enabling accurate and efficient field-to-field predictions. This method, by learning expert knowledge such as damage mechanisms and mechanical characteristics during the assembly process, constructs an end-to-end deformation prediction for the CFRP laminates. The predicted results can serve as a research framework for predicting other physical fields.

ANISOTROPIC TAILORED SPINODOID MECHANICAL METAMATERIALS: CONSTITUTIVE MODEL-GUIDED RAPID INVERSE DESIGN AND APPLICATION IN ARTIFICIAL BONE IMPLANTS

Zhanli Liu[*1], Ziming Yan[1] and Zhuo Zhuang[1]*

[1]*Tsinghua University*

ABSTRACT

Spinodoid mechanical metamaterials have garnered significant attention in designing lightweight, high-strength engineering structures and medical implants due to its tunable extreme anisotropic behavior. However, the lack of explicit relationship between complex topology and anisotropic mechanical properties severely restricts rapid inverse design and metal additive manufacturing for spinodoid materials with desired mechanical response. In this study, an integrated methodology leveraging constitutive model-guided rapid inverse design and additive manufacturing for spinodoid metamaterials is developed. First, the volume-fraction- and fabric-tensor-based orthotropic constitutive model for spinodoid materials is developed to describe how topological parameters determine effective mechanical properties. Guided by the parametric constitutive model, representative spinodoid structures are efficiently selected to characterize the mechanical property variation in the whole material space. Next, a deep learning-based model trained by 256 representative spinodoid samples is proposed to inversely design tailored spinodoid materials, which substantially reduces the training sample demand and promotes the pretraining efficiency of design model. Furthermore, by representing the complex 3D spinodoid structure as a two-dimensional topological parameter via dimension reduction method, the explicit structure-property relationship for arbitrary topological parameters is built and the target structure can be efficiently searched by a global optimization strategy. At last, the approach is successfully applied in metal additive manufacturing for tailored spinodoid materials with Ti6Al4V that matches the orthotropic mechanical properties of cancellous bones. The new approach paves an efficient way to build the property-structure-process relationship for precision-engineered spinodoid mechanical metamaterials with tailored mechanical performance in various applications.

STABILIZED UNFITTED FINITE ELEMENT METHOD FOR HYDRO-MECHANICAL COUPLING WITH WEAK DISCONTINUITY

Yimin Zhang[1], Yuxin Tong[1], Fanke Wu[1], Yongliang Wang[1] and Zhijun Liu[*1]*

[1]Lanzhou University

ABSTRACT

The traditional finite element method requires that the mesh must match with various discontinuous, which can significantly increase the difficulty of preprocessing for hydrodynamic coupling problems with complex boundaries and material interfaces. In such case, the finite element method using unfitted mesh is obviously more advantageous, however, this method also has certain problems, for example, irregular mesh cutting may lead to ill-conditioned coefficient matrix to appear, which in turn affects the accuracy and stability of the algorithm. The ghost penalty technique was proposed to overcome the ill-conditioning issue. Recently, an unfitted finite element was proposed for two-field poroelasticity problem, where stabilization terms based on the ghost penalty were developed. Material interfaces are even more difficult to deal with than the boundary as they require careful treatment of the weak discontinuity conditions as well as the mesh cutting stabilization. In this paper, we formulate an unfitted finite element for the poroelastic problem with both material interfaces and complex boundaries. A weak formulation based on the Nitsche's method was developed. Ghost penalty stabilization terms are designed for both sides of the elements intersected by the material interface. The performance of the proposed methodology is tested by several benchmark and practical hydraulic problems of complicated rock-soil mixtures. The numerical results demonstrate optimal convergence rates and low-level condition numbers independent of the mesh cutting.

ABSTRACT

When using frequency domain analysis methods to simulate random seismic actions, both traditional spectral representation and proper orthogonal decomposition belong to the conventional Monte Carlo simulation method. Currently, the conventional Monte Carlo simulation method still face difficulties such as large random variable dimensions, low accuracy of finite simulation samples, and random convergence. To solve these difficulties, this study first derives the original spectral representation (decomposition) of non-stationary random (vector) processes, The sources and significance of classical random amplitude method and random phase method are provided. On this basis, a dimension-reduction representation based on random orthogonal functions is further proposed, which introduces the constraint form of random orthogonal functions to accurately express the full probability information of the random (vector) processes of seismic ground motions with merely several elementary random variables. This dimension-reduction representation has achieved simulation of non-stationary ground motion processes, multi-point and multi-dimensional ground motion vector processes, and continuous ground motion fields. Benefitting from the dimension-reduction representation, each representative sample has assigned probability and all the probabilities constitute a complete set, which lays a solid foundation for the refined analysis of non-linear seismic response and dynamic reliability of engineering structures within the third structural design theory. By far, the dimension-reduction simulation method has been successfully applied to the stochastic dynamic response and overall reliability refinement evaluation of complex engineering structures such as high-rise buildings, large-span bridges, and dams under earthquake action.

DEVELOPMENT AND ANALYSIS OF THE THEORY OF COMPOSITE EXPANSION RING UNDER ELECTROMAGNETIC LOADING

Zongxing Liu[*1] and Jun Liu*[1]

[1]*Northwestern Polytechnical University*

ABSTRACT

High-speed impact collisions are common mechanical problems in engineering and life. Researchers have recognized that the response of objects under impact loads significantly differs from that under static loads. The dynamic mechanical parameters of materials are crucial for predicting their mechanical response under dynamic loads. Electromagnetic loading expansion ring test technology is essential to achieving a high strain rate tensile loading of materials. The intense pulse Lorentz force is sufficient for low resistivity specimens to achieve the desired strain rate. However, for high resistivity specimens, the induced current is relatively small under achievable loading voltages, making it challenging to obtain satisfactory loading results. Using a low resistivity pusher, the composite expansion ring loading scheme promotes specimen expansion and enables electromagnetic loading expansion ring tests to achieve dynamic tensile loading on most materials. Nevertheless, since this proposed test method, the theory of electromagnetic loading composite expansion rings has yet to develop fully.

This paper comprehensively analyzes the dynamic induction of coil, pusher, and specimen during the process where the pusher promotes the specimen's expansion. It considers the influence of electromagnetic-thermal-mechanical coupling on load results during electromagnetic loading processes and proposes a compound theory capable of accurately predicting composite expansion ring load processes. The simplified compound theory is also presented when dealing with specimens with relatively large resistivities.

The proposed theories in this paper are validated through numerical simulation methods. Furthermore, this paper analyzes the impact of driving ring materials on electromagnetic loading results and investigates how parameters such as coil and capacitance affect electromagnetic loading outcomes. Finally, the applicability of the simplified compound theory is discussed. This paper provides theoretical support for the design of the composite expansion ring under electromagnetic loading.

VARIATIONAL SYSTEM INFERENCE OF PHASE FIELD FRACTURE MODELS

Elizabeth Livingston[*1], Siddhartha Srivastava[2], Jamie Holber[1] and Krishna Garikipati[2]*

[1]University of Michigan
[2]University of Southern California

ABSTRACT

The mechanical behavior of biological materials is systematically studied in the paradigm of continuum mechanics. Complex phenomena, such as damage and fracture, have been modeled using the phase-field framework in which the total energy functional is minimized with respect to the deformation fields and internal variables (i.e. phase fields) to determine the material's mechanical response [1]. This approach is popular since it can model crack nucleation, propagation, branching, and merging without the need for distinct methods or additional discontinuities in the solution fields. In this work, we present a data-driven inverse method to infer the parameters of a phase-field model of fracture for materials exhibiting complex mechanical responses.

The phase-field fracture formulation has been applied in challenging biological applications such as angioplasty, aneurysm, and ligament tears [2]. This model utilizes hyperelastic free energy that degrades with evolving phase field to model damage and fracture in biological tissues. This general framework takes a modular approach to select a nonlinear stress-strain response and fracture dynamics from a set of hyperelastic models and fracture growth laws, respectively. In our data-driven approach, we identify the best hyperelastic free energy form and damage growth laws from a set of admissible candidates.

We formulate an algebraic optimization problem by considering the weak form of the momentum balance equation with different constitutive models and apply it to the deformation fields. We infer the parameters in the constitutive model and sequentially drop the non-contributing terms to infer the best-suited parsimonious model. This approach is referred to as Variational System Identification [3]. We demonstrate the performance of our methods in the face of noisy data that challenges the identification of mathematical models while attaining high accuracy in the predicted response of the inferred models.

COMPUTATIONAL MODELING OF MULTILAYERED BENDING PLATES (A 2D+ MULTISCALE APPROACH)

Pablo Wierna[1], Daniel Yago[1], Oriol Lloberas-Valls[1], Alfredo Huespe[2] and Javier Oliver[1]*

[1]Universitat Politècnica de Catalunya
[2]Centro de Investigación de Métodos Computacionales

ABSTRACT

This study introduces a novel 2D multiscale strategy, referred to as the 2D+ approach, employing a computational homogenization formalism tailored for modeling multilayered plates in situations dominated by bending. Such structural elements often involve advanced materials like laminated composites, characterized by a heterogeneous distribution of low-aspect-ratio layers exhibiting substantial nonlinear mechanical behavior across their thickness.

In this methodology, the macroscopic scale is represented by the 2D plate mid-plane, while the mesoscopic scale employs a 1D filament-like Representative Volume Element (RVE) orthogonal to the plate mid-plane, spanning the plate thickness. This RVE captures nonlinear mechanical behavior across the plate thickness at each integration point of the 2D plate discretization. The selected kinematics and discretization at these scales are chosen to effectively capture nonlinear mechanical behavior, achieve computational efficiency, and provide accurate stress distributions compared to high-fidelity 3D simulations.

The proposed strategy aligns with the standard first-order hierarchical multiscale framework, involving the linearization of the macro-scale displacement field along the thickness. It incorporates an additional fluctuating displacement field in the RVE to capture higher-order behavior, computed through a local 1D finite element solution of a Boundary Value Problem (BVP) at the RVE.
A notable feature of the 2D+ approach is the application of the Hill-Mandel principle, establishing mechanical energy equivalence in both macro and meso scales. This weakly couples the 2D macroscopic plate and the set of 1D mesoscopic filaments, resulting in significant computational savings compared to standard 3D modeling. Solving the resulting RVE problem in terms of the fluctuating displacement field enables the enforcement of an additional condition: the fulfillment of linear momentum balance (equilibrium equations). This yields a physically meaningful 2D-like computational setting for the considered structural object (multilayered plates under bending), providing accurate stress distributions typical of full 3D models at the computational cost of 2D models.

DEVELOPMENT, VERIFICATION AND VALIDATION OF 3D FEA-BASED SURROGATE MODELS FOR DAMAGE TOLERANCE APPLICATIONS

Adrian Loghin[1] and Shakhrukh Ismonov*[2]

[1]*Simmetrix Inc.*
[2]*Jacobs Technologies Inc.*

ABSTRACT

The two requirements for a cost-effective modeling procedure in probabilistic fatigue crack growth life assessment are solution accuracy and runtime speed. Quite often, solution accuracy is sacrificed for computational cost using reduced-order models, which can carry some level of solution uncertainty. To overcome such shortcomings, a 3D Finite Element (FE) modeling procedure capable of inserting, analyzing and propagating arbitrary-shaped cracks is employed to generate accurate solutions without the simplifications of geometry, crack shape/path and loading which are associated with reduced-order models.

Since 3D FEM solutions tend to be computationally expensive, machine learning algorithms (surrogate modeling) are used here to leverage the accuracy of the 3D FEM and reduce runtime. Depending on the type of the life assessment requirements, the deterministic solutions consisting of stress intensity factor values, remaining useful life or a 3D crack propagation path, are used for calibrating the surrogate models. The 3D FEA-based surrogate modeling allows for the parametrization of the geometry of interest, loading conditions, crack location, and can be further utilized in probabilistic life assessments. For instance, it can account for intrinsic fatigue crack growth rate scatter as a source of material behavior uncertainty.

Two types of surrogate models suitable for use in probabilistic fatigue crack growth life assessment are developed. For mode I applications, Gaussian Process Regression (GPR) is employed, while for mixed-mode loading cases, where the out-of-plane crack path is a critical output, Radial Basis Function (RBF)-based response surface modeling is utilized. A 3D finite element modeling procedure is used to generate accurate solutions to train the surrogate models, and verification is performed on both types of calibrated surrogate models. Experimental measurements are used to provide validation references for deterministic as well as surrogate modeling solutions.

It was demonstrated that the two surrogate modeling types (GPR and RBF response surface) significantly reduce the solution runtime compared to their deterministic counterparts, making them suitable for probabilistic damage tolerance assessments.

ABSTRACT

Multilayered aluminum components are of great interest in the aerospace industry due to their high strength-to-weight ratio and corrosion resistance. One of the common production methods of such layered components is diffusion bonding of similar and dissimilar metals. For load bearing applications the bond strength between the different layers is critical. Alongside experimental techniques for assessing bond strength in layered components, a computationally efficient method to model interface failure is the cohesive zone approach (CZM). In this framework the mechanical response of the interface is governed by a traction-separation law (TSL). The TSL represents the relation between the stresses across the interface and the relative displacement between layers, capturing the loss of load-bearing capacity before the final layer separation.

The TSL parameters are commonly determined by fitting of experimental load displacement data and numerical simulations (FEM). In such an approach, micromechanical aspects such as bonding defects (micro-voids) due to oxide layer fracture along the interface, which are known to greatly influence the bond strength, cannot be directly taken into consideration. The goal of the current study is to utilize a micromechanical based FE approach in conjunction with a Continuum Damage Model (CDM) approach to determine the TSL parameters, of diffusively bonded aluminum 7075 specimens, solely based on the defects pattern observed at the interface and a ductile failure law for Al 7075. First the flow-stress of Al7075 at temperatures of 400-500C was determined by cylindrical compression experiments and finite element modelling. Next, Al7075-Al7075 specimen pairs underwent diffusion bonding at 400-500C and thermo-mechanical finite element modelling was used to compute the time dependent thermo-mechanical fields at the specimen interface. Following the bonding experiments, small tensile specimens were cut from the bonded pairs and underwent characterization of the interface using a Scanning Electron Microscope (SEM) and subsequent mechanical testing. The, interfacial morphology observed from the SEM imaging was used to construct microstructural based Representative Area Elements (RAE) of the interface area. To model intact bond failure of the Al7075 in the RAE, a continuum damage approach for Al7075 previously published by the authors was utilized [1]. It is demonstrated that effective TSL can be obtained from the micromechanical models which explicitly take micro-structural parameters of the interface into consideration.

AN EXTENDED PHASE-FIELD METHOD FOR FRACTURE SIMULATIONS

Verena Curosu[1], Christian Krüger[1] and Stefan Löhnert[1]*

[1]Dresden University of Technology

ABSTRACT

The extended phase-field method (XPFM) combines the phase-field method for fracture with concepts from the extended/generalized finite element method. The approach aims at a significant reduction of the computational effort in comparison to the standard phase-field method while keeping the advantages of not having to explicitly track the crack geometry and to introduce additional crack propagation criteria.

The XPFM is based on a transformed phase-field ansatz and an enrichment of the displacement field. This allows for much coarser meshes, and it leads to truely mesh independent crack geometries including cracks that run through elements. The transformed phase-field ansatz incorporates knowledge about the analytical solution of the phase-field equation in 1D. The displacement enrichment is entirely based on the phase-field solution, and in contrast to the initial XPFM approach [1], in the present, refined version of the XPFM the necessity to calculate the direction perpendicular to the crack can be avoided completely. This allows for more general applications and the extension of the XPFM to 3D. The displacement enrichment is computed in a discrete way on a subgrid within each enriched finite element on which a phase-field dependent Laplacian problem needs to be solved for each direction. The respective scalar solution fields for the discrete displacement enrichment functions can be obtained in a very efficient way.

In this contribution, the latest developments for the XPFM including the algorithmic treatment will be presented, and applications to common academic examples for the simulation of fracture processes will be shown.

A NOVEL VARIATIONAL AUTOENCODER ARCHITECTURE FOR TEMPERATURE-ADAPTIVE ULTRASONIC GUIDED WAVE GENERATION

Rafael Junges[1], Luca Lomazzi[1], Lorenzo Miele[1], Marco Giglio[1] and Francesco Cadini[1]*

[1]Politecnico di Milano

ABSTRACT

Ultrasonic guided waves (UGWs) have recently captured the attention of the structural health monitoring (SHM) community. This heightened interest primarily stems from the remarkable sensitivity of UGWs to alterations in the properties of the medium through which they propagate. This makes such waves an interesting diagnostic tool to identify and describe damage affecting thin-walled structures. Among the results of damage diagnosis procedures, anomaly localization is fundamental to drive maintenance actions and restore the health state of the structure. To date, localization has predominantly relied on tomographic algorithms. Despite being widely adopted, they come with unsolved issues, including the generation of artifacts in damage probability maps and the bad performance under varying environmental and operational conditions (EOCs). Consequently, supervised data-driven approaches for UGW-based damage diagnosis have been proposed in the literature. Although such methods are characterized by satisfactory performance, a notable constraint is the requirement for large high-fidelity datasets for training the algorithms, which are typically unavailable for real-life structures. Furthermore, such methods still cannot deal with varying EOCs. A potential remedy lies in unsupervised machine learning methods. These methods have already found application in damage detection within the SHM field, but unsupervised approaches that can localize damage under varying EOCs still have to be investigated in detail. This work aims to overcome the limitations mentioned above by proposing a novel unsupervised network architecture based on variational autoencoders (VAEs). The algorithm was trained over an experimental dataset of UGWs acquired under varying temperature conditions. Testing was performed against experimental signals acquired at temperatures not seen during training to verify that the generative artificial intelligence tool is able to capture the influence of temperature on UGWs.

[4]ISAE-SUPAERO - Institut Clément Ader

ABSTRACT

Numerical simulation aided design of large-scale metal and alloy structures under extreme conditions, such as accidental mechanical overloads that may lead to failure, remains a major concern of various industrial sectors such as transportation, energy, and defense.

In this work, we present a three-dimensional numerical approach able to macroscopically account for various dissipative mechanisms (e.g., plasticity and ductile damage) leading to failure. The methodology is developed within the finite strain framework and is implemented into ABAQUS-std finite element computational code as a user finite element (UEL), in view of ensuring mesh-objective results.

Key features of the methodology include its treatment of both geometric and material nonlinearities using an updated Lagrangian formulation (ULF) [1]. The phase of more or less diffuse damage is reproduced by using Gurson-Tvergaard-Needleman (GTN) microporous plasticity model [2] employing standard finite element methods (FEM). Furthermore, the micro-void coalescence phase-induced dilation/shear band is modeled using an innovative extended cohesive finite element approach (XFEM-CZM) [3]. The progressive loss of cohesion culminating in ultimate cracking is addressed with the extended finite elements method (XFEM). A particular attention is paid to transition criteria (damage to localization, localization to cracking), the orientation of the localization plane (especially in Mode II), the cohesive zone model (empirical vs. inspired by the micromechanics of micro-void coalescence), and techniques for overcoming numerical challenges (e.g., volumetric locking [4], numerical integration [5]).

The unified methodology is shown to be able to replicate the degradation process until fracture (progressive drop in resistance, fracture surface orientation) in large elastoplastic deformation of structures used in laboratory tests, even with relatively coarse meshes.

MODELING SOLID-SOLID CONTACT IN A FULLY EULERIAN PHASE-FIELD FRAMEWORK

Flavio Lorez[1], Mohit Pundir[1] and David Kammer[1]*

[1]*ETH Zürich*

ABSTRACT

This work introduces a novel Eulerian finite element framework based on a phase-field representation of solids to model mechanical contact between elastic solids, with a particular focus on systems involving evolving and intricate surfaces [1]. Traditionally, Lagrangian frameworks dominate in modeling such interactions, yet they often demand sophisticated algorithms for contact detection and resolution. Furthermore, they face difficulties when dealing with solids undergoing dynamic boundary changes, such as crystals growing within confined spaces. Because the physical or chemical evolution demands an Eulerian framework, it is desirable to phrase the mechanical solid boundary value problem in such a framework as well, requiring novel approaches to contact modeling.

Our approach employs the phase-field method that includes a diffuse representation of geometries on a spatial mesh, streamlining the modeling of evolving surfaces. To model elasticity, we make use of the reference map technique [2]. A distinctive feature of our methodology is the introduction of volumetric penalty forces that weakly enforce the contact constraint. Capitalizing on the single reference system, the traction force is defined as a simple function of the phase-fields of the two bodies in contact, which renders contact search obsolete. We demonstrate the validity and versatility of our method through numerical examples, showcasing its capability to accurately capture complex solid-solid interactions.

The Eulerian phase-field formulation significantly simplifies the complexities associated with contact detection and resolution in traditional Lagrangian contact models. Additionally, our framework can be used to seamlessly integrate with other physical phenomena by incorporating multiple energy terms in the evolution of the phase-field. This enables the modeling of multiphysics scenarios, presenting a valuable tool for a broad spectrum of applications involving chemically or physically evolving deformable solids in contact. Such scenarios are, for example, prevalent in deterioration processes of porous media.

In conclusion, our Eulerian finite element framework provides an innovative and promising alternative solution for modeling contact between elastic solids, particularly in scenarios with evolving and intricate surfaces. The methodology's adaptability and capability for multiphysics modeling makes it a promising tool for addressing a wide range of applications, offering insights into the mechanical interactions of deformable solids in contact during processes like growing corrosion precipitates in porous media.

REDUCED ORDER MODELLING OF EXACT PERIODIC FLOWS USING A SPACE-TIME DISCRETISATION

Jacob Lotz[*1] and Ido Akkerman[1]*

[1]*Delft University of Technology*

ABSTRACT

Periodic flows are omnipresent in a large number of industrial applications. Examples include the flow past wind turbines, rotating flows in turbomachines and the pulsatile flow of blood. Simulation of periodic flows is computationally demanding for design and control applications as they need a long time domain for periodicity in the flow to develop. We circumvent the problem by using a parametric POD-Galerkin reduced order model, which exploits the nature of the problem.

In the full-order model, we apply the framework of residual-based variational-multiscale turbulence modelling and space-time iso-geometric analysis to solve the incompressible Navier-Stokes equations [1]. We convert the initial value problem to a boundary value problem by applying a periodic boundary condition in time to compute the time-periodic states directly. We use the Proper Orthogonal Decomposition (POD) to create a basis using parameter-dependent solutions from the full-order model. The time-periodic basis contains information on space and time, allowing for a dimension reduction in both. We create the reduced-order model using the POD basis and the same stabilisation as the full-order model [2,3]. The reduced-order model can use the DEIM, Q-DEIM and the S-OPT hyper-reduction techniques.

We apply the reduced-order model to flow past periodically heaving and pitching hydrofoils at a Reynolds number of O (103). Parameters include heave amplitude and motion period. The numerical experiments show a fast decay in singular values, allowing for small basis sizes. The results are in agreement with the results of the full-order model.

[3]*Johns Hopkins University*

ABSTRACT

In recent years, transformative technological advancements have markedly enhanced our ability to detect individual cancer cells and clusters within patients' blood, lymph nodes, and bone marrow. Despite these groundbreaking developments, the clinical significance of these detected cells remains elusive. This study addresses this uncertainty by introducing a systematic framework designed to select hypotheses that elucidate the population-level dynamics of non- and post-hypoxic cells during breast cancer metastasis to lung tissue. This framework leverages rich data obtained from meticulously conducted ex vivo experiments. Additionally, our approach employs an agent-based model, strategically translating macroscopic information into a microscopic perspective. This enables a comprehensive exploration of dynamic processes and facilitates the generation of novel hypotheses regarding breast cancer metastasis. The efficacy of our framework is demonstrated through the rigorous testing of 1152 candidate models at the population level, resulting in the efficient elimination of unlikely hypotheses and the revelation of valuable insights into the intricate metastatic process. Our multiscale model intricately unravels the proliferative advantage held by non-hypoxic cells within the lung tissue microenvironment. These findings contribute significantly to a deeper understanding of breast cancer metastasis dynamics and bear implications for the development of future therapeutic interventions. This integrated approach serves as a bridge between recent technological breakthroughs and sophisticated modeling techniques, thereby advancing our collective understanding of the complexities inherent in breast cancer metastasis.

A MULTI-FIDELITY APPROACH TO PREDICTION OF FLUTTER BOUNDARY UNDER UNCERTAINTY

George Lu[*1], Masayuki Yano[1], Amin Fereidooni[2] and Anant Grewal[2]*

[1]*University of Toronto*
[2]*National Research Council Canada*

ABSTRACT

We present a multi-fidelity uncertainty quantification (UQ) approach that leverages multiple computational aeroelasticity (CAE) models of various accuracies and costs to characterize the flutter boundary of a wing under uncertainties. The accurate determination of the flutter boundary, which corresponds to the point where the aeroelastic system exhibits zero damping and indicates the onset catastrophic unbounded oscillation, is crucial to aircraft certification. In the presence of model parameter uncertainties, aircraft may experience flutter far below the predicted flutter speed [1]. Our goal is to quantify this uncertainty and to provide the probability of flutter for a range of flight conditions. The problem can be considered a probabilistic extension of the deterministic flutter prediction using multi-fidelity models considered in [2]. Our multi-fidelity UQ approach builds on the following three ingredients: Gaussian process models, which readily incorporate sampled responses from models of various fidelities and provide probabilistic estimates of the damping coefficient over the parameter space; an input-dependent error estimate throughout the parameter space for each model, which is constructed by appealing to the predicted model discrepancies across levels of model fidelities; and contour-targeting adaptive sampling strategies, guided by the expected improvement in and/or estimates of approximation error, to select a sequence of models and sampling points that best improves the approximation of the flutter boundary while accounting for model evaluation costs. We demonstrate the multi-fidelity method for a transonic flutter problem using the following models: a Reynolds-averaged Navier-Stokes CAE model; a Euler CAE; and a traditional aeroelasticity model based on Theodorsen's aerodynamics. The multi-fidelity method enables efficient characterization of the probabilistic flutter boundary and accurately captures the sharp decrease in flutter velocity in the unsteady transonic flow regime with proper model selection.

EMULATING OCEAN MODELS TO QUANTIFY UNCERTAIN RESPONSES TO CLIMATE CHANGE

Hannah Lu[1], Siddhartha Bishnu[1], Simone Silvestri[1], Raffaele Ferrari[1] and Youssef Marzouk[1]*

[1]*MIT*

ABSTRACT

To better understand the responses of ocean systems to different forcings that represent climate change scenarios, we have explored a wide range of values for the parameters and initial/boundary conditions in an idealized ocean model on a global scale, NeverWorld2, which has intermediate complexity: it incorporates basin-scale geometry for an idealized Atlantic and Southern ocean, with non-uniform ocean depth to allow for mesoscale eddy interactions with topography. The simulation is implemented in Oceananigans.jl, a Julia-based software package for finite volume simulations of the nonhydrostatic Boussinesq equations on CPUs and GPUs. Due to the complexity of global circulation models, however, simulations of ocean processes are prohibitively expensive (even on GPUs), making the tasks of uncertainty quantification for future predictions and sensitivity analysis for model parameters extremely challenging. To address this challenge, we have investigated a wide range of deep learning tools to build dynamical emulators for targeted quantities of interest (QoIs). In addition, we have explored and developed systematic ways of identifying additional informative or dynamically relevant variables from the governing system, to make these QoI emulators more predictive and accurate. The efficient emulators will make it possible to capture interactions between the ocean and other components of climate models (e.g., atmospheric models, land models, human activities). This provides valuable scientific information for stakeholders in fighting climate change.

A GENERALIZED FRAMEWORK SUITABLE FOR DYNAMIC AND ELASTIC-PLASTIC CRACK GROWTH PROBLEMS: THE PRINCIPLE OF LEAST EXTERNAL WORK

Longkun Lu[*1]

[1]*Northwestern Polytechnical University*

ABSTRACT

Starting from the principle of least action, we propose the principle of least external work suitable for dynamic and elastic-plastic crack growth problems. Among those possible crack growth patterns, the principle of least external work indicates that the real one consumes the minimum value of the external work. Like the phase-field method, the proposed principle also converts crack growth problems into an energy minimization value problem, except that the energy term here is the work applied by external loadings. According to the first law of thermodynamics, external work can convert into kinetic energy, elastic and plastic deformation energy, or fracture energy. Therefore, the proposed principle can naturally apply to dynamic and elastoplastic crack growth problems.

Moreover, it can be proved that:
1) For the pure deformation of an elastic solid, the principle of least external work is equivalent to the principle of minimum potential energy;
2) In the case of quasi-static crack growth in elastic solids, the principle of least external work can give the Griffith criterion [1];
3)When a crack grows dynamically in an elastic solid, the principle of least external work can derive the dynamic fracture criterion proposed by Freund [2];
4) When a crack propagates quasi-statically in an elastic-plastic solid, the principle of least external work will give the fracture criterion based on the incremental J-integral [3].

MULTI-PHYSICS SIMULATIONS FOR LI BATTERY

Wei Lu[*1]

[1]*University of Michigan*

ABSTRACT

In this talk, I will present some of our recent work of developing battery simulation tools, and how these tools may help facilitate the battery design and management. The prediction of capacity fade and lifetime of batteries is important for cell design, determination of the optimal operation condition and control, and cell maintenance. Various mechanisms contribute to capacity fade. I will talk about a comprehensive capacity fade model and its experimental validation and application for battery optimization; a multiscale approach that couples mechanics and electrochemistry consistently at both particle and electrode scales which enables simulating various electrode phenomena; and approaches to optimize battery health while fulfilling both energy and power requirements. In simulation-based battery design, a large amount of simulations are required to determine the optimal design variables. The computational cost can be prohibitively expensive. I will introduce a new approach of Self-directed Online Learning Optimization (SOLO), which integrates dynamic deep neural network with finite element calculations. SOLO reduces the computational time by up to 5 orders of magnitude compared with directly using heuristic methods, and outperformed all state-of-the-art algorithms tested in our experiments. I will also show a pruner and sampler approach to determine model parameters or battery design parameters, which can reduce the battery testing time by about 75%. Finally, I will discuss simulations of concurrent dendrite and SEI growth.

ENHANCING FRACTURE RESISTANCE OF SOFT MATERIALS BY INTRODUCING AN INTERLAYER

Wenjing Lu[*1], Zidi Zhou[1] and Zishun Liu[1]*

[1]*Xi'an Jiaotong University*

ABSTRACT

Traditional soft materials often experience mechanical failure due to their low fracture resistance, limiting their suitability for various applications. Current approaches to enhance the fracture resistance of soft materials, such as fiber reinforcement and strain-induced crystallization, often involve complex preparation conditions. In this study, we propose a novel and simple strategy to enhance the fracture resistance by introducing an interlayer with lower modulus into the soft material. Through numerical simulation and experimental validation for proposed strategy, it is demonstrated that when a crack crosses the interlayer, the crack driving force decreases significantly and is much lower than that of homogeneous soft materials, thus enhancing the fracture resistance. Furthermore, a crack shielding effect is observed, wherein the material ruptures directly instead of experiencing crack propagation when reaching the stretchability limit, as if the crack were nonexistent. The crack shielding effect can be attained by optimizing both the modulus and width of the interlayer for a specific soft material. The underlying mechanism of this strategy can be explained as the stress de-concentration effect resulting from the introduced interlayer. We hope that this strategy can provide guidance for designing various soft materials with high fracture resistance.

ADAPTIVE IMPLICIT-EXPLICIT METHOD FOR ROBUST AND EFFICIENT FAILURE ANALYSIS

Xin Lu[*1], Ryo Higuchi[1] and Tomohiro Yokozeki[1]*

[1]*The University of Tokyo*

ABSTRACT

Although numerous methods have been devised for the failure analysis of quasi-brittle materials, substantial challenges persist in the numerical modeling and simulation of the progressive failure process. Specifically, the damage-induced strain softening may cause convergence difficulty in general implicit procedures, whereas lack of accuracy and restriction on time-step length are problems of concern for explicit formulations. Therefore, investigating and improving the performance of computational models has been of continuing interest within the scientific community.

In the context of continuum damage mechanics (CDM), an adaptive implicit-explicit method (A-IEM) is presented herein to enhance the robustness and efficiency of computational failure models. With standard Newton-Raphson method employed to solve the governing equations (balance of forces), the A-IEM is developed based on a constitutive model for the evolution of damage states. Initially, implicit algorithms are applied for non-linear failure analysis, during which critical nodes that hinder the convergence rate are identified through a concurrent monitoring algorithm. Upon fatal non-convergence, explicit constitutive law is enforced on the corresponding material points to evaluate the damage progression within the current time step. Once the analysis proceeds smoothly, the implicit method is re-activated for subsequent increments. By enabling the seamless transition between implicit and explicit schemes, the proposed A-IEM successfully ameliorates the intrinsic limitations of each standalone method while retaining their respective strengths.

The capability and performance of the proposed A-IEM are demonstrated through several representative benchmark problems. The progressive failure process of quasi-brittle materials is studied, where both A-IEM and conventional finite element schemes are applied for model comparison. The first example presents curved crack growth in an L-shaped plate while the second example considers a single-edge notched beam subjected to three-point bending load. To further validate the model adaptability, the anisotropic CDM is incorporated into the A-IEM framework, allowing for the failure analysis of a composite laminate in the last example.

PHYSICAL-BASED ESTIMATION OF INTER-SECTION BRIDGE RESPONSES UNDER VEHICULAR LOADING WITH BP-ANN

Xuzhao Lu[*1], Limin Sun[1], Ye Xia[1], Guang Qu[1] and Haibin Sun[1]*

[1]*Tongji University*

ABSTRACT

Estimation of inter-section bridge responses is a developing technique for monitoring bridge health. Monitoring data is used to estimate bridge responses at specific cross-sections by comparing them to responses at other cross-sections. These estimated responses serve as a baseline for comparison with the monitoring data. If significant differences are observed, it is possible that structural damage has occurred on the bridge.

Previous research has typically classified inter-section response estimation as a time-series prediction problem. To solve this problem, popular machine learning methods such as long-short-term memory (LSTM), convolution neural network (CNN), and transformer have been utilized. However, these methods primarily focus on time-dependent characteristics, including seasonal tendencies, yearly tendencies, and other periodic regulations. However, this paper demonstrates that the relationship between inter-section responses is essentially a time-independent mapping. The use of the aforementioned methods may lead to overfitting.

This paper analyzes the theoretical physical dynamics of a typical vehicle-bridge-interaction (VBI) system based on the derivation of dynamic equations. The inter-sensor relationship is represented as a transform determined by model shapes, which is proved to be time-independent. Then, the BP-ANN method is utilized for inter-sensor response estimation. The proposed method was validated using field monitoring data from a concrete bridge. Firstly, the dynamic responses of the bridge were separated into high-frequency responses and low-frequency driving-force related responses. Then, the BP-ANN was applied to each component. Responses from multiple sensors at certain cross-sections were used to predict the responses at a specific cross-section. The estimation results matched well with the monitoring data. Moreover, we proposed a comparison between the BP-ANN and other time-series prediction methods. Our findings indicate that the BP-ANN can effectively avoid over-fitting problems. Furthermore, our study demonstrates the potential for using small-scale monitoring data for long-term health monitoring, including temperature and traffic conditions. This approach can be widely applied in actual engineering.

EXTENDED TENSOR DECOMPOSITION MODEL REDUCTION METHOD: APPLICATION TO ADDITIVE MANUFACTURING RESIDUAL STRESS PREDICTIONS AND UNCERTAINTY QUANTIFICATION

Ye Lu[1]*

[1]*University of Maryland, Baltimore County*

ABSTRACT

Simulation-based science and engineering, including design and uncertainty quantification, usually necessitate fast responses of numerical models. Despite the significant improvement of the computer hardware over the last decades, real-time simulations of large-scale systems are still intractable with conventional finite element analysis (FEA). The repetitive evaluation of the numerical model using FEA makes the design process computationally prohibitive.

This work presents an eXtended Tensor Decomposition (XTD) method [1] for nonlinear model reduction. The XTD method is based on a sparse non-separated enrichment to the conventional tensor decomposition [2,3], which can improve the approximation accuracy and the reducibility (compressibility) in highly nonlinear and singular cases. The method has been successfully applied to parametric elastic–plastic problems for real time additive manufacturing residual stress predictions with uncertainty quantification. The efficiency of the method is demonstrated with comparison to full-order FEA. The proposed method enables a novel computational framework for fast manufacturing process design with uncertainties.

A NEW NONLINEAR SHELL FINITE ELEMENT WITH A CONSERVATIVE DYNAMIC ALGORITHM

Matheus Lucci Sanchez[*1] and Paulo Mattos Pimenta*[1]

[1]*University of São Paulo*

ABSTRACT

The exploration of shell simulation within the Finite Element Method (FEM) carries significant importance in the field of structural engineering and dynamic analysis, particularly when dealing with structures exhibiting considerable displacements, such as wind turbine blades. However, simulating extremely thin structures using prevalent commercial finite element software often encounters numerical limitations. These challenges typically manifest as the artificial numerical stiffness of the shell at the finite element level, commonly known as locking phenomena, or the use of non-conservative numerical schemes that fail to maintain energy and/or momentum conservation, resulting in unrealistic outcomes.

In response to these issues, the current research aims to introduce a novel FEM model that prioritizes simplicity and conservative dynamics. Building upon previous work conducted by our research group (refer to [1~5] for examples), our ongoing investigation focuses on implementing a new conservative finite element capable of simulating thin nonlinear shells in long-term dynamic boundary value problems.

This innovative element, featuring six nodes, employs a unique scheme with a non-conforming rotational field constructed from an incremental rotation variable φ_Δ (introduced in [1] by our group). This approach eliminates the need for employing numerical techniques like penalties, Lagrange multipliers, or any other artificial parameters to address C1 continuity—a kinematic requirement for Kirchhoff-Love shell theory. The standard six parameters representing the quadratic displacement field of the mid-plane are incorporated at the element's six nodes. The dynamic algorithm is rooted in previous work by [2], specifically developed for energy and momentum-conserving simulations of rod and shell finite elements. This algorithm is proficient in handling rotational degrees of freedom and general hyperelasticity.

THE CHOICE OF THE SHAPE PARAMETER IN THE SHIFTED SURFACE SPLINE

Lin-Tian Luh[*1]*

[1]*Providence University of Taiwan*

ABSTRACT

Abstract. This is a continuation of our previous study of the shape parameter contained in the shifted surface spline. We insist that the data points be purely scattered without meshes and the domain can be of any shape when making function interpolation by shifted surface splines. We also endeavour to make our approach easily accessible for scientists, not only mathematicians. However, the space of interpolated functions is smaller than the one used before, leading to sharper function approximation. This function space has particular significance in numerical partial differential equations, especially for equations whose solutions lie in Sobolev space. Although Fourier transform is deeply involved, scientists without background for Fourier analysis can easily understand and use our approach.

THERMOMECHANICAL FATIGUE IN HIGH TEMPERATURE STRUCTURES: DEFORMATION BEHAVIOR, DAMAGE MODELING AND LIFE PREDICTION

Cheng Luo[*1] and Huang Yuan[1]*

[1]*Tsinghua University*

ABSTRACT

Nickel-base single crystal superalloys (NBSX) are widely used in turbine blades of aero engines. As a multi-physics problem, thermomechanical fatigue (TMF) is considered to be a key factor limiting the safe service of hot-end components. Mechanical fatigue, thermal-induced creep and oxidation at elevated temperature are involved in TMF. It is important to model TMF damage and failure for structural integrity and strength design of engines.

In this study, TMF tests were conducted on both standard smooth specimens and film cooling hole (FCH) structure of DD6 alloy, including IP and OP loading paths. It was found that the fatigue life of TMF decreased by 90%-98% compared with the isothermal fatigue life at the same peak cycle temperature.

Secondly, damage mechanisms were revealed by microscopic characterization of fracture surfaces. Creep damage and fatigue damage dominated in IP-TMF. The effects of slip system on damage development and accumulation were discussed. In OP-TMF, oxidation assisted both fatigue crack nucleation and propagation. In the FCH structure, it was unveiled that stress concentration and stress ratio had tremendous impact on damage mechanisms. Transition from mode I to crystallographic fracture was captured.

Then, a novel crystal plasticity constitutive model was developed for TMF deformation behavior of NBSX. The influences of temperature on the elastic-plastic parameters and the activation of different crystallographic slip systems were considered. FEM simulation was conducted and stress-strain responses on various crystal orientations were well modelled. Local deformation around the FCH was simulated and verified by digital image correlation (DIC) method.

Finally, anisotropic fatigue damage and creep damage were modelled along slip systems based on continuum mechanics. The models were verified by isothermal low-cycle fatigue, pure creep and creep-fatigue test results. The oxidation damage was quantified by the thickness of the oxide layer. Based on the linear damage accumulation rule, a novel anisotropic TMF life prediction model was proposed. The effect of stress concentration on TMF life was incorporated. Experimental data of both smooth specimens under different crystal orientations and FCH structure were evaluated and most of the lifetime points fell within the 2-time scatter band.

Aiming at the TMF problem of hot-end structure, a systematic study of high temperature tests-mechanism analysis-deformation simulation-damage modeling-life prediction was conducted in this work. This study highlights how crystal anisotropy, stress concentration and loading paths affect deformation and various damage mechanisms, providing key insights into constitutive and damage modeling of high temperature structures under TMF conditions.

BI-DIRECTIONAL FIBER ORIENTATION DESIGN FOR MANUFACTURING IN FIBER-REINFORCED COMPOSITES

Chuan Luo[*1]*

[1]*Columbia University*

ABSTRACT

Optimizing continuous fiber orientation is crucial for designing fiber-reinforced composite structures, especially when employing advanced manufacturing techniques such as automated fiber placement and additive manufacturing. While existing studies effectively capture the bi-directional mechanical properties of fibers in the constitutive models, i.e., a fiber has same mechanical properties in the fiber direction and its opposite direction, representing their bi-directional geometric properties is often overlooked by traditional orientation representations. This oversight can impact manufacturing evaluations, as constraints vary when fiber orientation is flipped. The present work aims to address the following two key questions: first, can we represent the bi-directional properties of fiber orientations both mechanically and geometrically? Second, if achievable, how can we enhance design manufacturability under such bi-directional orientation representation to overcome limitations in the current design space?

The proposed methodology is applied to optimize compliance in 2D plates and 3D shell structures with continuous fiber paths. The design process integrates a thorough assessment and management of critical manufacturing constraints, encompassing both the minimum turning radius of fiber paths and the maximum density of gaps/overlaps. Numerical results demonstrate enhanced structural performance and effective control over design manufacturability through the bi-directional fiber orientation design for manufacturing in fiber-reinforced composites.

SHAPE OPTIMIZATION OF A GEOMETRICALLY-ADAPTABLE HEART-VALVED CONDUIT FOR PEDIATRIC APPLICATIONS

Chuan Luo[1], Kewei Li[1], Abigail Herschman[1], Haim Waisman[1], Vijay Vedula[1], Jeffrey Kysar[1] and David Kalfa[1]*

[1]*Columbia University*

ABSTRACT

Congenital heart valve disease in pediatric patients necessitates using prosthetic valves, yet conventional valves struggle to sustain optimal hemodynamic performance as the vascular system grows. The dynamic nature of infant cardiovascular development, where the valve diameter can double due to somatic growth, often leads to multiple replacements before adulthood, requiring high-risk open-heart surgeries. Overcoming this challenge involves the development of an adaptable heart valve with an optimized geometry capable of maintaining excellent cardiovascular performance across different growth stages. Here, we introduce an optimization framework for designing expandable bi- and tri-leaflet valved conduits. The leaflet shapes, represented by Bezier curves and other sizing parameters, are incorporated into a computer-aided design (CAD) model. The valve's closing and opening processes are modeled with physiologically relevant boundary conditions across three stages: pre-dilation, dilation, and post-dilation. The anisotropy of the polymeric material used for the valve is rigorously characterized through uniaxial tension tests and represented using anisotropic elastic-plastic material models. All the simulations are performed using a quasi-static finite element analysis (FEA) in LS-DYNA. During the iterative updates of the design variables, the CAD and the FEA models of the valved conduit with varying geometries are automatically generated. The objective is to minimize maximum principal stresses, plastic strain, and orifice area ratios in both pre-dilation and post-dilation performance evaluations. Genetic algorithms (GA) are employed to solve the multi-objective optimization problem, yielding a set of Pareto solutions. From this set, an optimized design is selected in the decision-making process. Subsequently, fluid-structure interaction (FSI) simulations are conducted to assess the performance of the optimized heart valve, ensuring its functionality in a physiological setting. This comprehensive approach aims to advance the design and development of prosthetic heart valves capable of adapting to pediatric patients' evolving cardiovascular needs, ultimately reducing the need for frequent surgical replacements and mitigating the associated risks.

EFFICIENT PDE-CONSTRAINED OPTIMIZATION UNDER UNCERTAINTY USING DERIVATIVE-INFORMED NEURAL OPERATORS

Dingcheng Luo[*1], Thomas O'Leary-Roseberry[1], Peng Chen[2] and Omar Ghattas[1]*

[1]The University of Texas at Austin
[2]Georgia Institute of Technology

ABSTRACT

We propose a novel machine-learning framework for solving optimization problems governed by partial differential equations (PDEs) with high-dimensional random parameters [1]. Such problems arise, for example, in the design of structures with uncertain material parameters/loads and the control of fluids under uncertain flow conditions. Optimization under uncertainty (OUU) is often orders of magnitude more computationally intensive compared to its deterministic counterpart due to the need to estimate the risk-based objective functions by stochastic integration. This requires numerous solutions of the governing PDE at every optimization iteration, potentially amounting to prohibitive computational costs.

To address this challenge, we consider a derivative-informed neural operator (DINO) [2] that approximates the solution operator of the PDE, mapping from the joint inputs of the random parameters and optimization variables to the PDE solution. In particular, we propose to incorporate the derivative of the PDE solution operator with respect to the optimization variables into the training loss. The additional information provided by the derivatives ensures that both the optimization objective function and its gradients can be simultaneously approximated to high accuracy with only a limited number of training samples, leading to more accurate OUU solutions.

We demonstrate the accuracy and efficiency of our approach through several numerical experiments of flow control problems in two and three spatial dimensions subject to random field inputs. Across the examples, the DINOs offer 3–7 orders of magnitude reductions in execution time. Moreover, the DINOs can produce OUU solutions of comparable accuracies to those from standard PDE-based solutions while being 10–100× more cost-efficient, even after factoring in the cost of training data generation.

EXPLORING INTERFACE CONSERVATION IN COMPUTATIONAL FLUID DYNAMICS

Hong Luo[*1], Gianni Luo[1] and Xiaodong Liu[1]*

[1]*North Carolina State University*

ABSTRACT

The necessity of enforcing conservation in computational elements or cells (element conservation) for discontinuous solutions is well understood and respected for solving conservation laws in computational fluid dynamics (CFD). In contrast, interface conservation, where the conservation across cell interfaces is enforced is long ignored, and yet is also ruled and required by the underlying physics just like element conservation. Violation of the interface conservation across discontinuities is the root cause why an exact discontinuous solution can never be achieved in shock capturing methods. The interface conservation is examined and explored thoroughly in this paper. A discontinuity indicator based on the interface conservation is developed to reliably detect and identify all types of discontinuities, as the interface conservation can never be attained across the discontinuities. The developed discontinuity indicator is used as an error indicator for h-adaptive grid methods to effectively increase mesh resolution near discontinuities and for r-adaptive grid methods to align mesh interfaces with discontinuities using a moving discontinuous Galerkin (MDG) Method. A number of numerical experiments are conducted to assess effectiveness of the interface conservation-based error indicator and performance of the MDG method. Numerical results for a variety of discontinuous flows obtained indicate that the error indicator based on the interface conservation can effectively detect all types of discontinuities and under-resolved flow regions and the MDG method by enforcing the interface conservation is able to reposition grid, align mesh interfaces with all types of discontinuities, and achieve the designed order of both h- and p-convergence even for discontinuous solutions.

INEXACT NEWTON WITH LEARNING-BASED PRECONDITIONER FOR HIGHLY NONLINEAR HYPERELASTICITY PROBLEMS ON THREE-DIMENSIONAL UNSTRUCTURED MESHES

Li Luo[*1]

[1]*University of Macau*

ABSTRACT

Inexact Newton-type method is widely used in many scientific and engineering applications, but in many situations it converges slowly or even fails to converge, for reasons that are difficult to quantify. We propose a novel nonlinearly preconditioned inexact Newton algorithm with learning capability to improve the convergence and robustness of the method. The proposed method searches through the nonlinear residual and stagnated solution spaces generated during the Newton iterations and identifies the "bad subspaces" using an unsupervised learning technique, namely principal component analysis. In the nonlinear preconditioner, a learned small-scale projected problem corresponding to the slow subspace of the nonlinear residuals is constructed and solved to provide a much better initial guess for the global inexact Newton method to converge nearly quadratically. As an application, we consider the modeling of the human artery with stenosis using the hyperelasticity equation with multiple material parameters. Due to the significant difference in the material coefficients between the plaques and the healthy parts of the blood vessels, the problem is nonlinearly very difficult. Numerical experiments demonstrate that the proposed nonlinearly preconditioned inexact Newton offers significantly reduced number of nonlinear iterations and robustness for this rather challenging hyperelasticity problem.

DISLOCATION DYNAMICS IN TANTALUM UNDER LASER SHOCK: ELUCIDATING THE CRITICAL ROLE OF ELASTODYNAMICS EFFECTS

Shichao Luo[*1] and Yinan Cui[1]*

[1]*Tsinghua University*

ABSTRACT

This report explores the significant role of dislocation elastodynamics in shaping the plastic behavior of metals under the extreme conditions of intense laser shock, with an emphasis on tantalum single crystal. It critically evaluates the shortcomings of conventional dislocation dynamics methods, which rely on elastostatics theory and often fail to adequately address the intricate spatio-temporal coupling effects manifesting in various dislocation velocities—ranging from subsonic to supersonic (in relation to the metal's shear wave velocity)—especially under high strain rates. By implementing an advanced three-dimensional discrete-continuous dislocation elastodynamics methodology, this report conducts a detailed comparative analysis against traditional dislocation dynamic approaches. It highlights the profound impact of dislocation elastodynamics on vital physical parameters, including the dynamic yield point, dislocation velocity, dislocation density, and the rate of plastic strain. This research offers valuable insights into the ultrafast mechanical behavior of metals and will play a pivotal role in the development of a dynamic constitutive metal model that comprehensively incorporates the elastodynamic effects of high-speed dislocations.

A CNN-BASED APPROACH FOR OPTIMIZING LAGRANGE-GALERKIN SEARCH ALGORITHMS IN FLUID DYNAMICS

Xuan Luo[*1], Zichao Jiang[1], Bohua Huang[1], Zhuolin Wang[1], Yi Zhang[2] and Qinghe Yao[1]*

[1]Sun Yat-sen University
[2]Guilin University of Electronic Technology

ABSTRACT

In this study, we introduce an innovative Lagrange-Galerkin (L-G) search algorithm, enhanced by Convolutional Neural Network (CNN) technology, to elevate the efficiency of large-scale simulations. The foundational L-G method merges a Galerkin finite element approach with a unique discretization of the material derivative, tracking fluid particle trajectories. This integration necessitates locating particles within finite elements, traditionally achieved through a step-by-step search algorithm. While effective in regular-scale simulations due to its stability and efficiency, this conventional method encounters considerable challenges in high-resolution models, particularly in handling extensive computations across densely-packed elements, thereby reducing the L-G method's iterative efficiency.

To address these limitations, the proposed method combines the L-G search algorithm with a CNN. This method leverages the CNN's capability to analyze spatial information within the finite element model and particles, extracting flow field characteristics and establishing a predictive mapping between particles and grids. Therefore, this predictive capability guides the step-by-step search algorithm towards target elements via a more direct path.

Numerical results demonstrate that the proposed method substantially reduces search costs while maintaining precision. Specifically, in the case of 3D flow simulations, the optimization rate of the proposed CNN-enhanced L-G algorithm reaches 80% compared to the classic search methods. This advancement significantly augments the L-G method's overall efficiency in large-scale simulations, offering a robust solution to the computational challenges in high-resolution flow simulation.

ABSTRACT

The conductive interconnect structure that connects the electrical functional devices is an important micro-nano structure in stretchable electronics. Considering that many devices rely on constant electrical currents to function, stretchable electronics would benefit from interconnects with minimal resistance variation during deformation. This paper proposes a topology optimization method for the design of stretchable interconnect structures with stable resistance under large deformation. In the proposed method, an equal material method considering geometrically nonlinear and electromechanical coupling effects is developed to evaluate the resistance of a deformed structure.

Besides, a new connectivity control method is proposed to ensure the connectivity between the inlet and outlet by making full use of the electrical problem itself. To realize the design of connected interconnect structures with minimal resistance variation during stretching, a topology optimization formulation for the design of stretchable interconnect structures is established, and the corresponding sensitivity is also analytically derived. Several numerical examples show that the proposed method is capable of computationally and intelligently generating stretchable structures with extremely small changes in resistance when stretching.

DE-DEM: DISCONTINUITY-EMBEDDED DEEP ENERGY METHOD FOR SOLVING FRACTURE PROBLEMS IN SOLID MECHANICS

Zhao Luyang[*1] and Qian Shao*[1]

[1]*Wuhan University*

ABSTRACT

Physics-Informed Neural Networks (PINN) have proven to be an effective tool for addressing forward and inverse problems of partial differential equations (PDEs). However, approximating discontinuous functions with strong nonlinearity by neural networks poses a considerable challenge, which results in high computational demands for standard PINN framework problems to solve fracture problems or multi-material problems. Besides, extra terms introduced in loss function for dealing with specific continuity requirements and internal boundaries also reduce the training efficiency. Additionally, the singular displacement and stress field in fracture problems cannot be accurately modelled in standard PINN framework.

To this end, we propose the Discontinuity-Embedded Deep Energy Method (DE-DEM). The proposed approach directly embeds the discontinuous features into the neural network by representing them with additional inputs that label specific discontinuous patterns. These additional inputs are constructed by level set functions (LSF) to flexibly represent interfaces and internal boundaries with arbitrary shapes. By controlling the properties of additional inputs, the neural network representation of physics field can be enforced to be discontinuous. This allows for the efficient solution of problems with discontinuous values or gradients at a lower computational cost. Besides, the weak form of the governing equation is utilized to train the neural network. The weak formulation intrinsically satisfies natural boundary conditions and requires lower order of gradients, augmenting the overall efficiency of the training process.

Numerical experiments are conducted on various crack patterns, including edge cracks, multiple cross cracks and interfacial cracks. Our results demonstrate the applicability of the proposed method to arbitrary crack patterns with low computational cost compared to existing PINN methods. Additionally, our approach accurately computes the singular crack tip field, enabling the straightforward computation of stress intensity factors (SIF) based on crack opening displacements. This, in turn, facilitates the prediction of the crack propagation path by combining the SIFs with suitable propagation criteria. The proposed DE-DEM framework can accurately and efficiently model the mechanical behaviors of fracture problems, which extends the application of PINN in solid mechanics.

TOWARDS EFFICIENT SIMULATION OF LARGE RESERVOIR FLOW MODELS: IMPLEMENTING AN ADAPTIVE MULTISCALE AND MULTILEVEL FINITE VOLUME TECHNIQUE FOR IMPROVED ACCURACY

Paulo Lyra[*1], José Cícero Santos[2], João Paulo Andrade[2], Artur Souza[3] and Darlan Carvalho[2]*

ABSTRACT

Currently, large reservoir fluid flow models may size up to a billion control volumes and sometimes the simulation of these fine-scale models is unfeasible. In general, upscaling techniques are applied to define coarser, i.e., smaller, models that can be treated by modern parallel machines at reasonable computer resources and time. This procedure naturally implies loss of information, such as small-scale fractures, vugs, and other details from the fine-scale mesh. Multiscale Finite-Volume Methods (MsFVM) have been developed to handle highly heterogeneous reservoirs using algebraic operators (restriction and prolongation) that are responsible for transferring information between the fine and coarse scales. They provide more accurate solutions than upscaled models and reduced CPU cost if compared to fine-scale simulations. Several authors have devised different strategies for obtaining accurate solutions by using multilevel or multiscale strategies. In this work, we have developed the Algebraic Dynamic Multilevel with Non-Uniform resolution (NU-ADM) using a Two Point Flux Approximation (TPFA) Finite Volume formulation for the fully implicit simulation of oil and water in highly heterogeneous petroleum reservoirs. The NU-ADM operators are based on the Algebraic Multi-Scale (AMS) operators. To better capture the physical phenomena involved, we have also developed a procedure that fits the multilevel resolution with the multilevel pressure field. This a priori procedure takes place before the pressure field calculation and is made through the fine-scale contributions to the coarse-scale transmissibility matrix coefficients. The saturation front is also adaptively captured. We have observed that the ADM outperformed the direct fine-scale solution by an order of 5. It is worth mentioning that most of these tests were conducted using the SPE10 comparative solution problem. In addition, we are using nonuniform ADM resolutions, aiming to reduce the number of active volumes of the fine-scale mesh, maintaining accuracy and improving CPU performance.

MECHANISTIC MACHINE LEARNING-BASED MULTISCALE MATERIAL MODELING OF METAL MATERIALS

Dandan Lyu[*1], Yuxi Xie[1], Haoyan Wei[1], Wei Hu[1] and C.T. Wu[1]*

[1]ANSYS

ABSTRACT

Metal materials have been widely used as the most important engineering materials in automotive, aerospace, and electronics industries. Manufacturing process of metals typically induces heterogeneous microstructures across different length scales, and predicting the resulting nonlinear anisotropic behaviors by conventional single-scale empirical approaches is challenging. In this work, a data-driven multiscale modeling platform that integrates Crystal Plasticity (CP) constitutive modeling and a mechanistic machine learning method referred to as Deep Material Network (DMN) [1] is proposed. This CP-DMN framework consists of an offline training phase and an online prediction phase. The training phase for the DMN is conducted by optimizing the network fitting parameters based on the linear elastic Representative Elementary Volume (RVE) database generated using Direct Numerical Simulation (DNS) so that the accuracy of the CP-DMN is dependent on the accuracy of the RVE modeling. In the online prediction phase, the trained DMN is evaluated on a rate-dependent crystal plasticity model for predicting the complex nonlinear behaviors of RVE microstructures. Using transfer learning technique [2], a unified DMN database is created to cover a full range of grain orientations, which allows for online network interpolations for prediction of new orientations multiscale constitutive behavior. One unique feature is that the physics embedded DMN can discover the morphological features, such as grain orientation distributions hidden in RVE of metal materials. One of the industrial applications is the multiscale cold metal forging analysis. The proposed CP-DMN platform opens new possibilities in the design and concurrent multiscale metal fabrication analysis.

A NON-ITERATIVE FORMALISM FOR RELIABILITY-BASED DESIGN OPTIMIZATION VIA DECOUPLED MULTI-PROBABILITY DENSITY EVOLUTION METHOD

Meng-Ze Lyu[1], Jia-Shu Yang[2] and Jian-Bing Chen[1]*

[1]*Tongji University*
[2]*Xi'an University of Architecture & Technology*

ABSTRACT

Reliability-based design optimization (RBDO) is a promising methodology to address the significant challenge posed by the new generation of structural design theories centered around reliability considerations. Solving RBDO problems typically requires iterations ranging from a dozen to several hundred, with each iteration dedicated to updating the values of design variables. Furthermore, RBDO necessitates hundreds of or even more representative structural analyses at each iteration to compute the reliability measure, which serves as a foundation for determining the search direction in the subsequent iteration. This results in the double-loop problem confronted by RBDO, leading to substantial computational costs for structural reanalysis, particularly in the cases involving complex nonlinear stochastic dynamical systems. Recently, a class of non-iterative RBDO paradigms has emerged based on the newly proposed decoupled multi-probability density evolution method (M-PDEM). Specifically, the reliability is expressed as the integral of the probability density function (PDF) of the extreme response within the safety domain. The reliability of different designs can be regarded as the integral of the conditional PDF of the extreme response given the values of design variables. By leveraging the decoupled M-PDEM, a series of one-dimensional partial differential equations (PDEs) named Li-Chen equations can be solved to calculate the joint PDF of multiple responses. This enables efficient computation of the joint PDF of design variables and extreme response based on finite representative structural analyses. This method transforms RBDO into true single-loop calculations, and thereby eliminates the significant computational burden associated with structural reanalysis at different intermediate designs during the optimization iteration. Finally, the accuracy and effectiveness of this novel method are validated through several numerical examples.

ANALYTICAL SOLUTION OF GENERALIZED PROBABILITY DENSITY EVOLUTION EQUATION FOR THE ONE-DIMENSIONAL DIFFUSION PROCESS OF CHLORIDE IONS IN CONCRETE AND DIFFUSION PROCESS ANALYSIS

Xiaofei Lyu[*1] and Jie Li*[1]

[1]*Tongji University*

ABSTRACT

In chlorine-exposed concrete structures, chloride ion erosion leads to issues like steel corrosion and concrete damage. The diffusion-driven chloride ion transport, described by Fick's second law, involves a random diffusion coefficient due to material uncertainties. Monte Carlo Simulation (MCS) is often used to study its impact on damage like steel corrosion and concrete cracking in previous studies, but it is computationally expensive and suffers from convergence problems, compromising accuracy.
In this work, the generalized probability density evolution equation (GDEE) for the one-dimensional diffusion equation is established based on Fick's second law, and the analytical probability density function (PDF) for the diffusion concentration of chloride ions in concrete is thus derived by solving the GDEE with the characteristics method. Then the stochastic diffusion process is analyzed with the chloride ion diffusion coefficient obeying a lognormal distribution and the result shows that there is a significant spatial and temporal variability in the PDF of chloride concentration. The mean value of chloride concentration increases with time and decreases with depth, while the coefficient of variation (COV) of chloride concentration shows a tendency of first increasing and then decreasing with both time and depth. This indicates that the probability density and variability of the distribution of chloride concentration not only depend on the randomness of the diffusion coefficient, but also are closely related to the stage of the diffusion process. Meanwhile, a comparison of the numerical solution of the GDEE with the analytical PDF solution proposed in this paper reveals that when the number of subdomains increases, the accuracy of the numerical solution will increase and gradually gets close to the analytical solution, which indicates that the analytical PDF can also serve as a benchmark for measuring the accuracy of numerical methods.

PERFORMANCE ANALYSIS AND OPTIMISATION OF SPATIALLY-VARYING INFILL MICROSTRUCTURE WITHIN CAD GEOMETRIES USING ASYMPTOTIC ANALYSIS AND MACHINE LEARNING

Chuang Ma[*1] and Yichao Zhu*[1]

[1]*Dalian University of Technology*

ABSTRACT

This research aims to offer an efficient digital solution to facilitate infill microstructural design within objectives generated from normal computer aided design (CAD) systems. Moreover, this approach entails a synergistic utilization of asymptotic analysis and machine learning, enabling rapid stiffness design and strength analysis of configurations filled with smoothly varying graded microstructures. The discussion is conducted in the context of an improved asymptotic-homogenisation topology optimisation (AHTO plus) framework[1]. Firstly, the key here is to deploy the microstructure and to analyse the performance of the resulting multiscale objective in the parameter domain, from which a CAD objective is mapped, usually by means of Non-Uniform Rational B-Splines (NURBS) functions. In the regularly shaped domain defined in the parameter space, another set of mapping functions are defined for the description of spatially-varying microstructure (in the parameter space), and the actual multiscale CAD objective gets represented through composition of these mapping functions with the NURBS-based functions for CAD geometry generation. When the introduced mapping functions are also NURBS-based, the proposed representation strategy becomes more favoured by CAD systems, in the sense that the CAD geometry and its infill can be tuned simultaneously but independently with a same set of NURBS basis. Moreover, our computer-aided engineering (CAE) module is also installed over the parameter domain, based on a machine-learning-based homogenisation formulation for compliance and strength analysis. Thus the finite element meshes stay unchanged although the accommodating CAD geometry keeps varying. With the aforementioned treatments, a consecutive CAD-consistent scheme is proposed. Our numerical results show that each time as the control points are moved (by a CAD designer), one may choose to wait several seconds for two-dimensional cases and/or a few minutes for three-dimensional cases, to get a CAD geometry filled with microstructure bearing optimised compliance.

RESEARCH ON HIGH-TEMPERATURE OXIDATION DAMAGE OF PS-PVD SPRAYED YB2SI2O7 ENVIRONMENTAL BARRIER COATINGS

Rong Ma[1], Jingjing Yang[1] and Xueling Fan[1]*

[1]*Xi'an Jiaotong University*

ABSTRACT

Abstract
Ceramic matrix composites (CMCs) have the characteristics of low density, high toughness, high temperature resistance, and oxidation resistance, making them the preferred material for the hot end components of next-generation aircraft engines. Environmental barrier coatings (EBCs) can effectively resist the erosion of corrosive medium such as oxygen, water vapor, and molten salts, protecting the integrity and functionality of CMCs during service. This article elucidates the microstructure and mechanical properties evolution of plasma spray-physical vapor deposition (PS-PVD) sprayed Yb2Si2O7 (YbDS) EBCs during continuous heat exposure at 1250 ℃ - 1350 ℃, develops a quantitative characterization method for isothermal oxidation damage of EBCs, and reveals the damage mechanism. The results indicate that element diffusion occurs between the top coating (TC) and bond coating (BC) layers during the oxidation process, and thermally grown oxide (TGO) is generated at the interface, which leads to an increase in nearby pores and microcracks. The TGO layer to some extent hinders the diffusion of elements, but the mismatch of thermal expansion coefficient will promote the generation of vertical and horizontal cracks in the TGO layer, which will become channels for oxygen diffusion, leading to continuous attenuation of the thickness of the BC layer. Ultimately, delamination and spalling occurred between the TGO layer and the BC layer. The oxidation kinetics curves of YbDS/Si EBCs exhibit a parabolic law. In addition, a degradation relationship was established for the mechanical properties of the BC layer. The oxidation inside the BC layer leads to an initial increase in the elastic modulus of the BC layer, which provides a pathway for internal pores and cracks caused by thermal mismatch, resulting in an irreversible decrease in the elastic modulus of the BC layer. Finally, a damage assessment method based on the fracture mechanics of the BC layer is established, providing theoretical and methodological support for predicting the lifespan of EBCs.

SIMULATION OF CRACK AND FRAGMENTATION OF MULTI-MATERIAL WITH MULTIPHYSICS

Xia Ma[*1]*

[1]*Los Alamos National Laboratory*

ABSTRACT

This study explores the simulation and modeling of crack spallation and fragmentation within multi-material systems, including both ductile and brittle components. The research, detailed in our recent publications (references 1 to 3), employs hydrodynamic simulations that intricately consider multiphysics phenomena such as chemical reactions, heat transfer, phase transition, and fluid-solid interactions. Understanding the behavior of cracks and fractures in energetic materials is crucial due to its significant impact on overall performance. However, the inherent prohibitive cost of experimental studies necessitates a comprehensive reliance on simulations.

This presentation highlights advancements in 3-D simulations, co-designed with experimental data and supported by a meticulous modeling process. Detailed aspects of the modeling approach are elucidated in various recent publications, acknowledging the limitation of three references. Our contribution extends beyond simulation techniques to novel insights, fostering a comprehensive understanding of multiphysics involved in crack and fragmentation dynamics.

The synergy of simulations with experimental data offers a comprehensive perspective on the behavior of multi-materials under extreme conditions with interaction of fragmentation of ductile metal and brittle energetic material. This research not only advances fundamental understanding but also provides practical insights into the design and behavior of materials subjected to dynamic multiphysics loading.

APPLICATION OF SYMPLECTIC METHOD IN FORCED VIBRATION OF ACOUSTIC BLACK HOLE BEAM, PLATE AND CYLINDRICAL SHELL STRUCTURES

Yongbin Ma[*1], Sen Zhang[1] and Zichen Deng[1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

In recent years, acoustic black hole structures (ABHs) have been revealed as an effective bending wave control technology. Several simulation strategies have been developed to analyze the ABH effect. However, ABH-profiled structures feature unique space-dependent wavenumber variation and wave celerity reduction over a broad frequency range. Therefore, most methods require a refined discretization scheme with high resolution in order to capture the strongly localized and highly oscillatory ABH behaviours, especially when the local wavelengths in ABH cells become shorter. Here, we introduce the symplectic method in forced vibration of acoustic black hole beam, plate and cylindrical shell structures. Various structural assemblies are provided, including: a primary beam attached by multiple ABH beams, a rectangular plate attached by multiple ABH beams, a rectangular plate attached by a ribbed or non-ribbed ABH plate, a circular cylindrical shell attached by a single ABH cylindrical shell or by periodical distributed ABH cylindrical shell. Analytical wave modes are obtained by solving the dual equations established from the vibration governing equations of each type of structural component. By considering the relationship of wave propagation, wave reflection and wave scattering, and using the developed equivalent dynamic flexibility and dynamic stiffness technique, the system equation of the structural assembly is formed in wave space. In numerical examples, forced vibration responses are calculated and validated. The significant vibration damping effect of the ABHs is verified and is explained from the point of view of waves.

IMPROVED ACCURACY FOR REGULARIZED LINE DELTA SOURCES

Jane Shaw MacDonald[*1], Nilima Nigam[1] and John M Stockie[1]*

[1]*Simon Fraser University*

ABSTRACT

The immersed boundary method uses the Dirac delta distribution to interpolate singular forces that arise in fluid-structure interaction problems containing flexible 1D structures that are defined along moving curves. Most numerical approaches regularise the Dirac delta distribution by discretising the interface at a sequence of points and then introducing a regularisation of the Dirac delta point-source over a finite support radius of size H centered at each interface point. The corresponding delta-forcing term is then interpolated onto an underlying fluid grid (with spacing denoted h) using appropriate quadratures. We derive an analytical form for a regularised line source that can be easily implemented in an immersed boundary framework. This regularisation is constructed independently of any specific numerical method and constrained to satisfy moment properties of the Dirac delta line source distribution. The regularisation can be chosen up to a predetermined spatial order of accuracy with respect to its support H. Using both finite element and spectral approximations of a 3D elliptic test problem, we compare the results for our regularised line source to that from the usual point-delta approximation and observe that the new line-delta regularisation exhibits much smaller numerical errors. This improvement is largely due to our capturing the invariance of the line source along the direction of the immersed structure, which cannot be done for point approximations. These conclusions are supported by a careful convergence analysis in both h and H. Finally, we present some preliminary results illustrating an application of this regularised line source to 3D simulations of periodically oscillating flow through kelp forests.

A POD-BASED METHODOLOGY FOR THE DESIGN OF MODULAR CARBON-REINFORCED CONCRETE STRUCTURES

Domen Macek[*1], Stephan Ritzert[1], Stefanie Reese[1], Tim Brepols[1] and Hagen Holthusen[1]*

[1]RWTH Aachen University

ABSTRACT

Finite element analysis of complex structural systems, which can be put together from independent modules, is computationally expensive. To increase computational efficiency, we have developed a new model order reduction technique that exploits the idea of reducing substructures independently of each other [1]. This means that the reduction of the degrees of freedom of the global system of equations is performed at the substructure level, i.e. modules (substructures) are reduced separately before being assembled. The dominant mechanical behavior of each individual module is represented by the POD modes, which form the projection matrix. The goal is to use this method to automatically generate and evaluate a large number of possible designs for carbon reinforced structures. The prediction quality of this model order reduction technique strongly depends on the selection of the sampled data. Therefore, we introduce and investigate new sampling strategies that are more suitable for the proposed method. The proposed model order reduction method is coupled with the tied contact algorithm [2] to allow for a more flexible connection of substructures. A handful of numerical examples are shown to demonstrate the suitability of the presented methodology for the design of complex carbon reinforced concrete structures.

AUTOMATED CALIBRATION OF SANISAND MODELS FOR PREDICTING SEISMIC LIQUEFACTION AND LATERAL SPREADING IN SLOPES

Jan Machaček[*1], Sheng Zeng[2] and Mahdi Taiebat[2]*

[1]*Technical University of Darmstadt*
[2]*University of British Columbia*

ABSTRACT

The reliable prediction of liquefaction and lateral spreading in soil slopes under seismic conditions is essential for earthquake hazard mitigation and depends on the precision of advanced constitutive models. These models require meticulous calibration to authentically represent soil behavior under cyclic loading, a critical factor in seismic analysis. Traditional calibration methods for such models demand a high level of expertise and are time-consuming, limiting their practical application. Addressing this challenge, this study introduces the Automatic Parameter Calibration Tool (ACT) to simplify and accelerate the calibration of the SANISAND model, directly addressing the challenges posed by modeling soil response to seismic forces. The ACT's effectiveness was extensively validated using the comprehensive dataset from the Liquefaction Experiments and Analysis Projects (LEAP), which provided detailed characterizations of Ottawa-F65 sand under cyclic shearing. The models, once automatically calibrated based on element-level tests, were applied to simulate LEAP's centrifuge tests, examining the seismic behavior of a liquefiable slopes. Incorporating the most recent enhancements to the SANISAND model, including memory surface and semi-fluidized state features, this study demonstrates the ACT's ability to not only improve the reliability of predictions but also to make the calibration process more efficient and less dependent on specialized expertise. This progress in calibration practice broadens the accessibility of sophisticated modeling techniques to a wider audience within the geotechnical engineering community. By improving the methodology for modeling slope behavior under seismic conditions, this study makes a substantial contribution to developing more precise and user-friendly seismic risk assessment tools.

SCRATCH TESTS MODELING USING FINITE ELEMENT APPLIED TO THE DESIGN OF MATERIALS' TRIBOLOGICAL PERFORMANCE

Vanessa Seriacopi[1], Ed Bordinassi[1], Adalto de Farias[1], Larissa Driemeier[2] and Izabel Machado[2]*

[1]Maua Institute of Technology
[2]University of São Paulo

ABSTRACT

Scratch tests can be developed on a microscale to study the tribological performance related to material phases. The investigation focused on the local effects of the second phase, which can help understand their responses when submitted to a unique abrasive action, which contributes to the design of material in tribological applications, e.g., biomedical, aerospace, and automotive. In this work, microscratch tests were conducted using a diamond cono-spherical tip of 10 um diameter against the following combination: (i) AISI 304 steel as soft homogeneous matrix; (ii) heterogeneous AISI 304 steel with TiN precipitates; (iii) AISI H13 as hard homogeneous matrix; and (iv) heterogeneous AISI H13 steel with NbC precipitates. Hard precipitates present between 6 and 10 times the matrix hardness measured using nanoindentation. During the tests, constant normal load ranges (50-150 mN: hard materials, and 40-80 mN: soft materials) were considered to assess the dominant abrasive mechanisms from the ploughing to cutting. An experimental-FEM numerical approach was implemented to obtain a robust comparison regarding the depth of penetration, friction coefficient, material removal, and specific cutting energy. The local results obtained for the hard second phases tend to allow conclusions as follows: decreased the local depth of penetration and, consequently, caused the reduction of local removed volume and increased local specific energy. When the penetration depth reached its critical size, particles were pulled out or fragmented on the material matrix, increasing the removed volume and modifying the amplitude of the specific energy. These achievements have made it possible to delineate maps to correlate abrasive micro-mechanisms on a microscale to the design of materials.

Design beyond optimization: Why, what if, and how much?

APPLICATION-DRIVEN MULTILEVEL DESIGN OF NONLINEAR MATERIALS

*Brianna MacNider**[1], Haning Xiu[1], Kai Qian[1], Ian Frankel[1], H. Alicia Kim[1] and Nicholas Boechler[1]*

[1]*University of California, San Diego*

ABSTRACT

Achieving high precision, wide ranging tailorability of nonlinear structural properties has the potential to enable custom ‘designer’ materials via the construction of bulk materials from repeated, designed unit cell structures. Such designer materials could be used for improved, even optimal, application specific performance. Recent advancements have led to the emergence of multiple methods for inversely designing structures for desired nonlinear properties, including both full topology optimization inverse design approaches [1, 2] as well as reduced order model and machine learning based methods [3]. Despite the great degree of recent interest, however, there has yet to be introduced a comprehensive design approach which incorporates both the identification of the ideal target nonlinearity (for specific loading conditions) and the realization of a structure demonstrating this identified nonlinear property. Depending on the situation and objective of interest, the introduction of nonlinearity in a system can actually have a detrimental effect on the performance. Thus, it is imperative that any approach looking to improve tailored materials for impact or wave tailoring consider both a search for an ideal target nonlinearity as well as the inverse design of the constituent structure. We address this by developing a multilevel design approach, with application to dynamic response problems. The resulting collective material response and performance are compared via simulation and experiment.

ABSTRACT

The rupture of earthquake-generating faults can be considered a catastrophic event generated by frictional instability propagating along a pre-existing shear crack. Initial stress in the vicinity of a fault is a major factor influencing the nature of the rupture. The most common approach for setting the initial stress is computing the fault normal and tangential stresses according to regional stress[1]. This empirical approach is an acceptable approximation for faults with simple geometric configurations. However, for faults with complex geometries and material distributions, it is challenging to identify initial stress that is consistent with fault geometry, residual stress concentrations, far-field loading, and the heterogeneous distributions of fault strength and material properties[1,2].

In this work, we propose a method to set the initial stress distribution entirely based on mechanical considerations according to the deformation induced by far-field loading and suitable friction laws. We model the fault rupture as a propagating crack front along a pre-existing shear crack under frictional contact. As the numerical method, we use PDS-FEM due to its simple and numerically efficient treatment for modeling discontinuities[3]. The ability to set the initial stress distribution entirely based on mechanical considerations makes it possible to set the initial stress consistent with any influencing factors such as complex fault geometry, nonlinear materials, and heterogeneous frictional properties. We verified the method by reproducing the supershear rupture of a straight fault in 2D settings and the underlying Burridge-Andrew rupture mechanism. Further, we simulate the rupture of the Palu-Koro fault under different initial conditions, producing a wide range of rupture behaviors, including sub-Rayleigh and supershear ruptures.

A MIXED HEXAHEDRAL SOLID-SHELL ELEMENT WITH SELF-EQUILIBRATED STRESSES FOR THE NONLINEAR STATIC ANALYSIS OF SHELL STRUCTURES

Antonio Madeo[*1], Francesco Salvatore Liguori[1], Giovanni Zucco[2] and Giovanni Garcea[1]*

[1]*University of Calabria*
[2]*University of Limerick*

ABSTRACT

Mixed finite elements with self-equilibrated assumed stresses have proven to provide several advantages for analysing shell structures [1]. They guarantee high performance when using coarse meshes and accurately represent the stress field.
This work exploits those advantages to develop a solid-shell finite element for the geometrically nonlinear static analysis of shell structures. In particular, an eight-node finite element, which has 24 displacement variables and 18 stress parameters, is developed. The displacement field is described only by translations, eliminating the need for complex finite rotation treatments in large displacement problems [2]. A Total Lagrangian formulation is used with the Green-Lagrange strain tensor and the second Piola-Kirchhoff stress tensor.
Thickness locking is cured using an assumed natural strain formulation for the transversal normal stress, and the assumed stress field eliminates shear locking. Nonlinear constitutive laws are considered using a dual decomposition approach [3]. In this way, the standard return mapping algorithms available in displacement-based formulations can be re-used for the proposed mixed finite element.
The resulting formulation is efficient and easy to implement. Computed numerical results show the accuracy and robustness of the presented element when used for both the linear and nonlinear elastic static analyses of shell structures.

TOWARDS A CLINICALLY RELEVANT MODEL OF THE HEART

Anna Madra[*1], Rika Kawakami[1], Katherine Murphy[1], Renu Virmani[1] and Aloke V. Finn[12]*

[1]*CVPath Institute*
[2]*The University of Baltimore*

ABSTRACT

The majority of mechanical simulations are being performed on highly simplified models of the human heart which do not necessarily capture details relevant for implant placement and pathological analysis. High-resolution volume imaging like X-ray microtomography (microCT) can be used as a source of data for generating anatomically correct models. The main challenge in rendering it useful for modeling is controlling the variability of the models, stemming both from the specimen preparation – influence of fixation, staining, and imaging parameters, and from morphological variability, even among normal, healthy hearts. We aim to explore a pathway towards tackling the second problem by proposing a framework relying on a reduced-order model representation of the human heart with specimen variability captured by the probability distribution derived from the experimental dataset imaged with microCT. The primary representation will address normal morphology in the function of relevant metadata like age, weight, height, and estimated calcium score. The added value of metadata parameterization will also allow to postulate models with abnormalities in need of different clinical interventions.

ABSTRACT

The finite volume method (FVM) enjoys widespread popularity in the realms of science and engineering for its ability to conduct high-fidelity simulations of complex physical phenomena. By discretizing the integral forms of governing physical equations, FVM enables the computation of approximate solutions while preserving conservation laws. Spatial discretization of a domain is typically achieved through the use of one of two main mesh types: structured and unstructured meshes. Structured meshes employ a periodic, grid-like structure to discretize the domain. Conversely, unstructured meshes do not abide by a periodic structure, permitting mesh components to be arbitrarily ordered [1].
Deploying fine meshes for high-fidelity FVM models often incurs high computational costs that become intractable for many-query tasks, such as design optimization, uncertainty quantification, and real-time rendering. To overcome this limitation, projection-based model order reduction (PMOR) has emerged as a field of applied mathematics that aims to reduce computational cost. PMOR achieves dimensional compression by computing a low-dimensional latent space in an offline stage based on several solutions of the high-dimensional model. Then, in an online stage, PMOR projects the high-dimensional model equations onto a low-dimensional latent space, thereby reducing operational count complexity.
Recently, the deep least-squares Petrov-Galerkin (dLSPG) framework has been developed to overcome the limitations of traditional affine latent spaces when applied to advection-dominated flows [2]. dLSPG leverages an autoencoder to find a nonlinear mapping between a high-dimensional system and a low-dimensional latent space. Unfortunately, dLSPG uses an autoencoder constructed with convolutional neural networks, which are inherently dependent upon structured meshes. As a result, direct application of dLSPG to unstructured meshes is currently untenable. Fortunately, graph neural networks have been developed to extract useful information from sets of unstructured and relational data [3], making them an appropriate candidate method for generating low-dimensional latent spaces of models with unstructured meshes. We present geometric deep least-squares Petrov-Galerkin, a PMOR method that leverages a novel graph autoencoder to perform dLSPG on FVM when deploying an unstructured mesh.

B-SPLINE S-VERSION OF FINITE ELEMENT METHOD FOR BOUNDARY VALUE PROBLEMS FOR FLUIDS

Nozomi Magome[*1], Naoki Morita[1], Shigeki Kaneko[2] and Naoto Mitsume[1]*

[1]*University of Tsukuba*
[2]*The University of Tokyo*

ABSTRACT

Our main focus is to analyze a flapping-wing motion of a free-flying insect as a fluid–structure interaction (FSI) phenomenon. Numerical methods to deal with moving boundaries in FSI analysis can be categorized into tracking and capturing methods. However, the tracking method may generate distorted mesh for a fluid domain, which makes the calculation unstable, because the flapping motion is associated with a large deformation, movement, and contact of boundaries. On the other hand, the capturing method can not maintain high-resolution boundary layer meshes for the moving boundary layers, resulting in low accuracy.

To overcome these challenges, we use structured meshes based on the interface capturing method, and for high spatial resolution in an arbitrary local domain, we try to apply s-version of FEM (SFEM)[1], which has been studied mainly in the field of structural mechanics. Because SFEM can reasonably model an analytical domain by superimposing meshes with different spatial resolutions, it has intrinsic advantages of local high accuracy, low computation time, and simple meshing procedure. For the first step of these challenges, we have developed B-spline based SFEM (BSFEM)[2] for the Poisson equation as a simple case. Although conventional SFEM has problems with the low accuracy of numerical integration and poor convergence for solving linear equations, we have proposed BSFEM that introduces both B-spline and Lagrange basis functions and has achieved significant improvements in accuracy and convergence.

The purpose of this study is to improve localized mesh refinement in interface-capturing approaches for moving boundary problems. As the next step, we apply BSFEM to boundary value problems for fluids. In this framework, one structured mesh based on the interface capturing method is applied to the entire domain, and a higher resolution mesh based on the interface tracking method is superimposed on the boundary layers and the surrounding area which require high spatial resolution. To describe boundaries in the structured mesh, we combine immersed boundary methods with BSFEM. We verify our proposed method by solving three-dimensional flow around a circular cylinder. The results confirmed that the proposed model can obtain sufficient accurate and stable solutions.

ML SURROGATES FOR MODEL CALIBRATION AND ERROR QUANTIFICATION IN HIGH-DIMENSIONAL PROBLEMS

Yulin Guo[1] *and Sankaran Mahadevan**[2]

[1]*University of California, San Diego*
[2]*Vanderbilt University*

ABSTRACT

We propose a novel approach for model calibration and error quantification for high-dimensional problems with ML surrogates. In this approach, model discrepancy can be propagated from the measured quantities of interest (QoIs) to quantify uncertainty in the predictions of unmeasured QoIs. Such extrapolation situations occur when the predicted QoI is at a different location/time than the measurement of the same quantity, or when the predicted QoI is altogether different from the measured quantity. In the proposed approach, all the outputs of the system model are first mapped to an uncorrelated latent space, and surrogate models are constructed for the dominant principal features. Such mapping can readily handle high-dimensional output; in addition, for high-dimensional input, active subspace discovery is used to reduce the input dimension. Discrepancy terms are introduced in the latent space and estimated through Bayesian calibration using the measured quantities. The posterior distributions of the discrepancy terms (in the latent space) and the model parameters and observation errors (in the original space) are then propagated through the physics model to quantify the uncertainty in the prediction of the unmeasured QoIs. The formulation of discrepancy terms in the latent space offers a rigorous and efficient approach to propagate the model discrepancy information from measured to unmeasured QoIs, compared to existing approaches that either modify/augment the model parameter distributions or estimate the model form errors in the governing equations. The proposed approach is demonstrated for an additive manufacturing application, employing a heat transfer model for temperature distribution and a mechanical model for residual stress prediction in the manufactured part.

SOMA: SCALABLE OPERATOR ABSTRACTIONS FOR REPRESENTING UNSTRUCTURED MESHES

Vijay Mahadevan[*1] and Lulian Grindeanu*[1]

[1]*Argonne National Laboratory*

ABSTRACT

Efficient representations of unstructured meshes play a crucial role in manipulating and navigating cell topology, a fundamental aspect of scale-resolving computational physics solver infrastructures designed for modeling complex phenomena on intricate geometries. Diverging from conventional pointer-based structures commonly found in many finite-element codes, our proposed redesign centers around incidence relation maps between entities of different types and dimensions, stored as either dense or sparse linear operators. This representation, coupled with a hash-based map for efficient entity storage and retrieval from memory, ensures portable scalability across heterogeneous architectures. This adaptability facilitates arbitrary relational queries between topological entities like up/down adjacencies and n-ring neighborhood queries to accelerate computational solvers. With support for MPI domain decomposition and a thread-safe, device-aware design, iterating through coincidence matrices stored as linear operators scalably enhances memory locality for both connectivity and adjacent queries. Additionally, the capability to define and serialize data fields on arbitrary entity types as contiguous in-memory ndarrays also provides coalesced access, especially for multicomponent systems.

In this talk, we present the details on the algorithmic infrastructure and implementation specifics of the new unstructured mesh C++ SOMA library based on a variety of backend adaptors for portably running on multinode CPU/GPU. We will also compare the computational complexity and memory footprint of our approach with some state-of-art mesh implementations, across a range of unstructured mesh query patterns that are common in solver workflows. Finally, some advanced use cases such as hierarchical mesh generation for multigrid solvers and conservative remapping for coupled multiphysics simulations which are streamlined by the algorithms developed on this infrastructure will be discussed.

COMPUTATIONAL MODELING OF UHMWPE FABRIC IMPREGNATED WITH A NEW CHEMICAL CROSSLINKER AND SHEAR THICKENING FLUID

Mahshid Mahbod[1], Stefania F. Musolino[2], Jeremy E Wulff[2], Reza Vaziri[1] and Abbas S. Milani[1]*

[1]*University of British Columbia*
[2]*University of Victoria*

ABSTRACT

Ultra-High Molecular Weight Polyethylene (UHMWPE) fabrics have seen widespread utilization across various engineering domains, with a particular emphasis on impact and puncture protection. This popularity stems from their superior mechanical attributes, characterized by high strength and modulus, along with low density [1, 2]. This study presents computational modeling of a new crosslinked UHMWPE fabric infused with a Shear Thickening Fluid (STF).
To assess the impact of STF and crosslinkers on the fabric's mechanical behavior, three sample groups were prepared: untreated fabric, crosslinked fabric, and crosslinked fabric impregnated with STF. A two-layer finite element model was developed using the VFABRIC feature in Abaqus/Explicit to simulate the nonlinear in-plane and out-of-plane bending behaviors of the base fabric material. The first layer represents the material's in-plane behavior using 4-node quadrilateral membrane elements, while the shell elements in the second layer represent the bending behavior. To characterize the in-plane and out-of-plane behaviors, tensile, bias extension and Pierce bending tests were conducted, and the numerical model parameters were calibrated accordingly. Fabric elements were deemed to have failed when their stress reached a critical value in either the weft or warp yarns. Verification of the model was performed for all three sample groups under tensile and shear loading modes. Subsequently, the crosslinked UHMWPE fabric/STF model was validated using an independent puncture test. Finally, a statistical analysis was carried out to determine the effects of simulation parameters and ascertain the stress threshold for element deletion. This investigation focused specifically on the friction coefficient, identified as a crucial parameter that proved challenging to reliably obtain from physical testing.
Keywords: UHMWPE fabrics, finite element simulation, Shear thickening fluid, Puncture testing.

HIERARCHICAL SHRINKAGE GAUSSIAN PROCESSES: APPLICATIONS TO COMPUTER CODE EMULATION AND DYNAMICAL SYSTEM RECOVERY

Simon Mak[*1]

[1]*Duke University*

ABSTRACT

In many areas of science and engineering, computer simulations are widely used as proxies for physical experiments, which can be infeasible or unethical. Such simulations can often be computationally expensive, and an emulator can be trained to efficiently predict the desired response surface. A widely-used emulator is the Gaussian process (GP), which provides a flexible framework for efficient prediction and uncertainty quantification. Standard GPs, however, do not capture structured sparsity on the underlying response surface, which is present in many applications, particularly in the physical sciences. We thus propose a new hierarchical shrinkage GP (HierGP), which incorporates such structure via cumulative shrinkage priors within a GP framework. We show that the HierGP implicitly embeds the well-known principles of effect sparsity, heredity and hierarchy for analysis of experiments, which allows our model to identify structured sparse features from the response surface with limited data. Finally, we demonstrate the improved performance of HierGP over existing models, in a suite of numerical experiments and an application to dynamical system recovery.

CHANGE POINT DETECTION FOR INDIRECT STRUCTURAL HEALTH MONITORING

Mehri Makki Alamdari[*1], Elena Atroshchenko[1], Kai-Chun Chang[2] and Chul Woo Kim[2]*

[1]*University of New South Wales*
[2]*Kyoto University*

ABSTRACT

The problem of Indirect Structural Health Monitoring or Drive-by Bridge Scanning has been extensively studied during the last decade [1]. Many of the developed frameworks suffer from the necessity for a large amount of indirect sensing data to learn and train data-driven models. Having access to such many observations may not be readily available in the context of drive-by inspection. Further, some of these techniques are based on supervised learning which makes them impractical as access to labeled data, if not impossible, is very challenging or expensive in a practical setting. In this paper, we overcome these burdens through a robust framework based on the concept of change point detection and unsupervised semantic segmentation. Time-series data are often characterized by a large degree of self-similarity due to the presence of repeated patterns. Unexpected irregularities due to any change in the state of a bridge structure introduce dissimilar patterns. Therefore, change point detection can be obtained by leveraging this self-similarity that exists in time series data. In particular, we rely on Matrix Profile, an emerging and promising tool for time series data mining, to conduct an all-pair-similarity search and discover any new patterns in time series of vehicle acceleration responses. The highest point on the matrix profile corresponds to the time series discord where a subsequence is maximally different from all other subsequences. In contrast, the lowest points on the profile correspond to the locations of the motifs with repeated patterns within the time series. Thus, by examining the matrix profile, the location of any potential anomaly can be inferred as the matrix profile at this location has its largest value due to the fact that this part is the most dissimilar part to the rest of the time series. The performance of the method is numerically evaluated through extensive investigations considering different damage cases where the effect of operational uncertainties such as road roughness, and variability in vehicle properties are taken into account. The technique is capable of working with a limited amount of data yet providing successful results which demonstrates the potential of the proposed method as a cost-effective and rigorous bridge inspection tool and opens up opportunities in the field of indirect bridge health monitoring.

ABSTRACT

The concentration of glucose in sweat has recently been measured with high sensitivity, selectivity, and reproducibility using nanostructured Ni/NiO electrodes that are manufactured through the glancing angle deposition (GLAD) technique. The GLAD technique generates nanocolumns with control over morphological properties, such as shape, porosity and film thickness, providing ample opportunities to enhance sensor performance. Currently, the selection of optimal GLAD parameters is determined experimentally through trial and error, incurring high costs in time and resources. Numerical simulations allow alternative parametric investigations of GLAD electrode geometries to obtain optimal sensor performance. In this study, surface reactions occur at the nano scale. To accurately capture these surface reactions at the nano level, our objective is to generate geometries that closely resemble the actual sensor structures to enhance the sensor modeling's predictive capabilities. To achieve this, we have utilized an on-lattice kinetic Monte Carlo (kMC) model for GLAD of Ni and NiO. Within the realm of kMC simulations, two fundamental processes occur: deposition, during which atoms settle onto the surface, and diffusion, in which atoms hop between different locations on the surface. Two crucial parameters in the deposition step, the incident angle of the incoming flux and the speed of substrate rotation are considered in the model. While the kMC method exhibits accuracy in our specific context, the process of generating a single GLAD sensor structure with a domain size of 100 nm × 100 nm × 1000 nm can be time consuming. Hence, the implementation of parallel simulation holds the potential to enhance the efficiency of the existing kMC scheme. To validate the model, the simulated structures are compared with SEM images from real cases. To the best of our knowledge, this model provides the first atomically resolved parallel model of the GLAD process. This research offers new guidance for rapidly designing highly effective sensors with increased sensitivity and lower limits of detection.

MODELING PHASE-FIELD FRACTURE USING PHYSICS-INFORMED DEEP LEARNING

Manav Manav[1], Roberto Molinaro[1], Siddhartha Mishra[1] and Laura De Lorenzis[1]*

[1]*ETH Zurich*

ABSTRACT

Phase-field modeling of fracture [1] recasts fracture as a variational problem which completely describes the fracture processes including crack nucleation, propagation, bifurcation, and coalescence, and obviates the need for any ad-hoc criteria. In this approach, a crack is regularized by introducing a phase-field in the formulation. Regularization leads to a nonlocal model which includes a small length scale. Resolving this length scale in computation is expensive. Hence, uncertainty quantification, material parameter identification, design optimization, among others, using this approach become prohibitively expensive. Recent advances in deep learning for applications in scientific modeling and computation [2] provide promising pathways to resolve this challenge. We explore their application to phase-field fracture modeling within the framework of physics-informed neural networks (PINNs). Since phase-field fracture is governed by a nonconvex variational energy, we employ Deep Ritz method (DRM) [3] in which the solution field is represented by a neural network (NN) and the training of the network proceeds by directly minimizing the variational energy of the system.

We solve some benchmark problems in phase-field modeling of crack nucleation, propagation, branching, and coalescence using deep learning. We first study crack nucleation in a 1-D homogeneous bar with prescribed end displacements. Using this example, we elucidate the challenges in obtaining solution using NNs with the same level of domain discretization as needed in finite element analysis. Then we discuss crack nucleation in an L-shaped panel and point to the challenges that NNs face in learning the nucleation of a crack in 2-D. We also study crack propagation and branching in a single edge notched plate under tension and shear loading. The presence of spurious energy minima makes it challenging to obtain the correct solution when prescribed displacement is not purely tensile. Finally, we show that appropriately designed NNs can learn crack coalescence as well. The details of the models and the challenges in obtaining the correct solution will be discussed.

ABSTRACT

Liver transplantation is the sole therapeutic remedy for addressing acute and chronic end-stage liver diseases. However, the increasing prevalence of elderly and multi-morbid donors and recipients introduces challenges. Grafts procured from such donors frequently manifest compromised quality due to hepatic steatosis, adversely impacting tissue structure, perfusion, metabolism, and overall organ function. The decision-making process by surgeons regarding the acceptance or rejection of marginal grafts faces a critical dilemma: The postoperative risk for the recipient has to be weighted against the risk of mortality while on the organ waiting list. Two primary challenges of marginal liver grafts involve the storage duration between organ procurement and transplantation (cold ischemia) and the ischemia-reperfusion injury (IRI).

A promising approach to unfold the intricate interplay of deformation, perfusion, and function in the liver involves computational continuum-biomechanical modeling of tissue (cf. [1]). The liver lobules, serving as the functional units, are hereby represented as a homogenized porous medium based on the theory of porous media (TPM). By incorporating cellular metabolic processes, a poroelastic multiphase and multiscale function-perfusion model is obtained (cf. [2, 3]), coupling partial differential equations on the lobular scale with ordinary differential equations on the cellular scale. Healthy liver, necrotic, and fatty liver tissue are considered as solid phases combined with a fluid phase with anisotropic perfusion. Systems biology approaches are utilized to include energy balance, death, and functionality on a cellular level. Consequently, a spatiotemporal model emerges, capable of describing the damage caused by oxygen and nutrient depletion during ischemia (cf. [3]).
The integration of experimental and clinical data for parameterization and validation alongside prior knowledge embedded in computational models significantly enhances its real-world applicability for assessing IRI based on simulating the spatiotemporal evolution of the system. A hybrid classical and machine-learning-based image analysis technique, extracts liver lobule geometry and steatosis zonation patterns from histopathological images. Laboratory data provides initial and boundary values, alongside information on the transplantation process, such as cold ischemia time. This comprehensive framework offers a predictive and patient-specific assessment of IRI, representing an important advancement towards a support tool for clinical decision-making (cf. [1]).

A DYNAMIC WEIGHTED LOSS FUNCTION FOR ENHANCING THE PERFORMANCE OF NEURAL NETWORKS

Chetra Mang[*1], Axel TahmasebiMoradi[1], David Danan[1] and Mouadh Yagoubi[1]*

[1]*IRT SystemX*

ABSTRACT

In machine learning process, hyper parameters are chosen in a way to decrease the prediction error and improve the convergence. However, the optimized hyper parameters have a limit in terms of enhancing the performance of the neural networks.
In this work, the datasets used for the numerical experiments arise from the resolution of partial differential equations (PDE) defined on a spatial domain. We propose a dynamic weighted loss function-based approach for neural networks that are used to learn these PDE's solutions. This a two-step process: first we train for a few numbers of epochs in a classical way then the dynamic weighted loss function replaces the classical loss function by leveraging the information from past training error histories. To validate this method, we carry out numerical experiments with different neural networks on datasets arising on three different physics: Goldstein equation [1], radiative transfer equation [2] and contact mechanics [3]. Thus, in order to demonstrate the relevance of this approach, we provide a comparison among a neural network model using a classical loss function, with and without hyper parameters optimization, and a dynamic weighted loss function for both versions.

AI BASED SHAPE OPTIMIZATION OF AUTOMOTIVE RUBBER PARTS

Tamás Mankovits[*1] and David Huri*[1]

[1]*University of Debrecen*

ABSTRACT

Rubber bumpers built into the air springs of buses perform several crucial functions, such as working together with the air spring as a secondary spring, thus modifying the original characteristics of the system when pressed together. It is a fundamental requirement that they should have a prescribed load-displacement curve. Setting this objective results in a shape optimization task. The optimization aims to achieve a specified characteristic through the geometric design of the rubber bumper while the material characteristics remain the same. In connection with the objective set, achieving the aim of the optimization will require an efficient force-displacement calculation, which is performed using the finite element method. Considering that the series of finite element runs of non-linear problems are time-consuming, therefore Support Vector Regression as a surrogate model was used to replace the costly engineering simulations and to support the shape optimization. A simulated annealing algorithm with an adaptive search space and different cooling schedules was developed for the shape optimization of rubber bumper. The novel method is capable to solve the optimization task of the rubber bumper with high accuracy in plannable time and high automation. Due to the automated process, the developed method can be integrated into product development.

DISCOVERING INTERPRETABLE PHYSICAL MODELS USING SYMBOLIC REGRESSION AND DISCRETE EXTERIOR CALCULUS

Simone Manti[*1], Mohammad Shojaeifard[2], Mattia Bacca[2] and Alessandro Lucantonio[1]*

[1]Aarhus University
[2]University of British Columbia

ABSTRACT

Mathematical modeling and numerical simulations are powerful tools for understanding physical systems within contemporary scientific research and engineering. The abundance of data has enabled the use of Machine Learning (ML) to enhance model identification from experiments and improve the accuracy and performance of the simulations. However, purely data-driven models often suffer from limited generalization and interpretability. To address these challenges, Symbolic Regression (SR) has been proposed to discover equation-based models, which are inherently interpretable and amenable to analysis. Previous investigations have been limited to classical equations of Physics and mainly to single-Degree-Of-Freedom or dynamical systems, which are governed by algebraic or ordinary differential equations. In this work [1], we advance the state-of-the-art by combining SR with Discrete Exterior Calculus (DEC) [2] to enable the discovery of field theories. The use of a universal, discrete mathematical framework specifically tailored for physics enhances the generalizability of the recovered models, even in small-data scenarios. Additionally, DEC allows to implement strongly-typed SR, thus ensuring the mathematical and physical consistency of the recovered model equations and reducing the search space of the SR. We validate our approach by successfully re-deriving three Continuum Physics models from synthetic experimental data: the Poisson equation, Euler's Elastica, and the Linear Elasticity equations. Finally, we present preliminary results regarding the use of our framework to derive coarse-grained models of crack propagation in soft polymers, a research problem that aims at elucidating the fundamental damage and fracture mechanisms in these materials, which are still poorly understood.

A C 1 CONFORMING ARBITRARY-ORDER TWO-DIMENSIONAL VIRTUAL ELEMENT METHOD FOR THE FOURTH-ORDER PHASE-FIELD EQUATION

*Gianmarco Manzini**[1]

[1]*Los Alamos National Laboratory*

ABSTRACT

We present a conforming virtual element method [1] for the two-dimensional High-Order Phase Field (HOPF) equation [2]. This is a fourth-order equation, and our numerical approximation relies on the design of an arbitrary order accurate, virtual element space with C 1 global regularity. Such regularity is guaranteed by taking the values of the virtual element functions and their full gradient at the mesh vertices as degrees of freedom. High-order accuracy also requires edge polynomial moments of the trace of the virtual element functions and their normal derivatives. A set of representative test cases assess the behavior of the method.

ABSTRACT

Machine learning has seen widespread application in fluid mechanics. Traditional neural networks, which approximate functions by mapping inputs (either scalar or fields) to outputs, are not well-suited for learning parametric systems. These systems typically involve inputs that include both parameters and coordinates, and their outputs are solutions. To address this, Deep Operator Networks (DeepONets) have been developed.

We present two papers focusing on the application of DeepONets in astrophysical fluid dynamics governed by the Navier-Stokes equations. The first paper introduces a ML tool based on DeepONets mapping PDE parameters to their corresponding solutions. This tool is trained using simulation data. We observed that vanilla DeepONets struggle to accurately represent sharp spatial features in solutions, which vary with input parameters. This indicates a difficulty in learning the nonlinear relationship between PDE parameters and coordinates. To overcome this, we propose a modified DeepONet architecture that converges faster and reduces the error in sharp features by an order of magnitude. Our tool can predict solutions at a rate of one per second on a CPU and forty per second on an NVIDIA V100 GPU, significantly faster than traditional numerical methods, which require thousands of CPU hours. We extensively tested the prediction accuracy of our tool and demonstrated its application in astronomical problems.

The second paper addresses the inverse problem: inferring parameters from unseen solution data. We combine trained DeepONets with a state-of-the-art optimization algorithm, the Covariance Matrix Adaptation Evolution Strategy (CMA-ES). This combination employs an iterative forward-backward approach. In each iteration, we update the PDE parameter samples to converge towards ground truth values, generate new parameter samples, evaluate the corresponding solutions using DeepONets, and compare them with the data to be fitted. The fitness of parameter candidates to the data is assessed by CMA-ES, which then updates the PDE parameter samples for the next iteration.

We tested our inverse problem solver on a group of datasets, each containing 256 solutions. Running on an NVIDIA GPU, this tool can evaluate 50,000 parameter candidates in thirty minutes and iterate the parameter samples a hundred times. Due to this extensive exploration of the parameter space, our method infers parameters with an error within 1% of the ground truth. It also remains robust with noisy or obscured data (data with missing pixel values), maintaining the same level of accuracy as with clear data. We demonstrate the potential application of our tool in astrophysical fluid dynamics.

Phase-field interface modeling for multiphase and multiphysics simulations

A 3D PHASE-FIELD BASED EULERIAN VARIATIONAL FRAMEWORK FOR MULTIPHASE FSI WITH CONTACT BETWEEN SOLIDS

Xiaoyu Mao[*1] and Rajeev Jaiman*[1]

[1]*University of British Columbia*

ABSTRACT

Using a fixed Eulerian mesh, interface-capturing approaches such as volume-of-fluid, level-set and phase-field methods have been successfully utilized for a broad range of moving boundary problems involving multiphase fluids and single-phase fluid-structure interaction. Nevertheless, multiphase fluids interacting with multiple solids are rarely explored, especially for large-scale finite element simulations. In this work, we introduce a novel parallelized three-dimensional fully Eulerian variational framework for simulating multiphase fluids interacting with multiple deformable solids with contact between solids. In the framework, each solid or fluid phase is identified by a standalone phase indicator. Moreover the phase indicators are initialized by the grid cell method, which restricts the calculation to several grid cells instead of the entire domain and thus evolved by the corresponding phase-field equation in the fixed mesh. A diffuse interface description is employed for a smooth interpolation of the physical properties across the phases, yielding unified mass and momentum conservation equations for the dynamics. For each solid object, temporal integration is carried out to track the strain evolution in an Eulerian frame of reference. The coupled differential equations are solved in a partitioned manner and integrated via nonlinear iterations. We first verify the framework against reference numerical data in a two-dimensional case of a rotational disk driven by lid-cavity flow. The case is generalized to a rotational sphere driven by lid-cavity flow to showcase large deformation and rotational motion of solids and examine the convergence in three dimensions. We then simulate the falling of an immersed solid sphere on a solid block under gravitational force to demonstrate translational motion and contact of solids in a fluid environment. Finally, we demonstrate the capability of our proposed framework for a ship-ice interaction problem involving multiphase fluids with an air-water interface and contact between a floating ship and ice floes.

ABSTRACT

Additive manufacturing (AM) allows for part fabrications by successive layer deposition with advantages like flexibility in design and material waste reduction [1]. Within the AM technologies, fused filament modeling (FDM) is one of the most widespread processes because of its low-cost implementation and accessibility [2]. However, empirical models are not adapted for the description of the behavior of AM parts. One of the challenges is to develop appropriate models for the prediction of AM material responses considering the range of process parameters. In this study, integrated digital image correlation (I-DIC) [3] is used for the identification of constitutive parameters of two configurations of acrylonitrile butadiene styrene (ABS) samples.
Two single edge notched tension (SENT) samples obtained by FDM have been tested. In one sample, the filaments were oriented at ±45° and in the other one they followed the direction of maximum strains. During the tests, the images of both sample surfaces were recorded. The acquired images were used for the calibration of constitutive parameters via I-DIC. Before launching the identification step, some pre-processing was made. The DIC results were used to determine the standard displacement and force uncertainties. Several computations using coarse meshes to approximate the solution at convergence, estimating the identifiability of the material parameters and checking whether the investigated solution corresponded to a local or global minimum were conducted. After this preliminary step, complete computations were run with fine meshes. The uncertainties associated with each calibrated parameter were estimated using their covariance matrix, and the evaluation of their identifiability using the total Hessian matrices at convergence were possible.
The calibrated parameters were used to conduct simulations of simple tensile tests. They were compared to stress-strain curves obtained in others studies on standard tensile tests. It is shown that an isotropic elastoplastic model calibrated from one SENT specimen described correctly the behavior of 3D printed ABS parts independently of the internal infill strategy.

DG0/CR DISCRETIZATION OF PHASE-FIELD FOR FRACTURE

Frederic Marazzato[*1] and Blaise Bourdin*[2]

[1]*University of Arizona*
[2]*McMaster University*

ABSTRACT

Phase-field methods for fracture have shown their great abilities over the last 20 years at computing crack paths in elastic domains. However, due to the Ambrosio-Tortorelli regularization of the elastic energy, one necessarily has $\sigma \cdot n = 0$ in the crack. This forbids the direct imposition of a pressure p inside the crack as $-pn \neq 0 = \sigma \cdot n$.

To remedy this problem, we propose a new discretization of the Francfort-Marigo functional which does not consist in using P^1 Lagrange elements and an Ambrosio-tortorelli regularization.
Building on the previous work [Bourdin and Marazzato, 2023], we use instead Discontinuous Galerkin (DG) and Crouzeix-Raviart (CR) mixed elements. The phase-field term is conserved in its usual form but the coupling between elasticity and phase-field happens in a penalty term and not through the elastic term. This allows to impose $\sigma \cdot n = -p n$ inside the crack.

We propose to explain why this new methodology is coherent with the Francfort-Marigo functional though Γ-convergence and show its relevance though numerical examples.

EXPERIMENTAL INVESTIGATION AND MODELLING OF DAMAGE PHENOMENA IN FDM-3D PRINTED MATERIALS

Sonia Marfia[*1], Denis Linardi[1] and Elisabetta Monaldo[1]*

[1]*Roma Tre University*

ABSTRACT

In the last decade, the additive manufacturing based on fused deposition modelling (FDM) has become increasingly attractive in diverse engineering fields. For successful applications of 3D printed structural elements as end-user parts, reliable performance in terms of stiffness and strength properties has to be ensured. There are numerous experimental studies that mainly investigate the stiffness properties of the 3D printed materials as a function of several printing parameters. However, only few studies, have characterized the failure mechanisms of 3D printed samples and the crucial role of the bond properties between adjacent fibers on the overall strength of printed elements [1].

This work aims to propose a deep experimental campaign in order to investigate the damage phenomena in 3D printed materials as a function of printing parameters. On the base of these experimental results, an innovative non-local orthotropic damage and plasticity phenomenological model is proposed. The effective mechanical behaviour of 3D printed structural elements is described by means of the composite laminate theory {2]. Each layer of the laminate is described with an orthotropic elasto-plastic constitutive behaviour and the Tsai-Hill yield limit function is adopted. Moreover, the stiffness degradation of the material is described by means of three damage variables specially introduced to describe the different damage phenomena (i.e., fiber failure, inter-layer and intra-layer damage) occurring under different loading conditions, as highlighted by the analysis of the 3D printed samples after the failure.

Some numerical applications are carried out, comparing numerical results with the experimental ones. The proposed model proved to be able to reproduce the range of failure modes from brittle-like to ductile that characterize the mechanical behaviour of 3D printed materials.

MODEL IDENTIFICATION: A HYBRID SINDY-NONLINEAR KALMAN FILTERING APPROACH

Luca Rosafalco[1], Paolo Conti[1], Andrea Manzoni[1], Attilio Frangi[1], Alberto Corigliano[1] and Stefano Mariani[1]*

[1]Politecnico di Milano

ABSTRACT

A new data-driven procedure for model identification in structural dynamics is proposed. The method features a combination of SINDy (Sparse Identification of Non-linear Dynamics) for model discovery and nonlinear Kalman filtering for data assimilation. To properly deal with problem nonlinearities, solutions based on the extended or the unscented Kalman filter are offered, in the latter case avoiding to handle the Jacobian of system evolution and leveraging parallel computing. SINDy is based on the solution of a sparse regression problem starting from time-series data [1]; Kalman filters can then be exploited to set the coefficients weighting a dictionary of pre-defined functions, that collectively mimic the actual system dynamics. Within a joint identification framework, the input to the data assimilation problem can be represented by system dynamics (like nodal displacements, velocities, and accelerations in a space-discretized model), forcing terms and, possibly, additional parameters describing some physical properties of the system itself (like e.g. its stiffness and damping). Aiming to provide an adaptive digital twin of mechanical systems, the aforementioned parameters may evolve in time due to degradation phenomena. To avoid performing SINDy anytime the output of the digital twin is characterized by a too-large drift away from the measured response, and to also account for prior information regarding the identified system, the use of nonlinear filters is here explored, see e.g. [2]. The offered solution has clear computational advantages to move towards real-time monitoring strategies of existing structures: by modifying on-the-fly the values of the physical parameters used as input for the SINDy functions, the methodology can also overcome issues related to the inadequacy of the modeling assumptions [3]. The methodology is assessed against some case studies characterized by either a linear or a nonlinear behavior, to testify the improvement over other state-of-the-art techniques.

ENERGY-CONSISTENT SPLITS IN PHASE-FIELD MODELLING OF ANISOTROPIC BRITTLE FRACTURE VIA PHYSICALLY INTERPRETABLE STRAIN MODES

ABSTRACT

In the realm of phase field models for brittle fracture, a pivotal consideration involves the division of strain energy density functions into damaging and non-damaging components.

In contrast to isotropic materials, strategies for decomposing the strain-energy density of anisotropic materials represent ongoing research challenges. Existing solutions often prove inconsistent, either from an energetic or a constitutive perspective. Consistent generalizations of strain-energy decompositions in anisotropic materials are limited [1]. One approach employs principal value decomposition, allowing for the introduction of either a generalized version of spectral energy decomposition or an orthogonal decomposition of the strain tensor using the scheme proposed by He and Shao [2]. Another approach is founded on a generalized version of the hydrostatic and deviatoric split in terms of energies.

Analytical formulas are notably absent in all cases, owing to the spectral decompositions of energy-related expressions or the stiffness tensor. Additionally, unlike isotropic materials, the proposed decompositions suffer from a weak kinematic interpretation, impacting the physical interpretability of results. Furthermore, existing approaches often exhibit weaknesses in terms of numerical robustness.

This study introduces a novel approach for transversely isotropic materials, providing easily applicable analytical formulas and a succinct physical interpretation. The method builds upon recent findings by Marino and Wriggers [3], utilizing Walpole's formalism for representing transversely isotropic stiffness tensors. Leveraging this framework, the study achieves an energy-consistent split, grounded in kinematic arguments, of strain energies for transversely isotropic materials. This innovative approach is detailed within the context of the phase-field method for brittle damage of transversely isotropic materials, with its effectiveness explored through numerous numerical examples.

A METHODOLOGY TO QUANTIFY ENTROPY GENERATED DURING FATIGUE OF CF/PEKK COMPOSITE LAMINATES: CONSTITUTIVE MODEL

Ricardo Marques[*1], Afzal Suleman[1] and Mehmet Yildiz[2]*

[1]*University of Victoria*
[2]*Sabanci University*

ABSTRACT

Fatigue failure of composite materials results from the accumulated effects of irreversible phenomena such as damage propagation and plasticity. Based on the Clausius-Duhem inequality representation of the second law of thermodynamics, any dissipative phenomenon generates entropy. Therefore, the concept of entropy generation yields a natural theoretical candidate to predict the fatigue lifetime of these materials. In fact, previous research has proven the total entropy generated during fatigue of composite materials to be constant, independently of stress ratio, loading frequency or stacking sequence, thus demonstrating promising capabilities as an alternative fatigue failure criterion. However, materials selected for experimental validation have solely consisted of thermoset-based composites. With the growing application in thermoplastic composites for aerospace structural components comes the interest to extend and validate the entropy generation concept to these materials. Given the rate- and temperature-dependent behavior of thermoplastics, the dissipation inequality formulation must account for dissipative phenomena such as plasticity, viscosity, and friction in the material constitutive laws. This work proposes a reformulation of the dissipation inequality using a continuum damage-based model at the laminate level that accounts for viscous, thermal, and plastic effects. Material properties included in the proposed constitutive model have been calibrated with experimental testing of carbon fiber/PEKK composite samples. Using the proposed form for the dissipation inequality, a second part of this work will quantify the entropy generated during stress-controlled tension-tension fatigue of carbon fiber/PEKK composite samples with two stacking sequences at different loading frequencies and maximum stress levels.

A HYBRID SHOCK FITTING-CAPTURING METHOD FOR HIGH-SPEED FLOWS

Roberto Aaron Marques Braga[*1] and Matthew Zahr*[1]

[1]*University of Notre Dame*

ABSTRACT

High-Order Implicit Shock Tracking (HOIST) is a class of methods that computes the solution of a conservation law and the nodal coordinates of the shock aligned mesh through the formulation of a PDE-constrained optimization problem. The PDE constraint uses a DG discretization with conservation, stability and high-order accuracy properties. A sequential quadratic programming method is used to converge simultaneously the DG solution and the nodal coordinates, which avoids nonlinear stability issues due to a non-aligned mesh. The method allows high-order approximations of high speed flows without requiring extensive mesh refinement in non-smooth regions. Curved interfaces are tracked to high-order accuracy by the use of high-order elements to generate curved elements.

This work presents a new methodology that integrates shock capturing and shock tracking to leverage the advantages of each. Strong bow shocks will be fully tracked because they play a critical role in the prediction of aerodynamic forces and can be readily fit with the grid using modern shock tracking techniques. Weaker secondary shocks that have proven more difficult (and less critical) to fit will be captured using artificial viscosity.

MODELLING OF SEISMIC WAVES USING A DECOUPLED DISCRETE-TIME GRID-WAVE PROPAGATION MODEL

Andrea Marti[1], Carlos E. Ventura[1] and José R. Martí[1]*

[1]*University of British Columbia*

ABSTRACT

The development of an Urban Real-Time Earthquake Early Warning system is being undertaken at the University of British Columbia. This system is based on having a coordinated dense network of low-cost seismic stations spaced 50-100 m apart in a grid formation. This grid formation allows us to achieve a very high spatial and temporal resolution within a city. It can capture seismic wave frequencies up to 20 Hz under high variability in soil conditions, which can change within as little as 1 km. The seismic stations are mounted to a building, house, bridge, substation, or other infrastructure. Each station comprises a MEMS tri-axial accelerometer, a Raspberry Pi processing board, and a 5G cellular transmitter. Associated with this physical hardware is a discrete-time wave propagation model between any two nodes of the grid, where every node in the wave model corresponds to the physical geographical coordinates of the seismic stations. As the data arrives at each physical node, the grid wave propagation model computes the predicted full shape of the strong S-wave and the other waves before they arrive at the infrastructure.

The grid-wave propagation model is an extension of the electromagnetic transients numerical solution method (EMTP), well-established in the field of electromagnetic wave transients in electric power systems. The EMTP-wave model is based on separating the 2nd-order wave equation into two 1st-order PDEs. This separation decouples each line between the connected nodes into two decoupled segments. Each segment contains a parameter called the characteristic impedance, representing the characteristic of the medium the wave propagates through, and a parameter representing the losses from wave attenuation. This decoupling makes the [Y] matrix in the grid solution [Y][A]=[B] to be fully diagonal making the solution to be of order N, where N is the number of nodes.

This decoupling is significant since it reduces the order of the solution from N^2 without decoupling using sparsity to only N for each point of the wave. For example, a 10km x 10km grid spaced 100 m apart (10,000 nodes) can be solved in approximately 80 milliseconds on a 3.7 GHz computer, while it would take 13 min for the non-EMTP solution. In addition, because each line segment contains the localized soil parameters, the strength of the wave is automatically accounted for when solving the system of nodal equations, allowing for a more accurate description of the wave magnitude before it reaches the Critical Infrastructure.

MODELLING AND SIMULATION OF THE DYNAMIC RESILIENCE OF COMPLEX SYSTEMS DURING LARGE DISASTERS USING THE I2SIM FRAMEWORK

Andrea Marti[1], José R. Martí[1] and Carlos E. Ventura[1]*

[1]University of British Columbia

ABSTRACT

i2SIM is a non-linear system optimizer and software package that models the interdependencies among a city's critical infrastructures and maximizes the allocation of resources towards a global objective function accounting for each infrastructure's physical constraints. Multiple heterogeneous physical and social infrastructures are affected after a disaster, such as electric power substations, water stations, gas pipes, communication networks, transportation routes, hospitals, emergency responders, and the community's economy, social cohesion, and livelihood.

In i2SIM, each infrastructure is considered a functional block (Cell) where the Cell's transfer function is defined by a relationships table called a Human Readable Table (HRT). The functional relationship for each Cell is given by the function: y(Cell)=min{f_1(input_1), f_2(input_2),..., f_n(input_n)}, where y(Cell) is the output of the Cell, and f_i is the functional relationship between input_i and the Cell's output, assuming all other inputs are available. For each input function, the HRT is constrained to an upper limit (infrastructure capacity) and lower limit (usually zero). These relationships define a closed-loop mathematical system of non-linear equations with limits. This closed-loop formulation allows a) the identification of the weakest (limiting) inputs to each system, b) the sensitivity of the output of each system on each one of its inputs, and c) the use of optimization techniques to find the minimum allocation of resources in each Cell that will result in the combined system of infrastructures objective function, such as community wellbeing.

During a disaster, when multiple systems fail simultaneously, the reliability of each system is a function of its level of operation and the level of operation of the other systems that it depends on. However, each individual infrastructure (e.g., the power grid) is unfamiliar with the internal details of the other infrastructures that it depends on (e.g., the water system, the health system). i2SIM calculates the functional and data requirements shared among infrastructures and communicates this information to all interdependent infrastructures. This coordination allows a global reliability measure to be defined and acted upon during the response without each infrastructure requiring full knowledge of the others' internal workings. One current use of i2SIM is for real-time consequence analysis when simultaneous wildfires occur, and decisions on which fire to extinguish first must be made. The consequences of a disaster depend on both pre-disaster measures for robustness and post-disaster coordinated response actions, and this pre-disaster-post-disaster timeline using i2SIM defines dynamic resilience indices for the total cost (monetary and social) of a disaster.

Novel mathematical and numerical models for multiphysics and multiscale systems

FINITE ELEMENT INTERPOLATED NEURAL NETWORKS FOR SOLVING FORWARD AND INVERSE PROBLEMS

Alberto F. Martin[*1], Santiago Badia[2] and Wei Li[2]*

[1]*Australian National University*
[2]*Monash University*

ABSTRACT

We propose a general framework for solving multi-scale forward and inverse problems constrained by partial differential equations (PDEs), where we interpolate multi-layer feed-forward neural networks onto conforming finite element spaces to represent the unknown model state variables (for forward and inverse problems), and the (partially) unknown data (only for inverse problems) [1]. This approach is coined with the term FEINNs. For forward problems, an approximate solution is obtained by designing a robust, well-posed PDE residual loss functional, which is then minimized using gradient-based optimization techniques. In the case of inverse problems, and additional term that measures the data misfit among (partial and potentially noisy) observations of the model state variables and the current model is also included in the loss function, and we propose an adjoint-free effective one-loop solver with an initial data fitting step to obtain a cheap initialisation of the neural network. The framework overcomes the challenges related to the imposition of boundary conditions and the choice of collocation points in physics-informed neural networks, as well as those related to the cell and facet integration of variational physics-informed neural networks. Besides, the framework is suitable to tackle multi-physics and multi-scale problems (e.g., problems with singularities and/or shocks) when combined with octree-based multi-resolution meshes and a-posteriori error estimators. A comprehensive numerical experiment set confirms the framework's capability of handling several forward and inverse problems, including some posed on complex geometries. While the experiments reported will be restricted to problems discretized using grad-conforming finite element spaces, the framework can be generalized to problems discretized using div- and curl-conforming spaces, such as, e.g., flow in porous media or the Maxwell equations. Remarkably, among other striking findings, the trained neural networks can be orders of magnitude more accurate than the finite element solution on the same mesh for smooth problems, even for those in which the solution has an internal shock, thus confirming the ability of the framework to unleash to a large extent the non-linear, built-in adaptive, approximability properties of neural networks. Besides, unlike adjoint-based inverse PDE solvers with finite element spaces to represent all unknowns, all the inverse problems tackled in the study with FEINNs could be flawlessly solved without the need of a regularization term in the loss functional.

SEISMIC ANALYSIS AND RETROFITTING SOLUTIONS FOR A PILE-SUPPORTED SHIPLOADING INFRASTRUCTURES

Edel R. Martinez[*1]*

[1]*CWA Engineers Inc.*

ABSTRACT

This paper provides a comprehensive exploration of seismic analysis and retrofitting solutions tailored to pile-supported shiploading infrastructures, with a specific focus on a Class D site near Vancouver. A critical assessment of ASCE 61-14, a key standard in marine seismic design, is conducted, integrating insights from observed marine facility behaviors during seismic events and tracing the evolution of seismic design provisions from historical practices to contemporary standards.

In the assessment phase, nonlinear static analysis is employed, emphasizing a high-fidelity finite element method. Our analysis centers on a specific case study, a pile-supported wharf near Vancouver, delving into damage localization in both superstructure and soil below the mud line. This illuminates the potential of advanced modeling techniques to enhance earthquake-resistant design in pile-supported structures.

Furthermore, the paper explores the consequences of relying on simplified seismic design analyses, particularly examining diverse impacts of earthquake ground motions. Through nonlinear dynamic analysis, the work unveils nuances associated with different seismic design strategies, highlighting the importance of dynamic analysis in fortifying earthquake-resistant design for such structures.

Principal contributions to the field include a nuanced understanding of seismic design requirements, advanced modeling techniques for damage localization, and insights into the implications of seismic design choices. By addressing these aspects, the paper contributes valuable insights and practical recommendations for enhancing earthquake-resistant design in marine facilities, particularly those with pile-supported shiploading infrastructures.

ABSTRACT

The combination of physics-based modeling with data-driven methods enables the clinical translation of computational cardiology. Today, the use of rigorous differential equations combined with machine learning tools allows patient-specific parameter personalization with uncertainty quantification in time frames compatible with clinical practice. However, accurate and efficient surrogate models of cardiac function are still mostly geometry-specific and require retraining for different patients and pathological conditions. We propose a novel computational framework to embed different cardiac anatomies into neural network based surrogate models. We generate a dataset of numerical simulations using mathematical models based on differential equations. We consider Branched Latent Neural Maps (BLNMs) as an accurate and efficient computational tool to encode complex space-time fields into a neural network. We employ statistical shape modeling and deep learning methods using signed distance fields to represent different human hearts. This framework would allow for fast and robust parameter estimation on patient cohorts without the need to modify the surrogate model.

GRAPH NEURAL NETWORKS FOR GEOMETRIC DESIGN OF STRUCTURES IN PLASTIC REGIME

Mikel Martinez[*1], Elías Cueto[1] and Francisco Chinesta[2]*

[1]*Universidad de Zaragoza*
[2]*ENSAM Institute of Technology*

ABSTRACT

This research is dedicated to advancing data-driven modeling of plasticity, with a distinctive emphasis on achieving speed-ups rather than developing constitutive models, which are already known to us. Our primary goal is to provide analysts with an efficient tool for designing and analyzing structures undergoing plastic strain within strict real-time constraints

Leveraging Graph Neural Networks (GNNs) and synthetic data generated from Finite Element Method (FEM) simulations, our approach showcases robust generalization capabilities. The motivation behind this work lies in the imperative need to reduce computational costs, a critical objective compared to the prevalent reliance on Finite Element Method (FEM) approaches. By incorporating prior knowledge through data-driven approaches, our research significantly accelerates predictions, potentially revolutionizing the process design for working with plastic materials.

Various parameters, including specimen height and length, underwent tuning to delineate diverse geometries. The model was then tested on unforeseen geometries, illustrating its robustness and generalization capabilities in both interpolation and extrapolation scenarios. This study contributes to the conference by introducing an innovative approach to plasticity modeling, with a focus on efficiency, generalization, and cost reduction in structural analysis. It marks a stride forward into novel and accelerated tools for the design of structures in the plastic regime, promising advancements in the field of real-time analysis.

PHASE FIELD MODELLING OF FATIGUE CRACK GROWTH: OPPORTUNITIES, ACCELERATION SCHEMES AND COUPLED PROBLEMS

Emilio Martinez-Paneda[*1]

[1]*Oxford University*

ABSTRACT

Predicting fatigue failures remains one of the most elusive challenges for scientists and engineers. In this work, we develop a comprehensive phase field model capable of predicting fatigue failures of arbitrary complexity. Through comparison with experiments, the model is shown to accurately predict the fatigue behaviour of materials, including S-N curves, Paris law crack growth, the influence of the load ratio, mean stress effects, stress concentrator factors and the endurance limit. In brittle and quasi-brittle solids, the model is able to predict fatigue crack growth rates from S-N curves, and vice-versa. Moreover, the framework is extended to account for the presence of hydrogen, which is known to significantly impact the fatigue resistance of metals. The resulting coupled deformation-diffusion-damage model is shown to be able to qualitatively and quantitatively capture the role of hydrogen in increasing fatigue crack growth rates and decreasing the number of cycles to failure. Our numerical experiments enable mapping the three loading frequency regimes and naturally recover Paris law behaviour for various hydrogen concentrations. In addition, Virtual S–N curves are obtained for both notched and smooth samples, exhibiting a good agreement with experiments. Aspects of the numerical implementation will also be discussed, showing how complex fatigue cracking phenomena in 2D and 3D can be captured, over millions of cycles, through the development and use of new acceleration schemes.

ABSTRACT

We introduce a hybrid twin approach to solve physical systems modeled by parametrized Partial Differential Equations (PDE). Our approach, combines the variational data assimlation(PBDW) [1] with operator learning(Deeponets)[2] to reconstruct the state of an imperfect physical system given many observations. The PBDW method is a non-intrusive, reduced basis, in-situ data assimilation framework, that estimates the solution of a biased model given many observations. This method provide a state estimate framework for parameterized model that estimate both the anticipated and the non anticipated physics while ensuring orthogonality between both parts. The anticipated physics is approximated by a background space constructed with reduced basis while the non-anticipated physics is infered by a Deeponets. The hybrid twin was performed using two approaches to ensure orthogonality. A first approach with a weak constrain, that regularizes the loss function of the neural operator with the dot product between the un-anticipated physics and the background space, in this case the trunk net learn from the whole space but the constrain is only garanteed in the training stage. And a second approach with strong constrain where the trunk is replaced by a set of basis function, each orthogonal to the background space by construction, that garantee orthogonaly in both the training and inference stage of the un-anticipated physics. The hybrid twin was applied on a 2D Helmoltz equation on a homogeneous and bounded domain with a biased source, to showcase its potential for solving complex physical systems.

MOMENTUM SPACE METHOD FOR ELECTRONICS OF MECHANICALLY RELAXED INCOMMENSURATE 2D MATERIALS

Daniel Massatt[*1], Mitchell Luskin[2] and Stephen Carr[3]*

[1]*Louisiana State University*
[2]*University of Minnesota*
[3]*HRL Laboratories, LLC*

ABSTRACT

Since their discovery by Geim, 2D materials have become a hotbed of research due to their novel structure. Layering materials with tunable relative twists allows for a vast range of possible materials and corresponding electronic and mechanical properties. However, this stacking typically leads to an aperiodic, or incommensurate, material due to lattice mismatch or rotational misalignment. When two materials vary only by a small twist, as is the case for magic angle physics, large moire patterns arise and mechanical relaxation effects have significant impact on electronic structure.

In this work, we discuss configuration and momentum space methodologies to build algorithms for computing electronic observables including quasi-band structure for incommensurate bilayers for ab-initio single-particle tight-binding models. Mechanical relaxation effects are modeled via a continuum model, and are incorporated into the electronic tight-binding model. These models allow for prediction of electron transport properties, and provide a platform for construction of many-body models describing unconventional superconductivity and other many-body effects at magic angles. We exploit the ergodicity of the misalignment, and for appropriate materials (such as those with conic or parabolic bands) we use carefully selected perturbative expansions in momentum space with a thorough error analysis to describe the effects of the large moire scale.

PHYSICS-CONSTRAINED DATA-DRIVEN VARIATIONAL METHOD FOR DISCREPANCY MODELING

Arif Masud[*1] and Shoaib Goraya*[1]

[1]*University of Illinois Urbana-Champaign*

ABSTRACT

The effective inclusion of a-priori knowledge when embedding data in physics-based models of dynamical systems can ensure that the reconstructed model respects physical principles, while simultaneously improving the accuracy of the solution in the previously unseen regions of state space. This talk presents a physics-constrained data-driven discrepancy modeling method that variationally embeds measured data in the modeling framework. The hierarchical structure of the method yields fine scale variational equations that facilitate the derivation of residuals which are comprised of the first-principles theory and sensor-based measurements of the dynamical system. The embedding of the sensor data via residual terms leads to discrepancy-informed closure models, thereby resulting in a method which is driven not only by boundary and initial conditions, but also by measurements that are taken at only a few observation points in the target system. Specifically, the data-embedding term behaves like a residual-based least-squares loss function, thus retaining variational consistency. The structure of the loss function is analyzed in the context of variational correction to the modeled response wherein loss function penalizes the difference in the modeled response from the measured data that represents the local behavior of the system. Formulation is then extended for transient analysis and the effect of the variationally embedded loss function on time dependent response of the system is analyzed under a variety of loading conditions. Specifically, the damped solution and correct energy time histories are recovered by including known data in the undamped situation. The enhanced stability and accuracy of the DDV method is manifested via reconstructed displacement and velocity fields that yield time histories of strain and kinetic energies that match the target systems. The proposed DDV method also serves as a procedure for restoring the eigenvalues and eigenvectors of a deficient dynamical system when known data is taken into consideration. Method is applied to smooth as well as non-smooth model problems and mathematical attributes of the formulation are investigated.

THERMO-CHEMO-MECHANICAL MODEL AND VARIATIONAL MULTISCALE METHOD FOR MATERIAL AND GEOMETRIC EVOLUTION IN FRONTAL POLYMERIZATION

Arif Masud[*1] and Ignasius Wijaya*[1]

[1]*University of Illinois Urbana-Champaign*

ABSTRACT

This talk presents a new thermodynamically consistent model for thermo-chemo-mechanical processes in frontal polymerization. The model is comprised of nonlinear elastic solids undergoing large strains, and locally undergoing advancing reactive fronts as the material is extruded. The development of the formulation starts from balance equations for mass, momentum, and energy. The constitutive relations are derived to enforce non-negative entropy production to satisfy the second law of thermodynamics for the open system where mass is continuously added to the system. The model considers factors, namely, heat generation, heat transfer, and reaction kinetics that incorporate the rate at which the monomers are converted into polymers and the associated heat release. The material parameters evolve as a function of time to model chemical curing of the polymeric material. The coupled deformation due to thermal and chemical effects is carried out via a multiplicative split of the deformation gradient.

A stabilized finite element form that is derived based on the Variational Multiscale framework is presented, and the constitutive model is integrated in the VMS stabilized method. This leads to a fully coupled method for modeling and simulation of the thermo-chemical effects and localized curing at the propagating front. The VMS stabilized form helps circumvent the inf-sup condition commonly termed as the Babuska-Brezzi condition for mixed field problems, thereby allowing the use of arbitrary shape function for the displacement and temperature field. In addition, it also addresses the incompressibility constraint on the material that otherwise requires special stress projection methods or reduced integration techniques. A ghost mesh technique is proposed for extrusion printing of material, and a moving point is defined to represent the kinematics of the printing nozzle. At each step, integration points around the nozzle are activated and assigned the actual stiffness and density of the material to simulate extrusion of the material. The model and method are validated with experimental data, and some interesting test cases are presented.

PREDICTION OF PRESSURE FIELD OF INCOMPRESSIBLE FLOW USNING CNN

Masato Masuda[*1] and Yoshiaki Tamura*[1]

[1]*Toyo University*

ABSTRACT

In the previous work, we proposed a prediction method of incompressible flow using ConvLSTM (Convolutional LSTM) based on pressure and velocity field of a couple of previous steps. To improve the proposed method, we have changed the procedure of the pressure prediction in which the pressure field of the current step and the velocity field of the next step (predicted by ConvLSTM as the same as the previous work) are given to CNN (Convolutional Neural Network), but not to ConvLSTM, as in Computational Fluid Dynamics (CFD), pressure field is solved by the Poisson equation which does not have a time derivative term. The results are compared with those obtained by the previous work.

ANALYSIS OF LAMINATED COMPOSITE AND SANDWICH PLATES SUBJECTED UNDER THERMO-MECHANICAL LOAD USING LEAST SQUARE FINITE ELEMENT MODEL

Christian Mathew[*1] and Yao Fu*[1]

[1]*Virginia Tech*

ABSTRACT

Combination of one or more Engineering materials on a macroscopic level produces composite. The composite materials have better engineering properties than parent materials individually. Laminated composites are widely used in many engineering industries such as aircraft and spacecraft, boat hulls, racing car bodies and storage tanks. This study presents the thermoelastic analysis of laminated composite plates subjected to sinusoidal thermal load (simultaneously loaded by mechanical and thermal loads) linearly varying across the thickness. Least square finite element solutions for thermal displacements and stresses are investigated by using a mathematical model, called a state-space model, that allows us to simultaneously solve for these quantities in the composite structure's domain and making sure that continuity conditions are satisfied at layer interfaces. We solve the governing equations that are derived from this model by using a numerical technique called the least-squares finite element method (LSFEM) which seeks to minimize the squares of the governing equations and the associated side condition residuals over the computational domain. Numerical results are presented to demonstrate the thermal response of the laminated composite plates using LSFEM and compared with three-dimensional elasticity solution available in the literature.

VANQUISHING MEMBRANE LOCKING IN QUADRATIC NURBS-BASED DISCRETIZATIONS OF NONLINEAR KIRCHHOFF-LOVE SHELLS: CAS ELEMENTS

Kyle Mathews[1] and Hugo Casquero*[1]

[1]*University of Michigan - Dearborn*

ABSTRACT

Continuous-assumed-strain (CAS) elements were recently proposed to remove membrane locking in quadratic NURBS-based discretizations of linear plane curved Kirchhoff rods [1] and linear Kirchhoff-Love shells [2] and shear and membrane locking in quadratic NURBS-based discretizations of linear plane curved Timoshenko rods [3]. In this work, we generalize CAS elements to remove membrane locking from quadratic NURBS-based discretizations of geometrically nonlinear Kirchhoff-Love shells. CAS elements are an assumed strain treatment. Leveraging the C1 continuity across element boundaries of the displacement vector given by quadratic NURBS, CAS elements bilinearly interpolate the covariant membrane strain coefficients at the knots resulting in assumed strains with C0 continuity across element boundaries. The benchmark problems show that CAS elements excise the spurious oscillations of membrane forces caused by membrane locking for an ample range of slenderness ratios. In addition to successfully vanquishing locking, CAS elements are a computationally efficient element type since no additional degrees of freedom are introduced, no additional systems of algebraic equations need to be solved, no matrix operations such as matrix multiplications and matrix inversions are needed, the nonzero pattern of the tangent matrix is maintained, and 2x2 Gauss-Legendre quadrature points suffice to integrate each element.

MODELING THE EFFECT OF BACKBONE INSTABILITIES AND GUEST OCCUPANCIES ON INTERFACIAL AND STRUCTURAL PROCESSES AND DYNAMICS OF SII GAS HYDRATE SYSTEMS USING MOLECULAR DYNAMICS

Samuel Mathews[*1], Phillip Servio[1] and Alejandro Rey[1]*

[1]McGill University

ABSTRACT

Gas hydrates are inclusion compounds comprising a backbone of water molecules that enclose guest molecules in separate cages. Each volume of hydrate contains 160 volume equivalents of gas. Initially, large scale gas hydrate research was centered around the flow assurance problems they cause in the extraction and transportation of petroleum and its derivatives. Naturally occurring gas hydrates are also studied to satisfy global energy demand. Their potential use in the removal of carbon from the atmosphere, carbon capture and storage, and for energy exploitation makes gas hydrates a prime candidate for climate change mitigation research. At the atomic scale, these structures may be perfect crystals, but at the macroscale they will display imperfections. These can present themselves as missing water molecules in the hydrate backbone, and missing guest molecules in otherwise filled structures. Naturally, the properties of hydrates are centered around the formation and population of voids in the cage structure – the guest molecule's presence serves to stabilize the backbone and its absence may induce structural instabilities. This work uses molecular dynamics as implemented in the Large-scale Atomic/Molecular Massively Parallel Simulator to characterize the temperature and pressure effects on the interfacial tension, energy of interfaces, and growth rate of natural gas hydrates to overcome the complexity of experimentally understanding their performance in extreme environments and prove that theoretical modeling, prediction, and advanced characterization techniques can explain the structural and transport properties that govern hydrate in engineering applications. Additionally, this work will use the same techniques to study how behavior at the interface is affected by the presence of voids in the crystalline structure. It is essential to understand the underlying behavior of the hydrate cages to characterize the macroscale properties of real materials that are not perfectly filled crystals. Also, by studying the principal phases involved in hydrate formation, hydrate/water, hydrate/gas, and hydrate/ice, the work seeks to determine how the population of vacancies may be controlled by tuning surface behavior during the melting and formation processes. Preliminary results confirm the presence of a novel pre-melting layer at the interface between structures that shows strong atomic alignment behaviors. Detailed dipole analysis shows that some tuning may be performed with external forces to change the transport properties through this layer. Combined with changes in temperature and pressure, voids in the background structure may be avoided or preferred, while achieving control of the cage populations.

PARTICLE-BASED REDUCED ORDER MODELING OF LAGRANGIAN FREE SURFACE FLOW USING DEEP LEARNING

Gen Matono[1] and Mayuko Nishio*[1]

[1]*University of Tsukuba*

ABSTRACT

Reduced order modelling (ROM) is a method to solve time evolution int a low-dimensional space and is widely used for control and optimization problems, since it can predict physical fields quickly. Deep learning models have been used to emulate the ROM. One of recent models allows order reduction while maintaining spatial continuity of the physical field, allowing it to handle large datasets such as meshes and point clouds [1]. This function allows it to be applied to problems involving Lagrangian particle tracking, particularly in scenarios such as free surface flows, which pose difficulties for conventional ROM. Deep learning-based ROM can be divided into the learning phase, where order reduction and reconstruction is learnt, and the prediction phase, where time evolution is performed on the low-dimensional space. In the prediction phase, time variables are evolved in time on a coded low-dimensional space using either prediction by a learning machine or iterative optimization with the governing equations as residuals. The latter is preferable to avoid the black-boxing of deep learning, but for problems where particles move in a Lagrangian description, the computational cost of the derivatives is high and iterative optimization with the governing equations as residuals is difficult. Then, the objective of this study is enhancing computational performance of deep learning-based ROM for free surface flow. To approach this problem, it is proposed to decode all physical values simultaneously and optimizing time-varying variables in low-dimensional space based on a comparison of explicitly calculated and decoded velocities. By encoding all physical quantities simultaneously, time evolution based on one physical quantity can also be used to time evolve other physical fields. Also, time evolution based on residual computed by explicitly calculated and decoded velocities eliminates the need to calculate residuals based on the governing equations every step in an iterative calculation. These methods were validated on a dataset of the water drop problem created by the SPH method. As a result, it is confirmed that the proposed decoding method can reduce order and reconstructed original physical field well and proposed optimization method can reduce computational const than the model proposed in previous studies.

AN ADAPTIVE SPACETIME WAVELET METHOD FOR PREDICTIVE COMPUTATIONAL SCIENCE WITH MULTIPLE SPATIAL AND TEMPORAL SCALES

Karel Matous[*1], Cody Cochran[1] and Jack Yost[1]*

[1]*University of Notre Dame*

ABSTRACT

Modern computational science and engineering applications are inherently multiphysics and multiscale. Therefore, novel algorithms are required to solve nonlinear Partial Differential Equations (PDEs) with features evolving over a wide range of spatial and temporal scales. In this work, we propose a wavelet-based method that is ideally suited for problems developing localized structures, which might occur intermittently anywhere in the computational domain or change their location and scales in space and time. Wavelets have generated tremendous interest in both theoretical and applied areas as they allow for efficient multiscale decomposition and large data compression. In our work, we develop the Multiresolution Wavelet Toolkit (MRWT), which requires far fewer unknowns than other algorithms when applied to problems with a great range of spatial and temporal scales. In addition, the computational grid can be refined locally, and our a priori error estimates safeguard the accuracy of the numerical solution.

MRWT has been implemented as a hybrid parallel framework using a modern programming paradigm to execute in a hybrid CPU/GPU environment. Consequently, MRWT provides high-fidelity simulations with significant data compression. We explain how this technique uses differentiable wavelet basis functions and second-generation wavelets to solve nonlinear PDEs on finite domains. Moreover, we provide a priori error estimates for the wavelet representation of fields, their derivatives, and the nonlinear terms in PDEs. Additionally, MRWT utilizes a predictor-corrector procedure within the time advancement loop to dynamically adapt the computational grid, retaining the prescribed accuracy of the solutions of the PDEs as they evolve. First, we employ an embedded Runge-Kutta (RK) integration scheme to control the temporal accuracy as the solution of the PDE advances. Second, we will also present a novel spacetime method and solve the full spacetime problem using adaptive wavelets. Our preliminary spacetime results on dense grids show promise for the development of sparse spacetime wavelet schemes.

We show rigorous verification of the MRWT algorithm for both time marching (RK integration) and spacetime problems, demonstrating mathematical correctness and physics simulation capabilities. Furthermore, we show that we achieve spatial convergence at a rate that agrees with a priori estimates. Whereas traditional numerical techniques require a sequence of solutions on multiple grids (i.e., solution verification), our adaptive wavelet method provides self-verification from a single simulation. Finally, we apply MRWT to problems with shocks in gases using compressible Navier-Stokes equations and to high-strain rate damage nucleation and propagation in nonlinear solids using Eulerian-Lagrangian dynamic damage modeling.

Multiscale computational homogenization for bridging scales in the mechanics and physics of complex materials

EFFECT OF THE INELASTIC SELF-HEATING ON THERMO-MECHANICALLY COUPLED TWO-SCALE BEHAVIORS

Seishiro Matsubara[*1], So Nagashima[1], Dai Okumura[1] and Kenjiro Terada[2]*

[1]Nagoya University
[2]Tohoku University

ABSTRACT

Thermo-mechanically coupled behaviors of polymer composites are challenging phenomena that are difficult to measure experimentally but critical issues in their design and manufacturing[1]. The viscous property in their matrix materials not only causes their temperature-dependent mechanical behavior but also generates the heat source by the inelastic energy dissipation. Such an inelastic self-heat acts as an instantaneous heat source, so that the unsteady thermo-mechanically coupled behavior emerges in their microstructure, which may be impossible to analyze overall responses experimentally. The conventional computational homogenization methods for thermo-mechanically coupled problems[2] are also not applicable to this problem because the unsteadiness disappears in an infinitely small unit-cell. For this reason, few researchers have comprehensively studied the effect of inelastic self-heating on the two-scale thermo-mechanically coupled behaviors in dissipative composites.

We formulate a thermo-mechanically coupled two-scale boundary value problem for dissipative composites and establish a method of two-scale analysis to capture the transient thermo-mechanically coupled behaviors caused by the inelastic self-heating. Under the assumption of a real-size unit-cell[3], the approximative two-scale decomposition and the suitable linearization for a coupled rate potential stored of dissipative composites yield governing equations that characterize the mutual relationship between mechanical equilibrium and unsteady heat conduction in both scales. We show that the periodic boundary condition for the microscopic temperature is only available to simulate transient two-scale behaviors, which is consistent with the results of single-scale analysis. The effect of inelastic self-heating on the transient two-scale behaviors is comprehensively studied through several numerical examples for plastic and viscoplastic composites.

DEVELOPMENT OF A MESH-CONSTRAINED DISCRETE POINT METHOD FOR MOVING BOUNDARY FLOW PROBLEMS

Takeharu Matsuda[*1] and Satoshi Ii*[1]

[1]*Tokyo Metropolitan University*

ABSTRACT

A particle-based method is a practical tool for simulating particle-laden flows. In recent years, novel types of methods have been proposed that guarantee convergence accuracy based on applying a moving least-squares (MLS) approximation (e.g., [1]). One of the disadvantages of the Lagrangian-type formulation is to encounter a sparse or dense arrangement of the particles even though an incompressible flow field is solved. Regarding this, an arbitrary Lagrangian-Eulerian (ALE) formulation has been implemented (e.g., [2]). However, since the particles at moving boundaries are tracked in a full Lagrangian manner, some problems have still remained for high computational efficiency and difficulty in parallel computations, which are attributed to the nonuniform distribution of particles and the update of their local arrangement over time. To tackle these problems, we have developed a novel particle-based (or meshless) method, termed mesh-constrained discrete point (MCD) method [3], in stationary boundary problems. A spatial discretization of the MCD method relies on the generalized finite difference method, a meshless method using the MLS approximation; however, the arrangement of particles (or discrete points (DPs)) is specialized, where their positions are constrained by background meshes to obtain a closely uniform distribution for the DPs even though an arbitrary boundary interface is immersed in an analysis domain. This achieves a reasonable approximation for spatial derivatives with compact stencils without encountering any ill-posed condition and would also lead to high computational efficiency. In this study, we develop the MCD method for coupled problems between an incompressible fluid and rigid bodies, where the ALE formulation is applied. To ensure the mesh constraint of each DP in moving boundary problems, the position of DPs is not only rearranged but also reassigned the role of being on the boundary or not. The developed method shows reasonable results in numerical experiments for both enforced displacement problems and fluid-solid interaction problems.

GAS-LIQUID-SOLID THREE-PHASE FLOW ANALYSIS WITH MULTIPLE OBJECTS USING FINITE ELEMENT METHOD

Junichi Matsumoto[*1] and Tomohiro Sawada*[1]

[1]*National Institute of Advanced Industrial Science and Technology (AIST)*

ABSTRACT

Numerical method of multi-phase-field model three-phase analysis in gas, liquid and solid using tetrahedron (unstructured grid) is investigated. The Multi-Phase-Field model employs the Cahn-Hilliard equation [1] with multiple objects. In this study, we propose a mixed finite element method with MINI element considering implicit method in time direction and stabilization in space direction [2]. In this paper, the Cahn-Hilliard equation with multiple objects is used as a gas-liquid solid by the multi-phase-field three-phase model, and the fall computation of the structure is performed as a computational example to show the effectiveness of the proposed method.

ABSTRACT

In this study, we present a novel modeling of particle suspension flow in the moving particle hydrodynamics (MPH) [1, 2]. Suspension flow and particle transport are important in the tape casting process used in the manufacture of ceramic capacitors, piezoelectric devices, and solid all solid-state batteries. Particle methods have advantages over mesh methods (e.g. finite volume methods) in dealing with the fluid-solid interface in suspension flows. For example, particle methods do not require a mesh and do not require complex processing due to the mesh. In this study, we present a new modeling of suspension flow using the MPH. Each solid particle in a suspension flow is represented by a group of extremely viscous fluid particles. Compared to the existing methods based on the explicit incompressible SPH, such as the method of Bian et al. [3], the proposed method has the advantage of being able to compute highly viscous fluids without being limited by the diffusion number and to compute the motion of solid particles in the fluid in a unified fluid calculation. This is due to the fact that MPH implicitly updates velocities and preserves linear and angular momentums. The presented method can simulate not only Newtonian fluids but also Hershel-Bulkley fluids.

DEVELOPMENT OF A REMOTE LEARNING SUPPORT FRAMEWORK UTILIZING VIDEO ANALYSIS AI

Masami Matsumoto[*1]*

[1]*National Institute of Technology, Yonago College*

ABSTRACT

In recent years, various ICT education environments have undergone significant development, with the widespread adoption of video systems bringing about transformative changes in education. Enhancing the learning environment to effectively support distance education has become increasingly crucial.
In this study, we present the development of a comprehensive framework comprising a server system implemented within a web-based operating environment and a content creation support system. The system integrates multimedia content delivery functionality through a combination of a Web server and a game engine. Acting as a portal for lecture content, a reverse proxy is deployed, and Python Flask is utilized for user management to delegate functionality. The use of a template engine for delivering lecture content is aimed at achieving a streamlined and lightweight design, ensuring rapid response times. Moreover, the system captures close-up images of students through a webcam connected to the client, enabling various functionalities, including emotion analysis, skeletal estimation, and recording vital data such as heart rate measurements derived from detected facial images. This feature facilitates the analysis of user emotions. The developed system successfully establishes a platform that supports remote lecture delivery. Future efforts will focus on utilizing the framework for both remote and in-person classes. Recognizing the large file sizes of multimedia content, the system is designed for operation on Wi-Fi/5G, with the assumption of a LAN environment. Additionally, by monitoring participants through the implemented emotion analysis feature, we aim to contribute to the creation of more engaging and enriching educational content.

TWO-DIMENSIONAL RIVERBED VARIATION ANALYSIS USING DISCONTINUOUS GALERKIN METHOD WITH SEDIMENT TRANSPORT EQUATION

Reo Matsumoto[*1], Seizo Tanaka*[2] *and Mitsuteru Asai*[1]

[1]*Kyushu University*
[2]*Hiroshima Institute of Technology*

ABSTRACT

In recent year, global warming has caused river inundation and storm surge on a global scale. Numerical simulation of damage prediction is strongly demanded for planning mitigation or prevention from these natural disasters. Shallow water equations (SWEs) can decrease numerical simulation cost keeping with its accuracy, and simulation tools based on the SWEs are widely used for these natural disaster simulations. In shallow water flow analysis, stabilized finite element methods that introduce upstreaming, such as the SUPG (Streamline upwind/Petrov-Galerkin) method, have been widely used due to numerical instabilities caused by the fact that the SWEs are hyperbolic partial differential equation [1].
On the other hand, a discontinuous Galerkin (DG) method [2] is effective and promising tool for the hyperbolic equations with discontinuities. The DG method has been applied and shown to be effective in the shallow water flow analysis recently [3]. However, there are few precedents for such analysis using the DG method, although riverbed variation analysis that considers sediment erosion and deposition in the river channel is necessary to accurately predict damage such as river flooding.
In this study, the DG method is applied to riverbed variation simulations, in which the governing equation are coupling of the SWEs and equilibrium sediment transport equation. Then, we confirmed the validity of the proposed method has been verified with numerical analysis such as erodible dam-break flow and sandbar migration simulation.

A COMPARATIVE STUDY OF CONVENTIONAL AND ADVANCED PARTICLE METHODS ON RESULTANT ACCURACY AND COMPUTATIONAL COST

Takuya Matsunaga[*1] and Hiroshi Okuda*[1]

[1]*The University of Tokyo*

ABSTRACT

Particle methods have received a great deal of attention in various scientific and engineering fields because of their remarkable capabilities in simulating complicated fluid flow problems such as free-surface flows with splash generation. The smoothed particle hydrodynamics (SPH) method and moving particle semi-implicit (MPS) method are the two most widespread particle methods with which a considerable number of studies have been conducted for over a decade. However, these traditional particle methods employ inconsistent discretization schemes, and ensuring the reliability of numerical results has been a major problem.

With this background, enhancing the accuracy of particle methods has been one of the main topics of active research. One of the most notable developments in this context is the least squares moving particle semi-implicit (LSMPS) method (Tamai and Koshizuka, Comput. Part. Mech., vol. 1, pp. 277–305, 2014). The LSMPS method is characterized by its highly accurate spatial discretization scheme. In a recent study, the authors have improved the numerical stability of the LSMPS method by incorporating several numerical techniques and proposed the stabilized LSMPS method (Matsunaga and Koshizuka, Comput. Methods Appl. Mech. Eng., vol. 389, p. 114416, 2022). The stabilized LSMPS method can be applied to complex free-surface flow problems in the same way as the conventional SPH and MPS methods.

In this presentation, several specific applications of the stabilized LSMPS method are presented in comparison with the conventional MPS method, demonstrating its effectiveness for highly accurate numerical simulations and providing insight into the feasibility of practical applications. More specifically, we show that significant differences are observed between the results of the two methods, particularly in problems where negative pressure plays an important role in fluid motion. Furthermore, we show that the method is highly effective also for the analysis of highly viscous fluids and surface tension flows. In addition, we compare the computation time to provide quantitative information on how much the computational cost increases when the conventional method is replaced by the stabilized LSMPS method.

NON-HERMITIAN DEGENERACY IN TWO-DIMENSIONAL OPEN ELASTIC SYSTEMS WITH HIGHER-ORDER EXCEPTIONAL POINTS

Kei Matsushima[*1] and Takayuki Yamada*[1]

[1]*The University of Tokyo*

ABSTRACT

In this talk, we present a numerical model of two-dimensional solid structures with cylindrical symmetry and demonstrate the existence of higher-order exceptional points in the elastic system. Elastic waves propagating in the system are subject to radiation loss, resulting in their associated eigenvalues becoming complex-valued. By tuning certain system parameters, we numerically demonstrate the simultaneous coalescence of complex eigenvalues and their corresponding eigenmodes. Our numerical experiments suggest that this non-Hermitian degeneracy stems from (higher-order) exceptional points in the parameter space. We expect that this discovery opens the possibility for a novel technique in mechanical sensing.

HIGH-FIDELITY SIMULATIONS OF LOWFREQUENCY SOUND IN REAL 3D APPLICATIONS

Ken Mattsson[1] and Gustav Eriksson*[1]

[1]*Uppsala University*

ABSTRACT

We have developed a high-fidelity numerical model to accurately simulate sound propagation in a realistic, stratified and windy 3D atmosphere over irregular terrain. In particular we are interested in low frequency sound propagation from large windfarms. The numerical simulations are validated against accurate measurements of sound pressure levels (SPL) all the way down to 1 Hz. Comparisons is done also against the most commonly used community sound propagation models in Sweden such as NORD2000. A previous study showed that some of the most commonly used methods for environmental noise [1] failed completely to predict the correct SPL in irregular terrains. The reason for this is related to the fact that they do not take the underlying physics into consideration and instead involve ad. hoc. tuning of non-physical parameters.

Outdoor sound propagation is highly affected by ground effects, refraction and damping in the atmosphere, topography, the sound power levels and relative positions of the sound sources [2]. To accurately simulate outdoor sound propagation requires a careful consideration of the underlying physics and good knowledge of the uncertainties in model data. Obtaining a stable and accurate solution of the 3D high-fidelity sound propagation model, in this case the acoustic wave equation, is a nontrivial task.

The huge computational 3D domain, and the need to accurately resolve low-frequency waves require the use of high-order accurate numerical methods, having minimal dispersion (and dissipation) errors. A robust and well-proven high-order finite difference methodology, for well-posed initial boundary value problems is to combine summation-by-parts (SBP) operators [3] and the simultaneous approximation term (SAT) method to impose boundary conditions (BC). This is the methodology adopted in the present study. In an effort to significantly reduce computational times the numerical SBP-SAT method is implemented on GPUs, resulting in relatively short simulation times, despite large degrees of freedom.

Uncertainties in (atmospheric, terrain and source characteristic) data is analyzed using uncertainty quantifications, which allow for reliable error bounds on the prognosis of SPL in the far field.

DATA-ASSIMILATION FOR NUMERICAL WEATHER PREDICTION WITH SCIENTIFIC MACHINE LEARNING

Matthew Poska[1], Alexander Wikner[2], Rao Kotamarthi[3], Troy Arcomano[3] and Romit Maulik[*1]*

[1]Pennsylvania State University
[2]University of Chicago
[3]Argonne National Laboratory

ABSTRACT

Data assimilation (DA) in geophysical sciences remains the cornerstone of robust forecasts from numerical models. Indeed, DA plays a crucial role in the quality of numerical weather prediction and is a crucial building block that has allowed dramatic improvements in weather forecasting over the past few decades. DA is commonly framed in a variational setting, where one solves an optimization problem within a Bayesian formulation using raw model forecasts as a prior and sparse experimental observations in a likelihood. In traditional DA, the forward model is numerically and computationally expensive. Here we replace the forward model with a differentiable surrogate model. Consequently, gradients of our DA objective function with respect to the decision variables are obtained rapidly via automatic differentiation. We use our proposed method for assimilating radiosonde observations for improved numerical weather prediction using a vision transformer surrogate. Our results indicate that emulator-assisted DA is faster than traditional equation-based DA forecasts by 4 orders of magnitude, allowing computations to be performed on a workstation rather than a dedicated high-performance computer.

VALIDATION OF DISPLACEMENT DAMAGE MODELS

Kathryn Maupin[*1], Jaideep Ray[1], Larry Musson[1] and Suzey Gao[1]*

[1]Sandia National Laboratories

ABSTRACT

As the third pillar of science, computational simulation has allowed scientists to explore, observe, and test physical regimes previously thought to be unattainable. High-fidelity models are derived from physical principles and calibrated to experimental data. However, missing or unknown physics and measurement, experimental, and numerical errors give rise to uncertainties in the model form and parameter values in even the most trustworthy models. Thus, rigorous calibration and validation of a computational model is paramount to its effective us as a predictive tool. The popularity of the Bayesian paradigm stems from its natural integration of measurement and model uncertainties. A systematic approach to model validation, as originally outlined by Oden, et al in [1-2], progressing from parameter and quantity of interest identification to sensitivity analysis, calibration, and validation, is applied to a drift-diffusion simulation code called Charon. Charon allows the computational qualification of semiconductor devices subjected to displacement damage. This work is dedicated to Dr. J. Tinsley Oden.

BAYESIAN OPTIMAL DESIGN OF PULSED POWER EXPERIMENTS

Kathryn Maupin[*1] and Chris Jennings*[1]

[1]*Sandia National Laboratories*

ABSTRACT

Traditionally, there are two pillars of science: theory and experimentation. These two inform one another and lead scientists to make educated guesses and decisions toward advancing science. More recently, the driving force behind scientific advancement has not just focused on how much information can be learned, but how quickly. Additionally, experimental data can be costly and difficult to obtain. With these motivations in mind, the field of experimental design aims to maximize the information gained from as few experimental data points as possible. Computation has emerged as a third pillar of science to complement the traditional two and has been used to facilitate optimal experimental design. However, missing or unknown physics as well as measurement, experimental, and numerical errors give rise to uncertainties in model output in even the most trustworthy models. These uncertainties are effectively acknowledged and incorporated during a Bayesian analysis. However, in many practical applications, high-fidelity physics-based codes are intensive, making them infeasible to use directly in design and optimization studies. To preserve confidence and capture uncertainties in these studies, it is imperative that surrogate or reduced order models accurately capture available data.

Sandia's Z machine is the world's most powerful and efficient laboratory radiation source. Z experiments often exhibit large current losses, so a principal uncertainty is how effectively current can be delivered. Power flow simulations are very intensive, making them infeasible to use in critical design and optimization studies. Generator and target design necessarily rely on highly-reduced circuit models with simplified current loss terms informed by Z experiments. However, incomplete experimental time histories and rigorous calibration and validation of surrogate models limit accurate constraints and introduce uncertainties into the characterization of loss processes. Developing a consistent picture of how losses develop and evolve would improve understanding of present-day experiments and better constrain circuit model representations, providing a basis for quantifying uncertainties in circuit models applied to Z and improve confidence in predictions of target performance. This presentation details the implementation of a Bayesian optimization study to maximize the information gained from Z experimental data and design.

DISTORTION MODELING OF PM HIP PARTS PRODUCED WITH AM HIP CAPSULES

Jason Mayeur[*1], Soumya Nag[1], Fred List[1] and Peeyush Nandwana[1]*

[1]Oak Ridge National Laboratory

ABSTRACT

Fabricating components via PM HIP is a well-established process capable of producing high quality near net shaped parts with excellent material properties. The process has been widely adopted by the offshore oil and gas industry and is increasingly being explored as an alternative process to make large parts for other energy sectors (e.g., nuclear, hydroelectric) to alleviate supply chain issues associated with large scale castings and forgings. The primary bottleneck of producing parts through the PM HIP route is the design and fabrication of the HIP capsule. HIP capsules are currently fabricated by hand through working and welding of sheet metal to produce the required capsule geometry, which can be a tedious process for complex geometries. To this end, there is interest in exploring the feasibility of fabricating HIP capsules via additive and/or hybrid manufacturing processes, which can drastically reduce capsule fabrication time. It is well known that the mechanical properties of AM materials may differ substantially from their wrought counterparts due to microstructural differences. Therefore, AM HIP capsules may present some challenges during the capsule design process related to mechanical property variations and/or anisotropy. In this study, we compare and assess the consolidation behavior of a PM HIP component using both conventional and AM HIP capsules and use a finite element model to understand the differences in consolidation behavior between the two cases.

ADVANCED NUMERICAL MODELING OF CONCRETE IN MESO-SCALE

Gianluca Mazzucco[*1], Beaudin Beaudin[1], Beatrice Pomaro[1], Jiangkun Zhang[1], Valentina Salomoni[1] and Carmelo Majorana[1]*

[1]*University of Padua*

ABSTRACT

Numerical modeling of concrete poses distinctive challenges owing to its nonlinear behavior, encompassing both hardening and softening characteristics. Undertaking long-term investigations further complicates matters, necessitating the precise representation of damage, creep, and fatigue [1]. This complexity adds layers to the already intricate processes of material characterization and modeling. Concrete is widely employed in diverse engineering applications, frequently entailing intricate multi-physics phenomena. These applications demand sophisticated numerical tools to ensure reliable predictions of associated state variables.
This study introduces a numerical approach focused on modeling cementitious materials at the constituent level. Specific constitutive laws are employed for the cement paste and aggregates, while the Interfacial Transition Zone (ITZ) is delineated using a cohesive algorithm [2]. The creation of realistic solid concrete models at the mesoscale is addressed through the utilization of advanced random distribution techniques and Computed Tomography.

REALIZABILITY-INFORMED LEARNING OF DATA-DRIVEN TURBULENCE MODELS

Ryley McConkey[*1], Eugene Yee[1] and Fue-Sang Lien[1]*

[1]*University of Waterloo*

ABSTRACT

Traditional turbulence closure models for Reynolds-Averaged Navier-Stokes (RANS) simulations rely on a mixture of physics-based intuition and heuristics. Recently, the application of machine learning towards replacing components of a closure model, or replacing the closure model entirely have attracted significant interest. Data-driven techniques offer a promising alternative to traditional closure modelling, since they offer the ability to leverage data from high fidelity numerical simulations to increase the accuracy of turbulence models for RANS. RANS remains an important and widely used technique for industrial users. Perhaps the most important issue for data-driven closure modelling is the issue of generalizability. Traditional physics-based closure models can generalize to a variety of flows. However, modern data-driven RANS closure models do not generalize well. In other words, though data-driven methods improve the accuracy of RANS simulation on similar flows to the training dataset, they do not make reliable predictions on flows that are significantly different than the training dataset.

The objective of the present study is to propose and demonstrate multiple techniques to increase the generalizability of data-driven closure models. A key issue among all modern data-driven RANS closure models is that they do not guarantee a realizable anisotropy tensor. Physical realizability is a constraint on the anisotropy tensor which arises from requiring the symmetric Reynolds stress tensor to be positive semi-definite. Since the training procedure for most data-driven closure models usually involves a simple mean squared error (MSE) or mean absolute error (MAE) loss function, the models often make unrealizable predictions. The most common technique to address this issue is to post-process the predictions using ad-hoc methods.

We propose the inclusion of a term in the loss function which penalizes unrealizable predictions at training time, thereby embedding additional physics-based information into the model. Along the lines of physics-informed machine learning, we term this technique realizability-informed learning. In the work to be presented at WCCM 2024, we will demonstrate that this penalty term reduces prediction error on new test cases, thereby demonstrating that realizability-informed learning enables data-driven closure models to generalize better. We will also demonstrate that a model trained using realizability-informed learning makes more realizable predictions that a model trained using a purely error-based loss function. In doing so, we aim to simultaneously address two key issues for data-driven closure models: making more realizable predictions, and improving the generalization of the model outside of the training dataset.

SPARSE REGRESSION, LP-REGULARIZATION, AND AUTOMATED MODEL DISCOVERY

Jeremy McCulloch[*1], Skyler St Pierre[1], Kevin Linka[2] and Ellen Kuhl[1]*

[1]*Stanford University*
[2]*Technische Universität Hamburg*

ABSTRACT

Sparse regression and model discovery are essential to gain physical insight from large amounts of data. These techniques allow us to discover interpretable and predictive models that provide simple relationships among scientific variables. While the statistical tools for model discovery are well understood in linear regression, their extension to nonlinear regression is often domain-dependent and can be computationally challenging. Here we integrate physical constraints and regularization to extract interpretable strain energy functions from mechanical testing data [1]. In particular, we used constitutive artificial neural networks to ensure that we discover models that satisfy known material symmetries and thermodynamic laws, and we used Lp regularization to reduce the number of parameters in the model [2]. We trained our networks on both synthetic and experimental data and observed the following trends: L2 ridge regularization fails to increase sparsity; L1 lasso regularization improves sparsity but introduces significant bias in the resulting parameters that hinders accuracy; L0.5 and L0 regularization allow us to fine-tune the trade off between interpretability and accuracy, but can be challenging to implement as the model complexity increases. With these insights, we demonstrated that constitutive neural networks can discover highly accurate parsimonious models with a few nonzero parameters. Our ability to discover interpretable constitutive models from data has the potential to provide physical and physiological insight into the mechanical properties of living systems. These insights can enable better understanding of disease progression, and can also allow for the development of better biomaterials. We expect that our results will generalize to other model discovery techniques, and to other fields including biology, chemistry, and medicine.

BAYESIAN LEARNING OF REDUCED-ORDER OPERATORS WITH GAUSSIAN PROCESSES

Shane McQuarrie[*1], Mengwu Guo[2] and Anirban Chaudhuri[3]*

[1]*Sandia National Laboratories*
[2]*University of Twente*
[3]*The University of Texas at Austin*

ABSTRACT

This work presents a data-driven method for learning reduced-order models whose predictions are endowed with uncertainty estimates. The operator inference approach to model reduction poses the problem of learning reduced-order model operators as a regression of state space data and corresponding time derivatives. When time derivative data are not natively available, as is often the case in applications, they must be estimated from the state data with, e.g., finite difference approximations. The accuracy of the estimation greatly affects the quality of the learned reduced-order model, hence learning accurate reduced-order models in this manner is challenging when available state data are sparse or noisy. Our approach incorporates Gaussian process surrogate modeling into the operator inference framework to (1) probabilistically describe uncertainties in the state data and (2) procure analytical time derivative estimates with uncertainty. The formulation leads to a generalized least-squares regression and, ultimately, reduced-order operators that are themselves defined probabilistically. The resulting model propagates uncertainties from the observed state data to reduced-order predictions.

SHAPE AND TOPOLOGY OPTIMIZATION OF COMPOSITE COMPLIANT MECHANISMS ACTIVATED BY PIEZOCERAMICS

André Piva Romeu[1], Juliano Fagundes Gonçalves[2], Ignacio Iturrioz[1] and Daniel M. De Leon[1]*

[1]Federal University of Rio Grande do Sul (UFRGS)
[2]University of São Paulo (USP)

ABSTRACT

This work aims to develop a formulation based on topology optimization technique for designing compliant mechanisms activated by piezoceramics. The novelty of the work is that not only the passive mechanism body, but the piezoelectric material shape is synthesized as well. Therefore, the actuator shape is studied together with the complaint mechanism. Another novelty of the work is that the passive material is made of composite material, having different mechanical behavior depending on the reinforcement orientation. The importance of designing such mechanisms is that piezoelectric actuators can be used in various applications, including embedded electronics and medical equipment, both requiring applications at micro and nanoscales. At these scales, compliant mechanisms have a clear advantage over other devices since they are built from one material layer, therefore are free of hinges and joints, minimizing the appearance of backlash and clearance when several cycles of application are required. The proposed formulation considers the active and passive material of the mechanism materials set in the topology optimization problem. The goal is to design mechanisms with a more efficient displacement transfer from the input to the output ports. The domain is discretized using the finite element method assisted by the implementation of Python libraries through FEniCS (Finite Element Computational Software) project and the derivatives are computed numerically using dolphin adjoint packages. Material interpolation scheme for the topology optimization problem is applied by means of the PEMAP (PiezoElectric Material with Penalization) method [1] that is a variant of the so-called SIMP (Solid Isotropic Material with Penalization) with the advent of extra terms that consider the piezoelectric effect in the active material phase. The optimization problem to be solved in this work is a multi-objective problem of minimizing mean compliance and maximizing mean transduction. The mathematical solver implemented is the so-called MMA (Method of Moving Asymptotes). Results show that the methodology applied works successfully for the examples with different polarization profiles.

UNVEILING AMORPHOUS MICROSTRUCTURAL FEATURES: A MANIFOLD LEARNING APPROACH USING DIFFUSION MAPS

Rahul Meena[*1], Spencer Fajardo[1], Michael Shields[1], Michael Falk[1] and Dimitris Giovanis[1]*

[1]*Johns Hopkins University*

ABSTRACT

Amorphous solid failure originates from local plastic rearrangements in the atomic configurations of the material during shear-induced deformation. By assessing the incremental stress needed to cause a local rearrangement, the Local Yield Stress (LYS) approach was recently developed to probe local regions and quantify their susceptibilities to plasticity. Despite its promising potential to deepen our insights into plastic deformation in amorphous solids, the method's computational demands limit its feasibility for predictive modeling. We propose a manifold learning-based framework to extract microstructural descriptors from atomistic configurations. More specifically, we deploy Diffusion Maps (DMaps, a nonlinear manifold learning technique) to systematically extract low-dimensional structural features from high-dimensional atomic configuration data. We then aim to relate this structure to material performance assessed by the LYS approach. In this manifold learning method, each data point corresponds to a geometric neighborhood of atoms, and thus a meaningful similarity measure between configurations must capture the “distance” between two neighborhoods. We utilize the newly developed Gaussian Integral Inner Product (GIIP) to measure this similarity, addressing important issues such as noise sensitivity, continuity, smoothness, permutation, and rotational invariance, making it robust for measuring similarity in randomly distributed atomic structures. We apply this method to a two-dimensional binary glass-forming system to characterize the local structure in the material, linking the diffusion coordinates from a neighborhood to well-known structural descriptors and new localized material performance measures. For example, we predict Conventional bond orientational order ($\Psi 5$, $\Psi 6$) and Generalized bond orientational order(Θ) with Gaussian Process Regression, showcasing the method's effectiveness in revealing the underlying structure. These relations have the potential to enhance our understanding of the complex interplay between microstructure and mechanical behavior in amorphous materials.

MACHINE-LEARNING-ENABLED SOLID BOUNDARY CONDITIONS IN MESH-FREE PARTICLE METHODS

Nariman Mehranfar[*1] and Ahmad Shakibaeinia[1]*

[1]*Polytechnique Montréal*

ABSTRACT

Meshfree particle methods such as Smoothed Particles Hydrodynamics (SPH) and Moving Particles Semi-Implicit (MPS) have become more popular in the simulation of flows with large interfacial deformations and fragmentations. These techniques use a kernel smoothing process to discretize the governing equations over the physical domain, represented by a set of free-to-move computational nodes called particles (Jandaghian, Krimi et al. 2021). Solid boundary conditions pose a challenge in these methods, primarily due to the near-boundary kernel incompleteness, which can negatively affect conservation properties. Various techniques are used to address solid boundaries in particle methods, including ghost (virtual) particles, mirror particles, boundary force, and polygon boundary conditions (Herman Musumari Siaben, Rubens Augusto Amaro Junior et al. 2023). While some of these methods have proven effective, their implementation presents challenges and is often computationally expensive, particularly when dealing with large-scale and complex geometries. This study introduces a novel machine learning (ML) technique for the implementation of solid boundaries in particle methods. Two distinct approaches are explored. The first approach develops a neural network (NN) to establish a relationship between geometric characteristics and boundary contributions within each MPS/SPH approximation operator. These include interpolation, gradient, divergence, and laplacian operators. In the second approach, a NN is designed to correlate geometric features with the total boundary contribution, specifically in SPH/MPS approximations of mass and momentum conservation in the Navier-Stokes equation. The ghost particle approach is used to generate a comprehensive training dataset of boundary contributions for various geometrical features. The trained models are subsequently tested in flow simulations involving diverse geometries. The results demonstrate the effectiveness of the developed approaches, with a significant computational cost reduction compared to the conventional ghost particle method.

RANDOM WALK AND CONTINUUM MODELS FOR THE PROPAGATION OF BONE ADAPTATION SIGNALS THROUGH THE OSTEOCYTE NETWORK

Adel Mehrpooya[*1], Vivien Challis*[1] and Pascal Buenzli*[1]

[1]*Queensland University of Technology (QUT)*

ABSTRACT

The adaptation of bone tissue to mechanical loads and the repair of bone micro-damage rely on the propagation of signaling molecules through the osteocyte network embedded in bone tissue. Osteocytes form a dense cellular network in bone able to sense mechanical deformation of bone tissue [1,2]. They regulate bone adaptation and regeneration by emitting biochemical signals that propagate through the network to the bone surface where they induce bone resorption and bone formation. How these biochemical signals propagate in bone is influenced not only by network topology but also by the spatial arrangement of osteocytes within bone tissue. Understanding the collective reaction-diffusion properties of these signals is important to evaluate when and where bone formation and bone resorption are initiated.

In this study, we explore stochastic and deterministic random walk models of signaling molecules propagating and reacting within osteocyte networks with various spatial arrangements of osteocytes and various osteocyte connectivities. By taking a continuum limit of the random walk models, we derive inhomogeneous reaction–diffusion–advection equations, where diffusivity and advective velocity depend on the local osteocyte density and connectivity within the network. Our findings reveal that heterogeneous osteocyte distributions induce large spatial variations in signaling molecule concentrations and influence their collective transport properties. Furthermore, we observe that noise within the stochastic random walk model is directly influenced by osteocyte density. We explore signal-to-noise ratios for different damage detection scenarios and demonstrate that the location of perturbations to the osteocyte network, representing micro-damage, can be detected by signals received at the network boundaries [3]. Finally, we apply this model of signal propagation to formulate a model of dynamic bone tissue with an evolving embedded osteocyte network, in which bone formation and bone resorption are controlled by osteocyte-generated biochemical signals received at the bone surface.

DESIGN OF A SOFT PNEUMATIC ACTUATOR USING TOPOLOGY OPTIMIZATION AND POROHYPERELASTICITY

Sumit Mehta[*1] and Konstantinos Poulios*[1]

[1]*Technical University of Denmark*

ABSTRACT

This work presents a novel nonlinear topology optimization formulation as a tool for the computational design of pneumatically triggered soft actuators. Soft robotic actuators, typically made of elastomers, undergo very large deformations which can be simulated by the theory of hyperelasticity. Pneumatic actuators produce the desired output motion by pressurizing certain cavities in the structure, thereby loading the surrounding elastomer solid. In a computational setting, this pressurization can be modelled by the Darcy flow equations, with high permeability in cavities and low permeability in solid regions. Hence, a model is necessary that includes both Darcy flow and hyperelasticity in the entire design domain, with stiffness and permeability coefficients that depend locally on the design variable. In the present work, the two-field porohyperelasticity theory by Simon et al. (1996) is adopted, where displacement and pressure fields are both used as primary variables. Porohyperelasticity extends the validity of the Darcy flow and elastic deformation equations to configurations that exhibit very large deformation. This is a major improvement compared to the linear poroelasticity topology optimization formulation previously introduced by Kumar et al. (2021). We combined the permeability interpolation and drain term proposed by Kumar et al. (2021) with the porohyperelasticity formulation by Simon et al. (1996), and the nonlinear topology optimization framework with void regularization by Bluhm et al. (2023), in order to create an efficient, accurate, and generic computational framework for soft pneumatic actuators. The proposed formulation has been used to maximize the bending response of a 3D tube segment under certain external resistance, obtaining optimized designs which can serve as building blocks for constructing, e.g., gripper fingers and dexterous endoscopy tubes. The obtained 3D designs, although topologically similar to classical human-engineered solutions, achieve better controllability through their higher geometric complexity.

Keywords: Pneumatic soft robotics, nonlinear topology optimization, porohyperelasticity

CHARACTERIZING HETEROGENEOUS ELASTIC PROPERTY DISTRIBUTION OF SOFT TISSUES BASED ON AN EXPLICIT INVERSE METHOD

*Yue Mei**[1]

[1]*Dalian University of Technology*

ABSTRACT

Characterizing heterogeneous material parameters plays an extremely crucial role in the field of biomedical applications. However, classical implicit optimization inverse methods require treating the material parameters of each node or element after the discretization of structural finite elements as optimization variables, leading to a high number of optimization variables. Additionally, for nonlinear constitutive models with multiple material parameters, solving processes can result in an exponential growth of optimization variables. To address these issues, we propose an explicit optimization inverse method based on movable and deformable components. The proposed method only involves optimizing the geometric parameters and material parameters of movable and deformable components, significantly reducing the total number of optimization parameters and improving convergence. The feasibility of the explicit optimization method in reconstructing heterogeneous material fields is validated through numerical comparisons with implicit optimization methods. Furthermore, the explicit optimization method not only provides accurate reconstruction results when using full-field displacement inversion but also achieves precise material distribution when only utilizing boundary displacement measurements. The approach presented herein is expected to effectively enhance the accuracy and efficiency of characterizing the biomechanical properties of soft materials, overcoming the bottleneck issues in performance.

THE PHYSICS-INFORMED DEEP COMPOSITIONAL OPERATOR

Weiheng Zhong[1] *and Hadi Meidani**[1]

[1]*University of Illinois Urbana-Champaign*

ABSTRACT

We focus on solving partial differential equations (PDEs) with variable parameters. To this end, neural operators as an effective machine learning method are trained as mapping from these parameters to their corresponding solutions. A significant challenge in training neural operators is the requirement for large datasets of paired input-output examples, which are often expensive and time-consuming to produce. As a solution, neural operators trained through physics-informed methods have gained attention. However, existing physics-informed neural operators struggle with issues such as accommodating irregular domain shapes or generalizing across different dimensions of parameter observations. We propose a novel model architecture that successfully overcomes these hurdles. It is designed to generalize across diverse parameter observation dimensions within irregularly shaped domains. Moreover, this innovative architecture is compatible with physics-informed training, thereby bypassing the need for finite-element methods in creating training data. Our results show that this novel model not only matches but potentially surpasses the performance of traditional data-driven neural operators.

A HIGHLY EFFICIENT COMPUTATIONAL APPROACH FOR FAST SCAN-RESOLVED SIMULATIONS OF METAL ADDITIVE MANUFACTURING PROCESSES ON THE SCALE OF REAL PARTS

Sebastian D. Proell[1], Peter Munch[2], Martin Kronbichler[3], Wolfgang Wall[1] and Christoph Meier[1]*

[1]Technical University of Munich
[2]Uppsala University
[3]Ruhr University Bochum

ABSTRACT

We present a fast method to simulate metal powder bed fusion additive manufacturing (PBFAM) processes on the part-scale to predict quantities of interest (QOI) such as temperature evolution, microstructural phase composition, and residual stresses. The fundamental computational challenge for part-scale simulations lies not so much in the requirements of the spatial discretization but rather in the large number of time steps necessary to resolve the fast-moving laser path. In contrast to many existing approaches in the literature, our model consistently resolves the physical scan path, enabling new and detailed insights into the scan-strategy-dependent evolution of QOIs, especially for complex geometries.

Starting from a highly efficient thermal model [1], we present an efficient implementation to predict the thermally induced microstructural composition and the residual stress distribution. An emphasis is placed on an implementation that best utilizes available hardware. We use well-established techniques for parallel evaluation on distributed, adaptively refined meshes to distribute the work among available CPUs. Appropriate single instruction multiple data (SIMD) techniques are utilized to speed up the evaluation times significantly. Applying SIMD techniques to constitutive equations and evolution laws requires careful analysis of the different conditional branches within the model equations. All vector accesses and updates are performed in a cache-efficient manner. A performance analysis demonstrates the high degree of optimization of the presented approach. The proposed computational framework allows to perform a coupled thermal microstructure simulation with a consistently resolved laser beam path for the complete build process of the AM Bench 2022 cantilever specimen (312 layers, 30 million spatial degrees of freedom, 50 million time steps) with a time-to-solution below two days. For the coupled thermo-mechanical problem, we present new application-specific solution schemes that enable fast simulations on hundreds of process layers.

ABSTRACT

One of the challenges faced by oil production systems is the formation of inorganic fouling, which is one of the problems of flow assurance, caused by the precipitation and deposition of substances such as barium and strontium sulfate, silicon sediments, calcium carbonate and sulfate, iron, and other insoluble solids, in a single phase or combination of different minerals. Effective methodologies are being sought to mitigate or prevent the damage caused by this phenomenon, such as the injection of inhibitors to prevent the nucleation and growth of fouling crystals. The solvent used by many of these inhibitors is monoethylene glycol (C2H6O2), which is a liquid substance of low toxicity, miscible in polar solvents and relatively non-volatile. For this approach to be effective, it is necessary to understand the behavior of the product used for this purpose inside the pipeline, as incorrect injection can accelerate and promote the recurrence of these formations. Therefore, in the present work, in order to understand the effectiveness of cases of inhibition of this phenomenon, we begin to investigate the behavior of the two-phase, multi-component flow resulting from the injection of monoethylene glycol into a mixture of oil and formation water in an oil production system pipeline, using Ansys Fluent, and through a Deep Learning model, in which the predictions obtained through the numerical simulations were used as a training data set. Using both methods, the distribution of the mass fraction of monoethylene glycol in this system was predicted and the influence of different transport speed profiles of this fluid on the coefficient of variation of this fraction was verified, to predict the uniformity of the resulting mixture between this substance and the formation water. Our preliminary results show that the deep learning approach has produced reasonably accurate results at much lower computational costs than that required to carry out the numerical simulations.

A PERFORMANCE ANALYSIS PROCEDURE BASED ON CORRECTED DISPLACEMENTS TO EVALUATE THE SEISMIC RESPONSE OF STEEL 2D FRAMES

Jose Mendoza[*1], Berardi Sensale[1] and Alfredo Canelas[1]*

[1]*Universidad de la República*

ABSTRACT

In the proposed methodology, a load pattern is applied in a non-adaptive fashion to obtain the seismic response of two-dimensional steel moment resisting frames. The proposed methodology is based on the structural dynamics theory and consists of a single run nonlinear analysis. This invariant load pattern is formulated by considering higher mode effects with the use of an effective modal mass contribution factor. Also, part of the proposed procedure, a corrective factor is employed to adjust the displacements obtained from the nonlinear analysis ensuring that the drift values obtained from the corrected displacements are adequate. The procedure allows the analysis of the structural response, i.e, story displacement and story drifts. To evaluate the methodology, three benchmark 2D moment steel frames with 3, 9 and 20 stories are analyzed. Material and geometric non linearities are considered for all the cases. The results are compared with the ones obtained by the Nonlinear time history analysis and the Force adaptive procedure.

TOPOLOGY OPTIMIZATION DESIGN OF FLOW MACHINE ROTORS FOR ROTATING RESONANCE SUBJECTED TO LOW DENSITY FLOWS

Diego Hayashi Alonso[1], *Renato Picelli*[1], *Julio Meneghini**[1] *and Emilio Carlos Nelli Silva*[1]

[1]*University of São Paulo*

ABSTRACT

Resonance is a phenomenon that can easily bring a fluid flow device to fail, and it also portrays different characteristics under rotational motion. Thus, this is an important aspect to consider in flow machine design, beyond just the fluid flow performance. Until now, only the fluid flow performance has been considered in fluid flow topology optimization, still missing the rotating resonance phenomenon. Thus, this work elaborates a new formulation for fluid flow topology optimization considering rotating resonance, while also taking a low mass density (compressible or incompressible) fluid flow into account. The fluid flow-based design now considers three different aspects: the modal analysis (for resonance), the solid structure (for the mechanical behavior) and the low mass density fluid flow (for the fluid flow performance). The topology optimization problem is exemplified for a predominantly radial rotor, which is considered through a simplified 2D model. The different design aspects are considered from a multiobjective function approach. The design variable is nodal, and the optimization algorithm is based on integer linear programming. Some numerical examples are presented for the new topology optimization formulation, showing how the modal and structural effects affect the topology optimization design.

A LENGTH SCALE INSENSITIVE PHASE FIELD MODEL BASED ON IRREVERSIBILITY CONSTRAINT OF FRACTURE PROPAGATION USING LAGRANGE MULTIPLIER

Li Meng[*1], Hsiao Wei Lee[1], Alireza Ashkpour[1] and Ahmad Najafi[1]*

[1]*Drexel University*

ABSTRACT

The classical phase field model with second order geometric function α(φ)=φ^2 (i.e., AT2 model), has wide applications in modeling brittle fracture, but nonlinearity and inelasticity are found in its stress-strain curve. The phase field model with linear geometric function α(φ)=φ (i.e., AT1 model), has a linear elastic threshold in its stress-strain curve, which is expected to better model brittle fracture. However, both AT2 and AT1 models are length scale sensitive phase field model, which could have difficulty in adjusting fracture strength and crack band at the same time through a single parameter (length scale). In this study, a generalized quadratic geometric function (linear combination of AT1 and AT2) is used in phase field model, where the extra parameter in this geometric function makes it a length scale insensitive phase field model. Similar to the AT1 model, negative phases can happen in the proposed generalized quadratic geometric function model. To solve this problem in the proposed model, irreversibility constraint of fracture propagation is realized through KKT conditions using Lagrange multiplier, instead of the KKT conditions using strain energy in the classical AT2 model. Several exemplary simulations verify the feasibility of the proposed phase field model, including Mode Ⅰ, Mode Ⅱ, and mixed mode cases. From these simulations, the proposed Lagrange multiplier works well on the irreversibility constraint of fracture propagation. For the proposed length scale insensitive phase field model, it can provide a linear elastic threshold, and a narrower crack band can be obtained, compared to the other two phase field models (i.e., AT1 and AT2).

TOPOLOGY OPTIMIZATION DESIGN UNDER STIFFNESS, STRENGTH, AND TEMPERATURE CONSTRAINTS OVER A WIDE RANGE OF TEMPERATURES

Qingxuan Meng[*1] and Bin Xu*[2]

[1]*Hebei University of Engineering*
[2]*Northwestern Polytechnical University*

ABSTRACT

This article proposes a thermo-elastic topology optimization with stiffness, strength, and temperature constraints involving a wide range of temperatures. The state equations for the linear elasticity and heat conduction are considered. Formulations involving minimum volume with compliance, stress and temperature limits under multiple thermal conditions are presented. The global stress and regional temperature metrics adopting the corrected aggregation function are used to evaluate the maximal stress and temperature, respectively. The stress stabilizing scheme is utilized to overcome the iteration oscillation stemming from highly nonlinear behavior of thermal stress constraints for multiple thermal conditions. To achieve clear optimized topologies under design-dependent loads, a continuation strategy for the relaxed Heaviside function is developed.

Two 2D numerical examples are employed to illustrate the validity and practicability of the proposed approach. The results show that the optimized structures designed by a certain temperature may be damaged or have thermal deformations once the ambient temperature changes due to the thermal residual stress. The designs covering wide temperature range achieved by neglecting stiffness or strength constraints can result in stiffness reduction or strength failure. Optimized topology for multiple heat fluxes works well at different temperatures. Designs with structural and thermal limits have good mechanical performance. Battery pack designed covering a wide range of temperatures validates the method. It is therefore imperative for the optimization to adopt a multi-physics model involving multi-constraints over a wide temperature range.

HOW DOES FRICTION AFFECT SLIDING CONTACT MECHANICS?

Nicola Menga[*1], Christian Mueller[2], Giuseppe Carbone[1] and Martin Mueser[2]*

[1]*Politecnico di Bari*
[2]*Saarland University*

ABSTRACT

Dealing with semi-infinite solids, interfacial friction is usually neglected, as normal and tangential displacements fields are independent on each other (unless material dissimilarity occurs).
However, contacts involving a sufficiently thin layer, do not stick to such a simplified assumption, as thickness related normal/tangential coupling occurs, and surface frictional shear stresses do matter. It is the case, for instance, of classical rotary seals in boundary lubrication regimes, where rough frictional contacts between thin polymeric sealing lips and rotating shafts occur. Also, functional coatings to control the interface (adhesive, frictional, chemical, etc.) behavior, may be very thin and compliant, and usually experience frictional sliding during operation. All the same, these examples indicates that conditions exists where elastic coupling between in plane and out of plane displacements cannot be neglected and must be considered, instead.
Here, we present our results [1-3] on the rough contact mechanics of elastic and viscoelastic thin layers. We assume sliding conditions and Coulomb friction at the interface, and we investigate the contact problem in the framework of linear (visco)elasticity, by relying on the Green's functions approach. We show that, due to the friction and coupling, the presence of interfacial friction may lead to a significant increase of the contact area (up to 10%), compared to the frictionless case, which may affect specific functional response of the interface, such as electrical and thermal conductivity. Since the normal gap distribution is also affected by coupling and friction, the leak rate at the interface turns out significantly altered too. Coupling and friction also affect the contact pressure, which presents a certain degree of asymmetry leading (even for purely elastic materials) to an additional interlocking contribution to the tangential force opposing the relative motion at the interface. Therefore, the overall macroscale friction cannot be predicted by summing-up the local (Coulomb) friction contributions occurring at microscale as commonly expected; it should instead include an additional coupled-induced term. The surface stress tensor is also affected, as due to friction and coupling very high tensile stresses are localized at the contact trailing edge, which are likely to induce material failure.
In conclusion, we show that the common practice to neglect in-plane interactions in contact mechanics may lead to misleading tribological predictions.

TOWARDS TRUSTWORTHY MACHINE LEARNING FOR WEATHER MODELING

Zhou Fang[1], Vishal Srivastava[1] and Gianmarco Mengaldo[1]*

[1]National University of Singapore

ABSTRACT

In recent years, machine-learning based weather models trained on historical and simulated data have attained an accuracy level that matches or even exceeds those of operational numerical models. Nevertheless, AI-based models are commonly perceived as black boxes, result in compromised credibility in the decision-making process.

This work endeavors to shed light on the reliability of AI-based weather forecast models. First, we introduce dynamical indicators into model evaluation, promoting correct modeling of the underlying dynamics. A comparison of mainstream machine learning and numerical weather models is provided. Second, we implement various post-hoc interpretability methods on GraphCast, fusing the knowledge learned by neural networks and understood by humans. Finally, we inject physical priors into data-driven models leveraging a DeepONet structure.

PERSONALIZED AND UNCERTAINTY-AWARE VIRTUAL PLANNING FOR CORONARY ARTERY BYPASS GRAFT SURGERY INFORMED BY CT MYOCARDIAL PERFUSION IMAGING

Karthik Menon[*1], Zachary Sexton[1], Owais Khan[2], Daniele Schiavazzi[3], Koen Nieman[1] and Alison Marsden[1]*

[1]*Stanford University*
[2]*Toronto Metropolitan University*
[3]*University of Notre Dame*

ABSTRACT

Coronary artery disease (CAD) is the leading cause of death globally. While coronary artery bypass graft (CABG) surgery improves mortality in patients with severe CAD, long-term outcomes remain a challenge, with 24% of patients reporting chest pain within a year. This is because revascularization is often guided by anatomical risk, which has worse outcomes than treatment based on hemodynamic severity. To address this, personalized computational fluid dynamics (CFD) simulations can improve CAD treatment outcomes via non-invasive hemodynamic risk assessment and virtual treatment planning.

CFD can non-invasively calculate clinically relevant hemodynamics by simulating blood flow in patient-specific anatomies based on non-invasive clinical imaging. However, while current CFD tools are mostly diagnostic, predictive surgical planning requires models that are personalized to the pre-treatment hemodynamics for each patient while linking clinical interventions in large epicardial vessels with downstream flow in myocardial microvasculature. This is a challenge because image-based models are limited to vascular scales that can be resolved by clinical imaging – resulting in models that omit small vasculature and do not reflect true patient-specific coronary flow. Moreover, these models distribute flow amongst arteries empirically, which ignores patient variability and microvascular disease. In addition, while current models are usually deterministic, rigorous uncertainty quantification is crucial for robust clinical translation of such virtual diagnosis and treatment planning tools.

To address these issues, we demonstrate a novel framework for accurate, personalized and uncertainty-aware virtual CABG planning that is informed by clinical data. This framework (1) creates realistic multiscale anatomical models by combining image-based models with synthetic vascular trees to represent arteries that are under-resolved in clinical imaging; (2) estimates personalized model parameters and flow distributions by incorporating patient-specific clinical CT myocardial perfusion imaging and measurements of cardiac function; (3) quantifies uncertainty in model parameters as well as clinically relevant hemodynamic metrics using Bayesian estimation. We show that this framework reproduces patient-specific coronary flow distributions significantly more accurately than the widely-used Murray’s law. Crucially, models personalized to pre-CABG clinical data are able to more accurately predict clinically-measured post-CABG outcomes. This is therefore a promising step towards personalized, multiscale and uncertainty-aware virtual CABG planning.

OPTIMAL GPU CONTACT IN SIERRA SOLID MECHANICS

Mark Merewether[*1], Matthew Mosby[1], Nathan Crane[1] and Kendall Pierson[1]*

[1]Sandia National Laboratories

ABSTRACT

Sierra Solid Mechanics (Sierra/SM) is the engineering mechanics simulation code developed at Sandia National Laboratories for modeling highly nonlinear large deformation mechanical events. These mechanical events often involve complex contact solutions. Previously, the Dash contact library, the production contact library in Sierra/SM utilized MPI to efficiently compute contact on CPU dominant architectures. This work extends the contact library to efficiently compute contact on the new GPU dominant architectures of the future.

This presentation will give a brief overview of the Dash contact algorithm in Sierra/SM. We will also look back on the history of porting Dash to the GPU and discuss why these efforts failed to produce satisfactory performance. We will then present the current performance of Dash contact on the GPU, showing the significant speedups realized over current CPU dominant platforms. Details of the contact algorithms used for GPU execution (coarse search, closest-point-projection, etc.) will also be explored. Finally, we will present the future of Dash contact on the GPU and Sierra/SM on the GPU in general.

IMPROVING ACCURACY, INTERPRETABILITY, AND GENERALIZABILITY OF STRESS INTENSITY FACTOR SOLUTIONS USING SYMBOLIC REGRESSION

Jonas Merrell[*1], John Emery[2], Robert Kirby[1] and Jacob Hochhalter[1]*

[1]*The University of Utah*
[2]*Sandia National Laboratories*

ABSTRACT

Finite element models can be used to obtain high-fidelity stress intensity factors (SIFs), but at the expense of a significant computational cost. In contrast, handbook solutions such as the models developed by Raju and Newman, provide SIF approximations using low-cost surrogate models. A limitation to such handbook solutions is their limited applicability to a set of highly idealized cases. Machine learning offers the ability to produce new handbook solutions for improved accuracy and more complex, practical cases. Genetic programming based symbolic regression (GPSR) adds the ability to maintain the SIF model interpretability that is beneficial to handbook solutions. Interpretable models are desirable due to improved trust. Perhaps equally important is that most engineering software can readily use analytical expressions, like those produced by GPSR, lowering the implementation barrier. In this presentation, we present a direct comparison to the Raju-Newman SIF solution for a semi-elliptical surface crack in a finite plate to models produced using GPSR. Comparisons are made using both accuracy and model complexity as comparative metrics. For GPSR to provide SIF models with acceptable accuracy, a mechanics-based approach (much like the technique used by Raju and Newman) is required in which a known analytical solution is combined (multiplicatively) with geometrical correction functions in a boosting-motivated approach. The GPSR models were found to outperform the Raju-Newman SIF models in terms of accuracy, complexity, and evaluation time.

ACCURACY AND CONVEXITY OF HOMOGENIZED MATERIAL STIFFNESS FOR NON-AFFINE FIBROUS MATERIALS

Jacob Merson[*1] and Md. Rifat Hossain*[1]

[1]*Rensselaer Polytechnic Institute*

ABSTRACT

Fibrous materials are an exceptional class of materials that are found in biological structures ranging from the scale of the cell nucleus to the tissue and organ scales. In the context of collagenous tissues, fiber diameters are typically orders of magnitude smaller than the structures of interest and complex behaviors emerge from the heterogeneous and nonlocal nature of fiber interactions. Capturing this emergent behavior has been a matter of intense interest in the biomedical engineering community spurring many novel continuum scale constitutive relations typically based on an assumption of affine fiber deformations which allows analytical homogenization of the micromechanical response.

Numerous works have shown that fiber kinematics is non-affine for the range of densities and bending lengths typical in biological tissues. And this non-affine behavior, drives the macroscopic behavior. Therefore, multiscale models that can capture the fiber micromechanics, but model problems of biological relevance are needed. To this end, we developed a multiscale finite element code for heterogeneous supercomputers, MuMFiM, that uses computational homogenization of fiber network subscale models, and used these simulations to create machine learned surrogate models. This talk focuses on the computation of the material stiffness as required for the macroscale finite element solve in MuMFiM. Due to factors such as nonlinearity and sub-isostaticity, network structures often have non-invertible Jacobians and are typically solved with explicit or dynamic relaxation methods. This has led to a range of methods for computing material stiffnesses. We will discuss the accuracy, convexity, and range of applicability for four methods as follows: 1) finite differencing of a dynamic relaxation solver [1], 2) machine learned surrogate models using Sobolev minimization to train on energy, stress, and stiffness [2], 3) a specialized non-affine approximation method for fibrous materials described in [3], and 4) and, the classical static condensation method.

DEVELOPMENT OF TAILORED FIXTURES AND CONDITIONS FOR 3-AXIS MECHANICAL SHOCK TESTING.

Mikhail Mesh[1] and Tyler Alvis*[1]

[1]*Sandia National Laboratories*

ABSTRACT

Components of aerospace systems are often subject to pyroshock and other shock loads and, as such, must be qualified for those environments. The most common laboratory setup using an air gun and resonant plate allows for testing in only one direction at a time. However, single axis tests can never perfectly reproduce the environmental loading the component will see in the field. Additionally, large input forces can be required to match certain loads in a single axis which could overload components in an off axis, causing damage or failures to occur. Therefore, it is crucial to design a proper 3-axis test to reproduce the environment as closely as possible. Three-axis tests are complex and tedious to set up to achieve the desired loads.
The first step in using analytical tools for the design of the test fixture is to show that simulation can accurately describe the behavior of the fixture during the test. We have previously developed and validated a fully non-linear finite element model of the airgun resonant plate 3-axis shock test. The model has all important features parametrized, including geometry of the fixture, location of the test object on the fixture, impact point, and dimensions and velocity of the projectile. To develop the fixture and test conditions that result in shock loads that match provided specifications, advanced optimization techniques based on design space exploration, construction of surrogate models using Gaussian Process Models, sensitivity analysis and global optimization both for scalar and functional quantities of interest were used.
The method developed for optimization of test fixture and conditions allowed for the reproduction of 3-axis shock loads in a single laboratory experiment without multiple iterations in hardware, thus not only facilitating qualification of components under more realistic conditions, but also reducing required time and cost.
We will present results of the fixture development for the real-world test and predictions of the designed test performance.

ON THE TRANSIENT BEHAVIOR OF ROTOR-STRUCTURE-FOUNDATION-SOIL SYSTEMS

Euclides Mesquita[*1] and Amauri Ferraz*[1]

[1]*University of Campinas*

ABSTRACT

The modelling of the transient dynamic response of rotor-structure-soil systems is important in many situations such as blade failure in the wind turbines, sudden electrical load changes in the wind turbine generator and incoming wave fields hitting the foundation due to earthquakes or blasts. The modelling and solution of the transient behavior of these coupled systems is a challenge due to the dynamics of the rotating system but also because of the soil response presenting geometric damping.

The frequency domain response of a Laval (Jeffcott) rotor interacting with a rigid foundation on an elastic half-space was presented by Maurer et ali. [1]. An extension of this work to include more complex and realistic viscoelastic and layered soil models was presented by Carrion et ali. [2].
In the present work a methodology is introduced that allows to model the transient response of a Laval rotor interacting with a frame structure supported by a foundation interacting with a soil profile. The system is subdivided into two sub-systems. In the first subsystem, the transient dynamic response of the structure-foundation-soil is obtained by a modified modal analysis procedure [Amauri, 3]. For the second subsystem, the governing equations of the Laval rotor with damping mechanisms are integrated in the time domain. The dynamic coupling of both subsystem by a numerical dynamic coupling scheme allows the determination of the transient behavior of the coupled RSFS system.

In the numerical examples, the role of the internal and external rotor damping mechanisms and the soil geometric damping are analyzed in a rotor run-up passing through its resonances.

EFFICIENT RANDOMIZED ITERATIVE SOLVERS FOR UNSYMMETRICAL PROBLEMS IN COMPUTATIONAL MECHANICS

Youssef Mesri[1]*

[1]*MINES Paris, PSL University*

ABSTRACT

Solving large-scale linear systems resulting from partial differential equations poses significant challenges in both computation and memory storage. This difficulty, however, creates opportunities to reconsider traditional numerical algorithms within the context of extensive data and massively parallel supercomputers [1]. In the last decade, a novel approach has emerged, leveraging randomization to accelerate linear algebra operations [2]. This method demonstrates impressive efficiency, achieving linear complexity O(N) with respect to problem size, as validated in various dense linear systems, including integral equations, statistics, and machine learning.
In contrast to our previous work [1,3] focused on dense and low-rank systems, this presentation explores the possibilities and hurdles of applying the randomization approach to intricate systems originating from Fluid and Solid Mechanics problems. These systems are characterized by sparsity and frequent ill-conditioning. The emphasis will be on incorporating appropriate sketching techniques into the construction of the Krylov method to enhance the performance of the underlying iterative solver. The talk will include the presentation of 2D and 3D applications to evaluate the efficacy of this new paradigm.

RECENT ADVANCES IN WEAK-FORM EQUATION LEARNING WITH APPLICATIONS TO MULTISCALE PHENOMENA

*Daniel Messenger**[1]

[1]*University of Colorado Boulder*

ABSTRACT

Equation learning has arisen as a paradigm for constructing governing equations for phenomena of interest using observations of the underlying system. In the context of differential equations, a consensus has formed that weak-form equation learning (WFEL) offers many advantages, such as implicit noise filtering, high accuracy, and reduced regularity requirements on the ground-truth data. In this talk I will review essential components and theoretical results of the WSINDy algorithm (Weak-form Sparse Identification of Nonlinear Dynamics) to demonstrate these advantages in the discovery of ordinary and partial differential equations. I will also delve into a new paradigm for which WFEL appears to be particularly well-suited, that of inference for multiscale systems. Recent works have shown that WSINDy can aid in the discovery of interpretable mean-field laws for large systems of particles, homogenization of highly-oscillatory media, and coarse-graining of Hamiltonian systems with approximate symmetries. I will survey these results and with applications to cell migration experiments, and provide a general outlook for this line of research.

ACTIVE LEARNING TO ACCELERATE THE QUALIFICATION OF ADVANCED MATERIALS FOR HARSH CONDITIONS

*Mark Messner**[1]

[1]*Argonne National Laboratory*

ABSTRACT

Under harsh conditions material properties are seldom static as the environment alters the material chemistry and microstructure over time. Qualifying materials for service in harsh conditions therefore often requires developing and fitting a model to predict how the material properties will change under the expected service conditions. Calibrating and validating these models usually requires some amount of long term testing in representative environmental conditions. Extensive long-term testing greatly slows the qualification of new materials, as, by definition, these tests have long durations and often require expensive test setups to replicate the target service environments. Traditionally, simple gridding approaches have been used to select particular test conditions within target windows and the maximum duration of tests have been selected with rules derived from engineering experience. This talk describes the potential in replacing these traditional methods with active learning approaches. Specifically, the talk focus on using active learning to select creep test conditions, with the goal of developing an accurate model for long-term creep behavior. Several active learning strategies are compared to gridding test conditions or selecting conditions randomly, in order to quantify the advantages of active learning in reducing the number of tests required to reach a desired level of accuracy.

A HOMOGENIZATION APPROACH FOR THE ANALYSIS OF SHELL STRUCTURES EMPLOYING IMAGE-BASED METHODS

Leonie Mester[*1], Simon Klarmann[1] and Sven Klinkel[1]*

[1]*RWTH Aachen University*

ABSTRACT

In the field of civil engineering, the enhanced corrosion resistance offered by textile reinforcement allows for the construction of slender structures. Nonetheless, the complex internal structure makes a detailed analysis challenging and computationally expensive. To address this issue, a multiscale method for the efficient structural analysis of shell structures is proposed. The structural problem is investigated at two scales: a macroscopic scale that describes the shell structure and a mesoscopic scale that describes the material response. The inherent global periodicity found in biaxial grid-aligned textile reinforcement, which is commonly used in civil engineering, facilitates the definition of a representative volume element (RVE). The RVE describes the characteristic geometric and material properties of the mesostructure. A volumetric representation is employed, allowing a detailed investigation of the mesoscopic constituents, namely the textile reinforcement and the surrounding matrix. Structural shell elements are used for analysis at the macroscopic scale, reducing the volumetric problem to a two-dimensional problem. This dimensional reduction simplifies the geometry. However, the reduced dimension, namely the thickness of the shell, is considered by the RVE, since a distinctive feature of the presented approach is that the height of the RVE corresponds to the macroscopic shell thickness. The presented multiscale method is a first-order homogenization approach governed by the Hill-Mandel condition. The focus is on the choice of appropriate boundary conditions for the RVE to ensure a consistent coupling between the macroscopic structural shell element and the mesoscopic volumetric description of the RVE. To enhance the accuracy of the geometric description of the textile reinforcement, image-based methods are combined with scaled boundary isogeometric analysis (SBIGA) at the mesoscopic scale. A parameterized RVE is presented, which considers the characteristic geometric properties of the textile reinforcement. Linear-elastic benchmark examples demonstrate the validity of the proposed approach. The homogenized stiffness components exhibit an erroneous dependence on the in-plane RVE size, which is effectively addressed by introducing an internal constraint. To show the suitability of the parameterized RVE using image-based methods, experimental data from carbon-reinforced concrete shell specimens is used. Finally, a simulation of a textile reinforced concrete specimen incorporating the nonlinear material behavior demonstrates the applicability of the present homogenization approach.

A NEURAL-NETWORK FINITE ELEMENT APPROACH FOR SIMULATING TRILEAFLET HEART VALVES WITH FULL MULTI-BODY CONTACT

Kenneth Meyer[*1], Christian Goodbrake[1], Shruti Motiwale[1] and Michael Sacks[1]*

[1]*The University of Texas at Austin*

ABSTRACT

Due to the inherent pathophysiological complexities of heart valve disease, computational modeling in directing patient-specific therapies has great potential to provide accurate predictions and determine optimal treatments. The Finite Element Method (FEM) solves the partial differential equations governing heart valve closure with high accuracy, but remains too slow to implement in clinically relevant timeframes. To simulate heart valve closure in clinically relevant timeframes, we adopted our Neural-Network Finite Element (NNFE) approach. Previous NNFE-related work has shown a Neural Network can capture the deformation of a flat plate under a pressure load without loss of accuracy when compared to FEM simulations [1]. To clarify, the NNFE approach is not data-driven, but rather it uses NN as universal function approximator of the displacement field, with training driven by minimizing the gradient of the potential energy of the system. Finite Elements are still used to discretize the physical domain, apply boundary conditions, and perform necessary numerical integrations. Recent developments have shown the NNFE approach can simulate contact of an elastic body using a frictionless symmetry plane [2].

This work extends upon these studies to incorporate full multi-body contact into the NNFE approach to simulate a trileaflet heart valve in a generalized manner. The energy penalty term used to enforce contact in [2] was modified to compute the distance between each leaflet pair to check for penetration. The NN displacement field was then trained over the physiologically admissible range of pressures a valve experiences during closure. Once trained (12hr), it takes the NNFE model only 5.34s to compute displacements on a NURBS mesh with 147 control points and 5.75s with 720 control points, while the traditional FEniCS solutions take 89.36s and 788.53s for the same problem sizes, respectively. Thus, as in our previous studies the scaling of problem size produced results without increased solve times when simulating full multi-body contact. To the authors knowledge, this is the first demonstration of full multi-body contact using NN methods. This work advances the capabilities of Machine Learning in cardiovascular modeling and simulation.

COMBINING PENN, EQUATION DISCOVERY, AND NOVEL PLASTICITY FRAMEWORKS

*Knut Andreas Meyer**[1]

[1]*TU Braunschweig*

ABSTRACT

When using neural networks as components in plasticity model evolution laws, it is possible to enforce physics directly [1]. These Physics Enforced Neural Networks (PENN) models intrinsically fulfill, e.g., the dissipation inequality and frame invariance. Such strong enforcement of physics has been shown to generalize better than penalty enforcement [2]. Consequently, PENN-based plasticity models hold promise for accurate and reliable predictions of material behavior. Another advantage lies in the flexible incorporation of desired model assumptions, such as isotropy and pressure-independent yielding, thereby reducing the required training data size. However, when enforcing such restrictions, it is paramount to not exclude relevant processes. One such restriction is the definition of a yield surface separating distinct elastic and plastic regions. As macroscopic constitutive models represent the homogenized behavior of a heterogeneous microstructure they must also consider how different parts will yield at different load levels resulting in a smooth elastic to plastic transition. A novel plasticity framework, denoted the "Degree of Plasticity" model, addressing this challenge is combined with PENN evolution laws in this contribution. Furthermore, using the equation discovery from [1], we identify analytical evolution laws from the trained neural network, resulting in an interpretable and efficient constitutive model discovered from data.

SEQUENTIAL DESIGN OF PLATE-LATTICES

Paul Philipp Meyer[1], Thomas Tancogne-Dejean[1] and Dirk Mohr[1]*

[1]*ETH Zurich*

ABSTRACT

Periodic architected materials, characterized by their fundamental building blocks as truss-, shell-, and plate-lattices, have garnered significant attention in material science and engineering. The elastic response of plate-lattices with cubic symmetry reaches theoretical limits for isotropic response, exhibiting optimal mass-specific stiffness. We believe the potential of plate-lattices extends beyond isotropic structures. The primary objective is the strategic development of stiff lattices with tailored properties. This study introduces a general construction method of plate lattices, defined as an assembly of plates and intersections. It involves sequentially placing plates within the unit cell, with the choice of an anchor point, a normal vector, and a thickness, under the constraint of periodic conditions. Building upon this general formulation, a large-scale comparison to the property spaces of truss- and shell-lattices is presented. We demonstrate that versatile arrangement of plates offers geometry control over a large macroscopic property space for the same constituent material. Furthermore, we describe a correlation between plate orientation and stiffness. To tailor the lattice properties, we utilize a recurrent neural network designed for the inverse question—mapping from property to structure. Our findings reveal the efficacy of the inverse model in generating lattices with targeted properties. Three illustrative cases, including the hexagonal honeycomb, SC plate-lattices, and SC-FCC plate-lattice, highlight the model's capacity to extrapolate lattice designs beyond training data parameters. We further demonstrate the model's ability to unveil the inherent invariance of stiffness to the plate position. In conclusion, this research not only advances the understanding of plate-lattice formulations but also introduces a groundbreaking approach to plate-lattice design through neural network-driven methodologies.

PREDICTION OF FORMING PROCESSES UNDER UNCERTAINTY

Paul Philipp Meyer[*1] and Dirk Mohr*[1]

[1]*ETH Zurich*

ABSTRACT

Sheet metal forming is a widely employed manufacturing process that enables the creation of intricate shapes and structures using flat metal sheets, which would be impractical or unfeasible with other manufacturing methods. The change in shape of the sheet metal directly affects the final product's quality, performance, and integrity. The design of forming processes (constrained to a targeted shape) poses a significant challenge due to the complex interplay of vast material, geometric, and other process parameters. The interplay of these parameters can give rise to several complicated phenomena. Wrinkling, for instance, manifests as unintended buckling or folding of the metal sheet, resulting in an uneven surface, typically near the sheet's edges or at the cup's bottom. Here, we propose to eliminate such uncertainties in the design of forming processes by analyzing a substantial portion of the design space efficiently. We provide evidence of the effectiveness of Convolutional Neural Networks (CNN) in accurately predicting the final shape of elastoplastic metal sheets during forming processes. We differentiate between two cases: the prediction of the forming process with fully known and partially unknown parameters. For the first case, our CNN achieves remarkable accuracy, with a Mean Relative Error below 0.1% when predicting the thickness distribution for previously unseen parameters. We analyze the model's performance dependence on factors such as model size, training process, and available training data. We emphasize the capability of neural networks to accurately predict nonlinear wrinkling of the sheet. For the second case, we develop an attention-based diffusion model mapping partial parameter sets of the forming process to the probability distributions of resulting shape. We find matching distributions between the predictions and the uniformly random sampled testing data. We leverage this capability to quantify the uncertainty resulting from unknown friction during forming processes. We obtain spatial uncertainty estimates, enabling the designers to judge the manufacturability and improve the process robustness efficiently.

RETHINKING TOUGHNESS: USING NANOSTRUCTURE TO ENHANCE THE DURABILITY OF ADDITIVELY MANUFACTURED MATERIALS

Lucas Meza[*1], Zainab Patel[1] and Kush Dwivedi[1]*

[1]*University of Washington*

ABSTRACT

Strength and toughness are both highly desirable properties of structural materials, but they are often considered mutually exclusive. Much work has gone toward developing materials that are both strong and tough using different composite architectures and material processing techniques, but they generally ignore the role of length scale and structural size-effects on toughness. In this work, we develop nanoarchitected polymeric materials that utilize both heterogeneity and size-affected ductility to enhance their toughness without sacrificing strength. We create specimens with layered architectures in a micro-single edge notch bend configuration using two-photon lithography and various post-processing techniques. Gradually reducing the layer thickness (D) resulted in an increased fracture energy and slower, stable crack propagation, a phenomenon that became pronounced as the layer thickness approached or was smaller than the material fracture process zone (D ≦ FPZ). The thinnest of these layered structures demonstrated an increase in toughness by 5x from 60 J/m2 to 300 J/m2 as interlayer spacing was increased from 0 to 4 um, a value that is augmented by the creation of heterogeneity along the crack path. Notably, these materials do not show an appreciable loss in strength or stiffness up to an intermediate layer spacing despite a ~40% reduction in density. The results of this study not only demonstrate the large degree of tunability in these architectures but also show how to fundamentally utilize size effects to create architected materials with unprecedented properties.

ESTIMATION OF DEPLOYMENT DYNAMICS OF A TAPE-SPRING BOOM USING RATIONAL LEAST-SQUARES FITTING

Deven Mhadgut[*1], Austin Phoenix[1], Serkan Gugercin[1] and Jonathan Black[1]*

[1]*Virginia Tech*

ABSTRACT

The need for composite booms in deployable space structures is ever-increasing. This effort studies the effects of environmental conditions on the material properties of a self-deployable carbon fiber boom with a parabolic cross-section. The deployment velocity and the internal strain energy of this boom are highly sensitive to temperature changes. The same boom will fly as the primary payload on Ut ProSat-1 (UPS-1), a 3U CubeSat designed and manufactured by students at Virginia Tech. The boom will be deployed repeatedly across the full range of spacecraft's environmental conditions. In addition, the boom has a flexible circuit near its tip. This circuit houses an inertial measurement unit (IMU) to measure the acceleration experienced by the boom during and at the end of each deployment sequence. A second IMU embedded on the payload control module near the root of the boom measures the base vibration response. The on-orbit data will validate the model obtained from the ground experiments described here. The boom was deployed inside a Tenney environmental chamber to simulate the space environment. The thermal cycling went from 4°C to 70°C and had dwell periods at each. A low vacuum pressure of 9 Torr was maintained throughout the test.

Characterization of the satellite payload parameters is necessary to validate these results and understand the effects of temperature changes on the deployments. Transfer functions were obtained from the two IMUs and then interpolated to form a low dimensional numerical model by minimizing the least square errors through the process of rational least-squares fitting via vector fitting (VF). While the ideal boom has a constant parabolic cross section, the deployed boom has a variable cross section due to its boundary conditions and small manufacturing defects. The 4-ft (~1.2 m) long boom was measured at 5 cm intervals, starting from the root to the tip, to create a continuous boom CAD model from these profiles. The modal analysis of the boom was obtained using a shell-based finite element (FE) model and the global mass, stiffness and damping matrices were extracted. These are used to obtain the state matrices of the system which are then compared to those obtained via the VF approach. Therefore, the FE model is used to validate the rational approximation procedure. These results will provide insight into the characterization of NASA's tape springs and aid in making informed decisions for future missions while enabling a validated temperature dependent model.

HOW DOES OFF-FAULT PLASTICITY CONTROL FAULT ZONE SEISMOGENESIS?

Md Shumon Mia[*1], Ahmed Elbanna[1] and Mohamed Abdelmeguid[1]*

[1]University of Illinois Urbana Champaign

ABSTRACT

Professor Selvadurai's foundational contributions in understanding the mechanics and physics of coupled processes in a variety of systems have inspired many works in biomechanics and geophysics including ours. Here, we investigate a long-standing challenge in geophysics related to genesis of fault zones and its connection to observed seismicity. We simulate the co-evolution of shear fractures on pre-existing fault surfaces and bulk inelastic deformation through modeling a sequence of (fast) earthquakes and (slow) aseismic slip of a 2D rate-and-state frictional interface embedded in a full-space elastic-plastic bulk. We use a computationally efficient hybrid finite element spectral boundary integral (FEBE) scheme that relies on domain decomposition in space and extreme adaptive stepping in time. The hybrid computational scheme enables exact near-field truncation of the elastodynamic field allowing us to use high resolution finite element discretization in a narrow region surrounding the fault zone that encompasses the potential plastic deformation. Wave propagation and long range static stress transfer in the exterior half spaces are handled using the spectral boundary integral equation. The adaptive time stepping is based on the maximum velocity jump across the fault surface. The resulting time step varies from milliseconds to days enabling the simulation of both slow deformation and fast dynamic ruptures over multiple earthquake cycles.

Our study reveals that off-fault plasticity can cause both partial ruptures and temporally clustered seismic activities as well as partitioning of permanent deformation between the fault and the bulk. If the yield stress is high relative to the fault’s frictional strength, the plastic deformation dissipates only a few percent of the total energy budget. Nonetheless the impact of plasticity in this case on the seismic cycle can still be significant through its effect on stress distribution and viscous relaxation. Conversely, if the bulk yield stress is low enough to be comparable to the fault's frictional strength, new rupture patterns emerge. These are marked by extensive energy dissipation within the bulk and slow or creeping ruptures on the fault without much noticeable inertia effects. Considering a Weibull distribution of yield strength, the long-term seismic pattern turns out to be governed by the average yield strength rather than its spatial variability. Our findings highlight the pivotal role of bulk strength in earthquake dynamics across different scales and propose a novel aspect of dynamic variability in earthquake physics, potentially influencing earthquake size and energy distribution.

HIGH-ORDER SIMULATIONS FOR FLUID-SOFT SUBSTRATE INTERACTION THROUGH EULER-LAGRANGE AND EULER-EULER FRAMEWORKS

Chen Miao[*1]

[1]*Technical University of Darmstadt*

ABSTRACT

Our research introduces an advanced extended discontinuous Galerkin method (XDG) tailored for the accurate simulation of multiphase scenarios, specifically addressing challenges associated with three-phase contact lines on deformable solids. Singularities at interfaces and contact lines, characterized by abrupt pressure and surface tension changes, present difficulties for high-order methods that traditionally rely on smooth functions for optimal convergence.

Our investigation focuses on simulating a water droplet on a surface made of silicone gel. This simulation incorporates Navier slip boundary conditions at the interface and Young's equation at the three-phase contact line. To provide a comprehensive analysis, we leverage both the Euler-Lagrange and Euler-Euler frameworks. This dual-framework approach enables us to capture the intricacies of the simulation from two distinct yet complementary perspectives.

In our forthcoming presentation, we will conduct an extensive comparison between the Euler-Lagrange and Euler-Euler models, featuring three-dimensional simulation results. Through the presentation of these results, we aim to provide valuable insights into the strengths and limitations of each model. This detailed analysis is designed to contribute to a deeper understanding of these frameworks in the context of simulating complex multiphase phenomena.

Multi-scale modeling and upscaling for flow induced vibrations, from local reference simulations to certified industrial tools

RANS AND LES SIMULATIONS OF FLOW-INDUCED VIBRATIONS IN ROD BUNDLES WITH MIXING GRIDS

Antoine Michel[1], Maria Adela Puscas*[1] and André Bergeron[1]*

[1]*CEA, Service de Thermo-hydraulique et de Mécanique des Fluides*

ABSTRACT

Flow-induced vibrations (FIV) are an important phenomenon to maintain operational conditions in existing nuclear power plants and for future designs. Vibrations arise due to the load induced by the fluid flow on long and slender rods in the core, steam generator and heat exchangers. Their effect can range from fretting to fatigue and may induce early wear or even failure of the mechanical components.
As part of the research effort conducted by the CEA on FIV, an Arbitrary Lagrange-Euler (ALE) method has been implemented in TrioCFD [1] to study fluid-structure interaction. This tool has been successfully employed to reproduce analytical results in state-of-the-art configurations [2], but its capability to predict the vibrations in a realistic setup has yet to be determined. In the present study, as part of the European GO-Viking project, numerical simulations are undertaken to assess the ability of TrioCFD to reproduce the FIV measurements performed on ALAIN experiment [3]. The investigated setup is made of a 5x5 rod bundle with a split-type mixing grid encased in a square duct in which water flows axially at Re=90 000, mimicking the core of a pressurized water reactor.
The ALE method is employed to account for the influence of the fuel-rod assembly moving boundaries on the turbulent flow. Comparison between the numerically predicted FIV and the experimental measurements is conducted for two classes of flow modelling approaches. One, in which the mean flow is determined by solving Reynolds Averaged Navier-Stokes equations (RANS), is commonly employed in industry. The second involves solving filtered Navier-Stokes equations to capture the largest eddies of the turbulent flow (LES) and includes a higher level of detail of the flow features. Analysis of the results provides insight into the capacity of the ALE module of TrioCFD to reproduce experimental FIV measurements, and allows to propose guidelines for FIV simulations in an industrial context.

DEEP REINFORCEMENT LEARNING-BASED FLOW OPTIMIZATION FOR IMPROVED WIND RESILIENCE OF SOLAR PANEL ARRAYS

Theodore Michel[*1], Philippe Meliga*[1] and Elie Hachem*[1]

[1]*Mines Paris - PSL*

ABSTRACT

Among the renewable energy solutions of today, solar - more specifically photovoltaic (PV) - power plants are seen as key actors of the energy transition in Europe, and are taking on new designs and functions, seeking more adaptability and efficiency. However, PV power plants still face the major risk of strong winds often leading to breakage, hindering the efforts of green energy development. The aerodynamic loading of PV panels in wind flow has become an important research topic to quantify breakage risk and limits, but such approaches in the literature have been limited so far to panel spacing and simple tilt configurations. We introduce here a novel approach combining high-fidelity numerical simulations of large scale PV fields subjected to a turbulent atmostpheric boundary layer wind flow, and a Deep Reinforcement Learning (DRL) algorithm trained to optimize the individual tilts for the purpose of maintaining safe aerodynamic efforts. An efficient and flexible computational pipeline has been developed, in which the mesh is adapted anisotropically around the fluid-solid interface using a metric map built after simulation-dependent parameters based on the boundary layer theory. The wind flow is computed with an in-house variational multiscale (VMS) stabilized finite element solver. The latter can be applied efficiently to high Reynolds number flows (since the built-in small-scale component of the solution operates as an implicit large eddy simulation) and supports elements of aspect ratio up to the order of 1000:1, which is key to solve the numerically complex strongly anisotropic wind motion generated by the extremely thin build of the panels. Finally, DRL optimization is achieved with the in-house single-step PBO algorithm, that interacts once per episode with the environment to learn the mapping from a given initial state to the optimal action, and uses heuristics from the CMA-ES evolution strategy to exploit the anisotropy of the cost function in the descent direction. The main sub-processes of PV field simulations are seamlessly integrated within a single agent-environment workflow. This includes the geometric computational domain creation from an array of panel tilts, the mesh adaptation algorithm, CFD simulations, and reward computation. We will discuss results obtained for 2d and 3d arrangements of 6 full-scale panels mounted on stands, whose individual tilts are optimized under various reward functions and using different turbulence models. Each optimal configuration is non-intuitive and reward-specific, and will be shown to perform better than the classic tilt configurations found in the literature.

ABSTRACT

Healthy articular cartilage is comprised of a layered architecture, characterized by superficial, middle, and deep zones, with each zone's components differing in biochemical and mechanical properties and critical for the maintenance of cartilage function. Osteoarthritis (OA) disrupts the zonal architecture of cartilage, where proteoglycan loss leads to loss of mechanical function (eg, decreased compressive strength) [1]. Noninvasive imaging techniques such as elastography show potential to quantify material stiffness and provide a powerful approach to understanding structure-function relationships in load-bearing tissues, specifically in cartilage. Elastography is any imaging approach that is commonly used to quantify the average and spatially resolved stiffness of soft tissues. In cartilage, softening and decreased stiffness in the superficial zone is a functional hallmark of osteoarthritis (OA) pathogenesis due to structural changes to the collagen network and depletion of proteoglycans. As proteoglycans are a primary determinant of stiffness in articular cartilage, the ability to spatially map local stiffness changes within articular cartilage presents a direct link between structural cartilage changes and stiffness, and an opportunity to diagnose early OA via noninvasive imaging.

Recently, our group developed a biomechanically based elastography imaging method that utilizes spiral displacement encoded stimulated echo MRI (spiral DENSE) displacement data as an input [2, 3]. In this work, we used forward finite element (FE) simulations of cartilage-like geometrical shapes and material properties to validate the method, resulting in an average voxel-wise error of less than five percent. We then utilized spiral DENSE displacement data to quantify relative modulus of femoral cartilage in human participants [2]. Other work within our group has established spatial gradients indices of structural (relaxometric) MRI as a method that can evaluate structural and functional heterogeneity through the cartilage depth as a sensitive biomarker of early OA [1]. In this work, we collected spiral DENSE MRI data on 35 patients at approximately 6 months post ACL surgery, as well as an age, sex and BMI matched control cohort. We used the DENSE MRI displacement data as input to our elastography pipeline to calculate maps of spatial modulus within the cartilage. We then calculated spatial gradient indices, defined here as the through-thickness spatial gradient for the modulus, to assess cartilage stiffness heterogeneity [3]. We expect that through-thickness moduli gradients will be more uniform in the control cohort compared to the joint-injury cohort.

MODIFIED IMMERSED FINITE ELEMENT METHOD (MIFEM) FOR EXPLICIT EULERIAN TO EXPLICIT LAGRANGIAN COUPLING

Scott Miller[*1], Anthony Agelastos[1], Mark Christon[1], David Hensinger[1], Chad Hovey[1], Matthew Mosby[1], Jennifer Rees[1], Jesse Thomas[1], Benjamin Treweek[1] and Michael Wong[1]*

[1]*Sandia National Laboratories*

ABSTRACT

The modified Immersed Finite Element Method (mIFEM) [1] is an overlapping mesh method that couples a Lagrangian foreground solution with an Eulerian background solution. We explore using the mIFEM to couple two production codes: an explicit Lagrangian solid mechanics code (Sierra Solid Mechanics) and an explicit, Eulerian (Lagrange step plus remap step), finite element, multimaterial shock physics code (SABLE). Temporal accuracy and stability are essential for the blast-on-structure and impact/penetration classes of problems for which the coupling is designed. We present the details of the mIFEM coupling method and numerically investigate the accuracy and stability properties on a set of exemplar problems. Finally, the fully parallelized implementation is demonstrated with a full scale example problem.

SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

Current trends and advances in enriched finite element methods and coupled simulations

TEMPORAL ANALYSIS OF THE GENERALIZED FINITE ELEMENT METHOD FOR MULTI-SCALE HEAT TRANSFER PROBLEMS

TJ Miller[*1], Jack McNamara[1] and Patrick O'Hara[2]*

[1]The Ohio State University
[2]Air Force Research Laboratory

ABSTRACT

The extreme thermal environments encountered by high-speed flight vehicles dominate the design process. The appearance of impinging shock waves and complex shock interactions create sharp, localized thermal gradients that challenge numerical simulations. These challenges are amplified when non-stationary gradients are present due to translating shocks. The combination of these issues leads to standard methods producing accurate solutions inefficiently and at a large computational expense since broadened regions of fine-scale resolutions are required. Thus, there is growing interest in developing methods capable of producing high-fidelity solutions to multi-scale problems at a reduced cost via coarser meshes and less degrees of freedom. The generalized finite element method (GFEM) offers the potential to achieve this goal by modifying the FEM framework for the inclusion of solution-tailored functions into the computational domain and aid in approximating fine-scale features. Therefore, I hypothesize that GFEM can lead to time-accurate solutions at a reduced computational cost compared to standard methods.

The temporal behavior of the GFEM is studied under a model problem exhibiting localized, sharp, and translating gradients. The GFEM framework is leveraged to build global-local enrichments tailored to localized features within the problem domain. The results presented will compare the temporal accuracy, convergence, and computational cost of the global-local GFEM (GFEMgl) and polynomial-enriched GFEM applied to the model problem with the generalized alpha-method as the time integrator. Demonstrative results reveal the solution-tailored enrichments achieve high-order solutions at a significant reduction in computational cost while retaining the expected convergence criterion compared to polynomial enrichment bases. The GFEMgl can resolve fine-scale features on significantly coarser meshes and less degrees of freedom. The temporal robustness of the GFEMgl will be demonstrated through parametric studies to show the method's predictable behavior for various situations. Results will highlight that temporal convergence and accuracy can be safely predicted. The culmination of the results obtained will signify the GFEM’s capability as a high-order numerical method granting high-fidelity solutions efficiently and inexpensively.

COMPUTATIONAL MODELING OF CATEGORY 5 HURRICANE LOADING EVENTS ON A COMPLEX STRUCTURE

Andrew Mills[*1], Joshua Brinkerhoff[1] and Abbas Milani[1]*

[1]*University of British Columbia*

ABSTRACT

Often when hurricanes make landfall, they destroy civil and electrical infrastructure leaving communities without critical infrastructure for long periods. As climate change is causing hurricanes to increase in frequency and forcefulness, designing in coastal areas must consider hurricane resilience. This research has determined the resilience and robustness of an architecturally unique and geometrically complex structure designed for electrical and civil infrastructural applications when subjected to category 5 (CAT 5) hurricane conditions. A history of hurricanes impacting The Bahamas and how their characteristics can be modeled is briefly reviewed. Computational fluid dynamics (CFD) is used to characterize the loads (shear stress and pressure loading) induced by a CAT 5 hurricane on the structure. The CFD software used in this research is OpenFOAM®. The mean wind direction of the hurricane relative to the structure that causes the most severe loading was tested and determined. Both steady and unsteady CFD methods were used to identify the magnitude of loading. Both wind and storm surge loading conditions are considered in the analysis. The wind conditions were modelled using the upper limit of possible CAT 5 wind profiles. The storm surge conditions were modelled after the infamous storm surge profile caused by the 2019 tropical cyclone, Hurricane Dorian, as it passed over The Bahamas. The structural response of the structure under the identified loads found is evaluated via an uncoupled finite element analysis (FEA) approach. The FEA solver Abaqus® was applied to test the complex structure’s robustness and resilience to severe hurricane loading. The two materials considered in the FEA model were a proprietary composite material specifically designed for this application and 1080 steel. The results of the two materials were then compared. Considering the scope and limitations of the research, more work is needed to better understand how resilient the structure is to impact wave loading. The work presented will show that it is possible to design geometrically complex structures and accurately model them using computer aided engineering (CAE) for resiliency to natural disasters.

A FAST METHOD FOR COMPUTING ARBITRARY-ORDER STRESS INTENSITY FACTOR DERIVATIVES OF 3D FINITE ELEMENT SIMULATIONS USING HYPERCOMPLEX AUTOMATIC DIFFERENTIATION

Mauricio Aristizabal[1] *and Harry Millwater**[1]

[1]*The University of Texas at San Antonio*

ABSTRACT

This work presents a novel approach to efficiently compute arbitrary-order derivatives of Stress Intensity Factors (SIF) from Finite Element analyses. The method can compute SIF derivatives with respect to any design parameters like material, loading, and geometrical properties (e.g. crack length). The method consists of three steps: first, conventional software is used to compute the displacements of the finite element problem. Second, the stiffness matrix of the conventional problem is computed in a separate module. Finally, Hypercomplex Automatic Differentiation (HYPAD) is used on the residual form of the problem to form systems of equations that solve the derivatives of the displacements with respect to each parameter of interest. The displacements and its derivatives are used in hypercomplex form on the Interaction Integral calculations to compute the stress intensity factor and its derivatives. Preliminary case studies on a flat and inclined penny-shaped crack 3D simulations show that derivatives up to third order with respect to 4 parameters (34 derivatives in total) were computed within the equivalent time of an additional finite element simulation. Derivatives show excellent agreement with the corresponding analytical solutions, with errors within the same order of magnitude as the original displacement solution error. Derivatives of the SIF can be used to generate reduced order models of the SIF, uncertainty analysis, advance the crack front, optimization, and inverse problems.

[2]*INRAE*
[3]*Université Savoie Mont-Blanc*

ABSTRACT

The COVID-19 pandemic of 2020 has been of epic proportions that has led to a surge in the modelling and simulation of infectious diseases. The paper develops a new model that uses a mechanistic approach to describe interactions between discrete entities (agents) driven by social, cultural, epidemiological, and virological rules in a disease infected population. This ‘granular’ view is borrowed from geomechanics of granular media where large-scale systems such as sand masses derive their behaviour and strength from the mutual interactions between particles through simple force contact laws. Specifically, the proposed computational framework is multiscale starting from the virological-immune system interaction at the scale of an individual to transmission of the virus at the individual-to-individual scale according to rule-driven interactions that are non-probabilistic in contrast to other approaches. As such, the dynamics of the various multi-scale processes of naturally upscale in a nonlinear fashion to larger population sizes with new properties just like in complex systems.

The starting point is a population of discrete particles (individuals) that is initially uninfected—then infections are seeded in the population. Contracting an infection depends on characteristics of each individual—age, underlying conditions, and socio-economic status as well as the viral transmission which is linked to the viral load carried by each infected individual. At the individual (local scale) level, the biological processes are mathematically described through a Lotka-Volterra set of two ordinary non-linear differential equations to describe a predator-prey mechanism where viral growth rate is antagonized by the activation of the immune system.

Mobility of individuals within the population is computed within a discrete element approach driven by social policies such as public health restrictions and workplace protocols. The global population is allowed to evolve over both time and space to lead to the emergence of structures of Susceptible-Infected-Recovered (SIR) type populations using non-phenomenological data. The model is non-probabilistic with the important feature that the viral load evolves for everyone in a population so that at any one time, individuals may be at different deterministic positions within their personal viral load timeline. Airborne aspect of virus propagation can also be incorporated in the model such as the distribution and location of tiny droplets (aerosols) produced by a cough using computational fluid dynamics. Numerical examples are provided to illustrate the computational model construction and the results of such an approach.

INTERPLAY OF ACTIVE SELF-ORGANIZATION IN DENSE NEMATIC CYTOSKELETAL STRUCTURES AND CELLULAR SHAPE CHANGES

Waleed Mirza[*1], Alejandro Torres-Sánchez[1] and Marino Arroyo[2]*

[1]*European Molecular Biology Laboratory*
[2]*Polytechnic University of Catalunya*

ABSTRACT

Endothelial cells respond to both internal and external mechanical stimuli. Forces within the cytoskeleton and cell-substrate interactions regulate their elongation. This study examines the interplay of these forces in cellular alignment using mathematical modelling. In this work, we formulated a coarse-grained active nematic model that accounts for the viscoelastic properties of the actin network, active forces from bundling proteins, actin turnover, interactions between the actin network and the extracellular matrix via focal adhesion complexes, and contrasts between isotropic and bundled nematic actin networks. We investigate low and high-friction substrate regimes. In each regime, the numerical solution of the model reveals the internal mechanism involved in the progression of cell elongation. Initially, within a circular, well-spread cell configuration, a retrograde flow of transverse and radial stress fibres emerges due to a symmetry-breaking phenomenon. These bundles are highly contractile and give rise to anisotropic contractile forces. These contractile anisotropic forces in stress fibres, along with their interaction with the substrate, lead to alignment in the overall cellular morphology. Furthermore, the mathematical model shows that cell elongation is small on soft substrates, but it is pronounced on high-stiffness substrates due to the formation of a large number of focal adhesions. This allows the stress fibres to exert higher anisotropic forces on the cells, creating more pronounced elongation. Our model effectively predicts both the cellular shape and the internal structure of the actin cytoskeleton, showing good qualitative agreement with experimental observations on endothelial cells.

OPTIMIZING TEMPERATURE UNIFORMITY IN AN INDUSTRIAL SIZE ELECTRIC FURNACE: A COMPUTATIONAL FLUID DYNAMICS APPROACH

Sajad Mirzaei[1], Farzad Bazdidi-Tehrani[2], Jean-Benoit Morin[3] and Mohammad Jahazi[1]*

[1]École de Technologie Supérieure (ETS)
[2]Iran University of Science and Technology
[3]Finkl Steel, Sorel

ABSTRACT

Large size industrial furnaces are crucial in producing steel with specific mechanical properties, notably hardness. This hardness across different steel block zones is intricately linked to the temperature and duration of exposure in each zone [1]. Achieving uniform heat transfer distribution, and thus uniform temperature, is vital for desired hardness levels. Heat transfer in these furnaces takes place via radiation, absorbed by blocks' surfaces, and convection, by the internal flow pattern.
In this study, a comprehensive Computational Fluid Dynamics (CFD) simulation was conducted to study temperature evolution in an industrial size heat treatment furnace used in steel industry. The focus is on a furnace design with three ceiling-mounted axial fans, operable between 800 and 1800 rpm.

For the simulation purposes, the unsteady SIMPLEC algorithm for pressure-velocity coupling in compressible flow, the realizable k-ε turbulence model, and the DO radiation model were used. The simulation, refined through a mesh study to a 4.7 million cell mesh, demonstrated a maximum of 4.5% error in temperature readings compared to actual data from an instrumented loading cycle. This cycle involved two high-strength steel blocks, each weighing approximately 29 tons, stacked atop each other [2]. The simulation revealed that the upper block experienced a surface temperature non-uniformity reaching 236°C and a surface-to-center variance of 222°C, while the lower block exhibited a surface non-uniformity of 221°C and a surface-to-center difference of 202°C.
The study methodically analyzed the effects of fans' rotation speed and distance from the furnace ceiling, examining fans' speeds from 0 to 2500 rpm and distances from 10 to 60 cm. Results showed that 1750 rpm minimized temperature non-uniformities. Deviations from the 1750 rpm, whether higher or lower, led to more significant non-uniformities: up to 20.5°C at 0 rpm and 12°C at 2500 rpm. Adjusting fans' distance to 40 cm from the ceiling significantly enhanced uniformity, reducing the upper block's maximum non-uniformity by up to 14.5°C and the lower block's by up to 17°C. The study concludes that fans' rotation speed primarily impacts the upper block's temperature distribution, while fans' distance from the ceiling affects the lower block more significantly.

MATERIAL-INTEGRATED DESIGN OPTIMIZATION THROUGH PROBABILISTIC PROPERTY DISCOVERY

Amir Mirzendehdel[*1], Adrian Lew[12] and Morad Behandish[1]*

[1]*SRI*
[2]*Stanford University*

ABSTRACT

Existing computational design paradigms, such as shape/topology optimization, are traditionally rooted in a material-first approach, where the selection of materials precedes the actual design and optimization process. In other words, the materials are treated as predefined inputs into the design process, confining the exploration to the mechanical and physical properties that these materials inherently possess. Such a sequential process of choosing materials based on availability and familiarity, followed by designing within their constraints greatly narrows the design space. It limits innovation to the existing catalog of materials, often forcing designers to make trade-offs between material properties and the envisioned structural performance. We present a material-integrated design optimization (MIDO) approach to enable efficient discovery of novel properties tailored to a part's geometry and its operational objectives.
To push the boundaries of what is possible with existing alloys, we present a material-integrated design optimization (MIDO) approach, comprising two phases: (1) the property discovery (PD) phase, which will search for the best part designs for performance and durability, using candidate material properties deemed realizable with high likelihood, and (2) the recipe realization phase, that will find the best recipe (i.e., composition and thermal history) to fulfill the target properties, while accounting for deleterious phases and supply chain risks.
In this project, we focus on the formulating and developing the PD phase. While the PD phase need not be burdened with how exactly the properties are realized, it must be constrained by how likely it is for the material to exist. The goal is to develop the mathematical and computational foundations for concurrent optimization of material and shape by considering material properties, referred to as property bundles as explicit, independent, and continuous design variables. Our proposed approach enables rapid exploration of the expanded design space of alloy properties within reasonable feasibility bounds imposed with respect to known materials. Specifically, we (a) present a gradient-based optimization framework to enable automated discovery of properties, a.k.a. property bundles. In this view, the underlying design representation is expressed as a collection of property bundles, (b) impose a global property feasibility constraint based on a differentiable probabilistic function that controls the novelty aggressiveness/conservatism of the optimized property bundles, and (c) demonstrate the effectiveness of our approach through benchmark examples in 2D and 3D.

ABSTRACT

The understanding of the collapse dynamics in earthquake engineering plays a crucial role in their incorporation into building standards. This investigation originates from a groundbreaking series of mass timber building projects carried out on the world's largest outdoor shake table in San Diego, California, spanning the years 2022-2024 (NHERI Tallwood and NHERI Converging Design projects). After extensive full-scale testing, including the ten-story Tallwood and six-story Converging Design, the upper stories were deconstructed, transforming the taller structure into a representative three-story collapse test specimen. The post-tensioning of the original walls was reconfigured to ensure consistency with a potential design specification proposal. This presentation specifically explores the comparison between the results of full-scale collapse tests, focusing on the seismic force-resisting system (SFRS) of the three-story building, and the numerical predictions formulated prior to the test through nonlinear time history analysis. The SFRS incorporates mass timber panels as rocking walls and U-shaped flexural plates (UFPs) within each story level, augmenting energy dissipation capabilities. Additionally, post-tensioning rods provide re-centering for each wall, and the specifically designed integration of floors and rocking walls effectively uncouples lateral and vertical movements. Through a detailed examination of the modeling intricacies, this presentation aims to contribute valuable perspectives on accurately predicting the behavior of innovative SFRS during severe shaking to better inform margins against collapse.

MODELING ADDITIVELY MANUFACTURED METALLIC MICROSTRUCTURES FOR DYNAMIC RESPONSE

John Mitchell[1], Stewart Silling[1], Edwin Chiu[1], Stephen Bond[1] and Timothy Ruggles[1]*

[1]*Sandia National Laboratories*

ABSTRACT

Additive manufacturing of metals produces material microstructures which are inherently different from those of wrought materials as they arise from a complex temperature history associated with the additive process. Because of complex microstructure morphologies and spatial heterogeneities, material properties are heterogeneous and reflect underlying microstructure. This paper describes a workflow for simulating the dynamic and spall response of additively manufactured metals [1]. The approach consists of simulating microstructures associated with the additive manufacturing process, methods for representing spatially heterogeneous microstructures on a peridynamics discretization, and a specialized material model for handling dynamic material failure under spall conditions. Material properties are spatially distributed onto the discretization so that microstructure effects arising from additive manufacturing can be systematically incorporated into engineering scale calculations. Model simulations are compared with laboratory flyer plate test data.

GENERALIZATION OF GHOST CELL BOUNDARY MODEL FOR PARTICLE-BASED SIMULATION OF WAVE–STRUCTURE INTERACTIONS

Naoto Mitsume[*1], Takayuki Tsunemi[1] and Hiroyuki Omura[2]*

[1]*University of Tsukuba*
[2]*National Research Institute for Earth Science and Disaster Resilience*

ABSTRACT

This study proposes a highly accurate ghost cell boundary (GCB) model [1] for mesh-free particle methods that applies semi-implicit time integration including stabilized incompressible smoothed particle hydrodynamics (ISPH) [2]. The GCB model enables us to directly use meshes such as finite elements as the wall boundary of complex shapes and be suitable for fluid–structure interaction analysis using both mesh-free particle and mesh-based methods. However, conventional GCB model does not satisfy wall boundary conditions strictly, and is limited in its scope of application to particle methods with explicit schemes. Our proposed method is applicable to semi-implicit type particle methods including the stabilized ISPH and can use an arbitrary number of integration points. We also clarify how to apply formulation of the fixed ghost particle [3] to the integral points of the GCB model and realize the strict imposition of the wall boundary condition. We conduct wave–structure interaction problems and validate the accuracy and applicability of the proposed method by comparing numerical results with experimental ones.

ABSTRACT

The perpetual advancement in computational capabilities, coupled with the continuous evolution of software tools and numerical algorithms, is creating novel avenues for research, exploration, and application at the nexus of computational fluid and structural mechanics. Fish leverage their remarkably flexible bodies and fins to harness energy from vortices, propelling themselves with an elegance and efficiency that captivates engineers. Bats fly with unparalleled agility and speed by using their flexible membrane wings. Wave-assisted propulsion (WAP) systems, utilizing elastically mounted hydrofoils, convert wave energy into thrust. Each of these problems involve a complex and elegant interplay between fluid dynamics and structural mechanics. Historically, investigations into such phenomena were constrained by available tools, but modern computational advancements now facilitate exploration of these multi-physics challenges with an unprecedented level of fidelity, precision, and realism. In my presentation, I will discuss projects that harness the capabilities of high-fidelity sharp-interface immersed boundary methods to address a spectrum of engineering and biological challenges involving fluid-structure interaction.

ADVANTAGES OF 500 HZ MONITORS IN E-SPORTS

Hideo Miyachi[1] and Teruki Sawa*[1]

[1]*Tokyo City University*

ABSTRACT

Computer monitors work on 60 Hz generally, but higher refresh rates of 240 Hz and 350 Hz are used for e-Sports. In 2023, 500Hz displays were launched on the market in the U.S. in 2023. We have been investigating whether using a display with a high refresh rate has an effect on winning or losing in e-sports. As a preliminary investigation, we conducted a simple reaction test, pressing a button as fast as possible when the color of the display changed. The results showed that most people were able to respond to high refresh rates regardless of their game skill[1].

In addition, the effect of monitor refresh rate on gaming in a complex shooter game was examined in two subjects. First, both players fought with a 360-Hz frequency monitor, and their respective win rates were used as their reference win rates. Second, the players played against each other with 360-Hz monitors versus monitors below 60 Hz, and the player with the 360-Hz monitor recorded a win rate that was 10 to 20% higher than the reference win rate. The present study will examine whether these results are similar when using a 500 Hz monitor.

[4]*Science and Disaster Resilience*

ABSTRACT

In previous studies, the authors conducted finite element (FE) seismic response analyses using a high-fidelity integrated model of a nuclear power plant. The high-fidelity finite element mesh employed tetrahedral elements for components such as the pressure vessel, containment vessel, suppression chamber, vent pipes, various supports, and the reactor building. In this study, the concrete material within the reactor building and support structures, including the pedestal of the pressure vessel, is represented using a concrete constitutive model with a tensile crack model proposed by Yamashita et al. Subsequently, a seismic response analysis using the FE model is executed on the supercomputer Fugaku. The analysis reveals numerous tensile cracks in regions experiencing tensile stress.

DEVELOPMENT OF TRAFFIC NOISE EVALUATION SYSTEM USING FINITE ELEMENT METHOD

Haruki Miyauchi[1], Kazuo Kashiyama[1] and Hitoshi Yoshikawa[2]*

[1]*Chuo University*
[2]*Kyoto University*

ABSTRACT

Noise is one of the seven major types of pollution in Japan, and it leads to the highest number of complaints according to a survey published by the Ministry of Internal Affairs and Communications in December 2023. There have been presented a number of numerical methods to evaluate the traffic noise. Based on the frame of reference used, those methods can be classified into two categories: 1) Methods based on the geometrical acoustic theory and 2) Methods based on acoustic wave theory. Both methods have advantages and disadvantages. For geometrical acoustic theory methods, the CPU time is very short but the numerical accuracy is low comparing with the methods based on the acoustic wave theory. On the other hand, the method based on the acoustic wave theory gives accurate solution but the simulation becomes a large scale simulation.

This paper presents a noise evaluation system based on acoustic theory. The finite element method is employed for unsteady wave equations, which is suitable for arbitrary shapes and has excellent applicability to non-uniform materials. The 3D wave equation is employed for the governing equation and the Perfectly Matched Layer (PML) method [1] is utilized as a treatment method for boundary condition. In order to consider multiple moving sound sources such as a traffic noise, a time-variant convolution method [2] is introduced. In addition, the transmittance and reflectance are evaluated by performing the analysis taking into account the microscopic structure within the sound barrier. The auralization method based on VR technology is also introduced to understand the noise level intuitively.

DATA-DRIVEN TOPOLOGY DESIGN FOR TURBULENT CHANNEL FLOW

Yukako Miyazaki[*1], Yoshinao Komatsu[1] and Kentaro Yaji[2]*

[1]*Mitsubishi Heavy Industries*
[2]*Osaka University*

ABSTRACT

Topology optimization technology using the gradient method has traditionally been applied to create new concepts to improve the competitiveness of products.However, gradient-based topology optimization can fall into a local optimum, and its calculations are often unstable for complex flow fields in actual products. Therefore, it is important to construct a method that can stably search a wide range without gradient information. In this study, we focus on data-driven topology design, which can search for diverse shape designs based on the combination of a genetic algorithm and a deep generative model. This approach enables gradient-free topology optimization under a high degree of design freedom from initial shape given by parametric designs and topology-optimized designs using low-fidelity models.In this study, we apply the approach to turbulent channel flow. In addition, regarding the concept extracted from the obtained shape, we demonstrate the relationship between shape and pressure loss through the numerical example.

AN ATTEMPT TO CONSTRUCT A RESPONSE DATABASE FOR THREE-DIMENSIONAL FRAME MODELS

Yasunori Mizushima[*1], Masaki Gohara[2], Takuma Kawakami[3], Motoki Uchiyama[3], Motonobu Maekawa[3], Shuei Ikeda[3], Motoki Akazawa[3], Sota Murashima[1] and Yasuyuki Nagano[2]*

ABSTRACT

Recent advances in computing technology enable seismic response analyses of buildings using not only mass-spring models but also three-dimensional frame models. Mass-spring models are widely used in time-history response analysis in Japan because of their simplicity and low computational cost. However, we believe the mass-spring models are accurate enough to represent buildings due to the simplification, especially for geometrically complex buildings. Conversely, three-dimensional frame analysis, which models the structure of a building by replacing columns and beams with linear elements of specified cross-sectional properties connected at nodes, allows for a more detailed understanding of response behavior. The demand for such three-dimensional analysis has increased in recent years due to some reasons. For example, there is a need to understand the nonlinear behaviors of each member of buildings subjected to long periods and duration seismic ground motions.

However, three-dimensional frame models require numerous input parameters and output data. The number of variables makes it difficult to extract correlations and causal relationships. This study attempts to construct a response database for three-dimensional frame analysis including both the input variables and the results. The input variables were randomly generated. A base model was designed using integrated structural design software, and the parameters of the base model were tuned based on the input variables database. The structural analysis was conducted using LS-DYNA, which is commonly known as high-efficient parallel nonlinear structural analysis software by adopting the explicit time integration scheme. As output data, the maximum story drift, story shear force, and so on were extracted and stored in the database. On the response data, basic statistical analysis, multiple regression analysis, and clustering by the t-SNE method were performed. From the statistical analysis, the response of the building is related to the column dimensions.

This study represents a first step in enabling designers to comprehend complex and large-scale analysis models, leading to more effective and efficient building designs. Through statistical analysis, we were able to derive simple relationships between input and output, a finding we consider crucial as a foundational step. As a further step, we aim to conduct various analyses to comprehend the relationship between building characteristics and seismic responses.

A NEW PARADIGM FOR MULTIPHYSICS AND NON-LINEAR MECHANICS MODELING: INTEGRATED FINITE ELEMENT NEURAL NETWORKS (I-FENN)

Mostafa Mobasher[*1], Panos Pantidis[1] and Diab Abueidda[1]*

[1]*New York University Abu Dhabi*

ABSTRACT

The growing complexity of the phenomena sought to be modeled using computational mechanics tools is leading to an unprecedented need for more sophisticated coupled models. Such models are encountered by many challenges, one of which is their tremendous computational cost. The recent advances in scientific machine learning (SciML) have been more frequently investigated as possible alternatives to more established numerical methods, such as FEM. While SciML models have shown some tangible promising results in the field of computational mechanics, they suffer from fundamental shortcomings that currently prevent them from becoming rigorous and reliable alternative numerical solvers as standalone methods.

These challenges have inspired our group to establish a new method coined as Integrated Finite Element Neural Network (I-FENN). The proposed method attempts to couple traditional FEM solvers with the newly established deep learning approaches. The fundamental idea is to decompose coupled problems in a way that allows a neural network to predict one aspect of the physical processes, then integrate the network prediction within a generic FEM solver in a fashion that resembles a typical user-defined material model. The resulting coupled solver is expected to be much faster than traditional mixed FEM thanks to the smaller sized system of equations, and possibly faster convergence in the case of non-linear models. We herein present two applications of I-FENN: modeling gradient non-local damage mechanics and fully coupled transient thermoelectricity.

In the case of gradient damage, a neural network is first trained to predict the non-local strain from local strain, thus representing the solution of gradient non-local diffusion equation. The network output of non-local strain is then integrated within a local damage solver system. Thus, the resulting I-FENN algorithm provides the solution of a non-local damage model at the reduced cost of a local one. In the case of transient thermoelasticity, the network is trained to predict the temperature based on the solution of the balance of heat energy equation. The output temperature is then fed into the traditional FEM solver of the balance of momentum. Hence, the resulting I-FENN solver solves the coupled thermoelasticity model at the cost of uncoupled model. Various types of networks have been investigated including physics-informed, temporal convolution networks, and variational-based networks. The presentation will include the various types of networks developed, investigation of their convergence and numerical behavior, and efficiency and scaling of the computational savings as the investigated models grow.

ASSESSMENT OF UNFITTED FINITE ELEMENT METHODS FOR FLUID-STRUCTURE INTERACTION OF FLOATING OFFSHORE STRUCTURES

Jan Modderman[*1] and Oriol Colomés*[1]

[1]*Delft University of Technology*

ABSTRACT

To transition towards a carbon neutral future, we are required to look for new sources of renewable energy. The potential of the sea for capturing renewable energy is immense, but it requires us to move towards deeper waters. Therefore, there is an increased demand for research into floating renewable energy capturing devices which are accompanied by their own unique challenges. One driver in further increasing the feasibility of floating energy capturing devices is an increase of fidelity and efficiency in modeling of Fluid-Structure Interaction (FSI) problems involving free surface flows and floating bodies. One of the main issues in computational FSI for floating renewables is the need to deal with complex structural geometries. This is especially relevant in the design optimization phase, where an optimal structural solution must be defined for site-specific conditions in a limited time. Unfitted/immersed/embedded Finite Element (FE) methods are convenient for these situations, avoiding the need of ad-hoc mesh generation.The challenge here is how to deal with an unfitted structure that interacts with free surface flows.

In this talk we will present a single-phase FE approach for free surface flows, where only the wave-structure interaction is accounted for, in combination with an unfitted floating structure with arbitrary geometry. In this work we propose a monolithic method, ensuring robustness and efficiency of the solution, for several unfitted FE methods. We will demonstrate the capabilities of the proposed framework with a series of tests for wave-structure interaction problems for offshore engineering applications, assessing accuracy and conservation properties. Lastly, we will compare the performance of the following unfitted FE methods, namely CutFEM [1], AgFEM [2] and (W)SBM [3].

SYMBOLIC REGRESSION VIA NEURAL NETWORKS

Jeff Moehlis[*1], Nibodh Boddupalli[1] and Tim Matchen[1]*

[1]*University of California, Santa Barbara*

ABSTRACT

Identifying governing equations for a dynamical system is a topic of critical interest across an array of disciplines, from mathematics to engineering to biology. Machine learning—specifically deep learning—techniques have shown their capabilities in approximating dynamics from data, but a shortcoming of traditional deep learning is that there is little insight into the underlying mapping beyond its numerical output for a given input. This limits their utility in analysis beyond simple prediction. Simultaneously, a number of strategies exist which identify models based on a fixed dictionary of basis functions, but most either require some intuition or insight about the system, or are susceptible to overfitting or a lack of parsimony. Here, we present a novel approach that combines the flexibility and accuracy of deep learning approaches with the utility of symbolic solutions: a deep neural network that generates a symbolic expression for the governing equations. We first describe the architecture for our model and then show the accuracy of our algorithm across a range of classical dynamical systems.

This is joint work with Nibodh Boddupalli and Tim Matchen, and has appeared in Chaos, 33: 083150 (2023).

PROJECTOR ASSEMBLY: BRIDGING POISSON AND ELASTICITY FORMULATIONS

Tiago Moherdaui[*1], Alfredo Gay Neto[1] and Peter Wriggers[2]*

[1]*Universidade de São Paulo*
[2]*Leibniz Universität Hannover*

ABSTRACT

Virtual element methods define their shape functions implicitly (tailored to each element's geometry), foregoing the typical reference element and transformation scheme usually employed by the finite element method. The formulation leverages the use of polynomial projections supplied by heuristic stabilizations when necessary. These projections are represented by projector matrices, which require the solution of a local system. Elasticity formulations usually employ an L2-projection from a displacement multifield onto a strain multifield, requiring the solution of a considerably larger system than a typical Poisson problem would require, with dense matrices and lots of zeroes. This work presents a way to obtain the projections for elasticity formulation by assembling from the L2-projection for each derivative of the one-field a Poisson formulation, resulting in smaller local systems being solved and more efficient storage. This approach is based on the linearity of both projections and derivatives, and is shown in the examples to preserve the convergence rate of the method.

EFFICIENT AND ACCURATE THERMOMECHANICAL MODELING OF FUSED FILAMENT FABRICATION PROCESS

Satyajit Mojumder[*1] and Wing Kam Liu*[1]

[1]*Northwestern University*

ABSTRACT

Process modeling plays a significant role in process optimization and in-situ process control for defect mitigation and part qualification. Here, we present a GPU-accelerated and higher-order accurate thermomechanical modeling of the fused filament fabrication (FFF) process for thermal response and residual stress of the printed part. The higher-order accuracy compared to finite elements is achieved by implementing a new deep learning-based computational theory called Convolution-Hierarchical Deep-learning Neural Network (C-HiDeNN) [1] where a customized neural network architecture is used for incorporating nonlinearity in the calculation. C-HiDeNN is computationally efficient as it requires less degrees of freedom for similar accuracy of FEM and a higher convergence rate. Also, the high-temperature gradient during the FFF process can be captured more accurately using C-HiDeNN approach. The C-HiDeNN FFF process is validated against the experimental results and investigated for various process parameters such as nozzle speed, nozzle temperature, layer thickness, raster distance, bed temperature, and tool path orientation in this study. The FFF process modeling tool not only provides guidance for choosing appropriate process parameters but also optimizes it for desired part performance. In addition to accuracy, C-HiDeNN allows the creation of a differential simulation capability for FFF process optimization. These data-driven modeling and simulation capabilities provide new opportunities for developing novel material systems and their process optimization using the FFF process.

A FINITE-ELEMENT BASED METHOD FOR THE INTERACTION OF FLUIDS WITH EVOLVING BEDFORMS

Jorge Molina[*1] and Pablo Ortiz*[1]

[1]*University of Granada*

ABSTRACT

Prediction of fluid-terrain interactions involving the transport of cohesionless sediment is fundamental for understanding the morphodynamics of natural systems and its effects on civil structures. However, the simulation of such phenomena is challenging due to the necessity of handling several interfaces, including fluid/erodible layers, erodible/non-erodible layers, fluid/non-erodible layers and, in the case of multiphase flows, interactions between different fluids [1].
This work introduces a continuous finite element model to reproduce the fluid flow-bedform interaction. The approach employs a Non-oscillatory Finite Element Method (NFEM) to solve both the complete Navier-Stokes equations [2] and the fluid-bedform interface evolution. This evolution occurs due to spatially non-balanced sediment fluxes and is addressed through the solution of a conservation equation for the erodible layer thickness. Sign preservation is particularly relevant for landform tracking when interfaces limiting with non-erodible beds are present, thus ensuring the positivity of the erodible sediment layer thickness [3]. Besides, the fluid/terrain interface is explicitly captured through a surface tracking methodology. First, new nodes fitting the interface are incorporated into the finite element mesh, then elements beneath this interface are deactivated while intersected elements are restructured to get a mesh composed exclusively of tetrahedral or triangular elements.

Numerical experiments demonstrate capabilities of the method by exploring relevant problems related with civil engineering, such as the evolution of dunes and trenches, the scour of submerged piles and dam-break type problems on erodible beds.

CHEMO-HYDRO-MECHANICAL VARIATIONAL PHASE-FIELD FRACTURE MODEL

Mostafa Mollaali[*1], Renchao Lu[1], Vanessa Montoya[2], Keita Yoshioka[3] and Olaf Kolditz[1]*

[1]Helmholtz Centre for Environmental Research – UFZ
[2]Belgian Nuclear Research Centre - SCK CEN
[3]Montanuniversität Leoben

ABSTRACT

We present a chemo-hydro-mechanical variational phase field model for simulating fracture initiation and propagation. By employing a staggered approach, we couple three key subprocesses: (i) fluid flow in porous media, (ii) reactive transport, and (iii) mechanical deformation/fracturing of porous media. In our approach, we integrate the geochemical package PHREEQC [1] within an operator-splitting framework, coupled with a finite element transport solver to compute chemical reactions in thermodynamic equilibrium (dissolution or precipitation) that alter the porosity.

To account for the mechanical damage caused by the chemical reaction, a variable is introduced into the constitutive relation, representing the degree of chemical damage ranging from 0 (indicating intact material) to 1 (indicating damaged material) [2]. Furthermore, we consider the influence of fractures and changes in porosity on both hydraulic conductivity [3] and the effective diffusion coefficient [2].

We verified our model through benchmark examples in capturing fracture initiation and propagation resulting from chemical reactions. The implementation of the proposed model was carried out within the open-source finite element framework OpenGeoSys. The research work is part of the EURAD project.

MULTISCALE MODELING OF SHORT HYPERELASTIC COMPOSITE RODS: APPLICATION TO ELASTOMERIC ISOLATORS

Eduardo Montalto[*1] and Dimitrios Konstantinidis*[1]

[1]*University of California, Berkeley*

ABSTRACT

Elastomeric isolators have been used extensively for the seismic protection of new and existing structures. Extensive research has been done regarding the hysteretic behavior of these devices, and several phenomenological models have been proposed to predict their behavior. The nonlinear geometric effects have also been extensively studied from an experimental perspective, but their numerical implementations have been restricted to simplified models. Today, even the most widely used numerical models for rubber isolators are discrete spring models in which the isolator is treated as a rigid element connected by discrete springs representing their axial, rotational and shear stiffness. The definitions of these springs are manipulated analytically such that the model captures fundamental behaviors such as the buckling of the isolators. This approach presents drawbacks for capturing some behaviors of the isolators, such as accurately predicting the local stresses which are important in predicting the cavitation under tensile stress (or detachment in the case of unbonded elastomeric isolators), as well as incorporating the response for non-standard boundary conditions such as supports under rotations. In this study, a fully mechanical multiscale model for elastomeric isolators is proposed that considers the continuous deformations in the isolator while also accounting for the periodic microstructure formed by the alternating rubber and reinforcement layers. At the macroscale, the isolator is treated as a one-dimensional continuous Cosserat rod which allows for finite deformations. At the microscale, a unit cell formed by a single rubber layer and two half-thickness reinforcement layers is analyzed using finite element simulations; different alternatives with varying levels of complexity, computational cost and accuracy are evaluated for the analysis of the microscale response. The proposed model is compared against high-fidelity finite element simulations and results from previous experimental programs, showing promising results.

ABSTRACT

Plastic deformation of β-tin (Sn) is significantly affected by strain-rate and temperature. Consequently, different experimental procedures are needed to characterize the deformation behavior of this material, especially since the changes in behavior are observed over a large range of temperatures and strain-rate regimes that span multiple orders of magnitude. This complex behavior exhibited by tin poses significant challenges when attempting to fit the observed behavior to traditional, fixed-form, empirical models. This often limits the model's applicability to specific temperature and strain-rate regimes. In this work, we address this impasse by leveraging genetic programming in order to perform symbolic regression to establish a set of data-driven models that are valid across multiple strain-rate and temperature regimes. These models are trained on a set of compression tests and split-Hopkinson pressure bar (SHPB) tests at various strain rates and temperatures. We leverage the analytical nature of the resultant models to integrate them into a continuum dynamics simulation code and perform Taylor impact simulations to demonstrate the validity of the developed models. Finally, a comparison of the data driven model predictions against conventional strength models is presented.

VALIDATING FLUID-PARTICLE INTERACTION MODELS IN DENSE GRANULAR FLOWS: A PEPT-MEDIATED APPROACH

Taswald Moodley[*12], Indresan Govender[123] and Lawrence Bbosa[1]*

[1]Mintek
[2]University of KwaZulu-Natal
[3]University of Cape Town

ABSTRACT

Dense granular flows are prevalent in industries (such as mining and pharmaceuticals) and natural disasters (including landslides and tidal waves). Enhancing the understanding of these flows is crucial, both financially and environmentally. Unfortunately, the absence of a constitutive law governing their rheology necessitates using dimensional analysis for insight. Rheological models proposed by researchers like Jop et al (2005) and Pahtz et al (2019) incorporate dimensionless numbers as functions of dynamic properties like pressure and granular temperature. These dynamic properties, occurring at the momentum transfer timescale (10-6s), are challenging to measure experimentally, leading to reliance on numerical methods like the Discrete Element Method (DEM) for understanding.

DEM, traditionally tracking individual particle movements, can be extended using techniques like Smoothed Particle Hydrodynamics (SPH) or liquid bridge modelling to account for fluid effects. SPH simulates fluid as particles, whereas liquid bridge modelling considers capillary forces between particles. Both approaches hold promise in dense granular systems, offering unique advantages. SPH captures fluid behaviour more explicitly, while liquid bridge modelling provides a detailed representation of inter-particle forces, enhancing the overall understanding of fluid-particle interactions in these complex systems.

Despite the advancements in numerical techniques, there remains a notable gap in the literature concerning experimental validation which limits our confidence in the predictive capabilities of these models. Positron Emission Particle Tracking (PEPT) is a nuclear imaging technique capable of tracking particles with millisecond temporal and millimetre spatial resolution. Coarsening these outputs, using carefully selected representative voxel elements, allows for a continuum description of kinematic fields.

This study employs PEPT to validate—or select—a suitable method (either SPH coupled or considering liquid bridge forces) for describing fluid effects on DEM. Rotating drum experiments, featuring a 460mm diameter and 200mm length, are conducted using a 50% volume filling of 10mm glass beads (DEM particles) in a water-glycerol suspension with a viscosity of 0.011 Pas. Rotational speeds, covering a range of Froude regimes, provide insights into the behaviour of dense granular flows subjected to fluid forces and the appropriate modelling thereof.

THB-SPLINE BASED VOLUMETRIC FITTING USING DIFFERENTIABLE PROGRAMMING

Ajith Moola[*1], Aditya Balu[1], Adarsh Krishnamurthy[1] and Aishwarya Pawar[1]*

[1]*Iowa State University*

ABSTRACT

Converting imaging data from different modalities into computational models that are suitable for analysis is a major challenge in the biomedical field. Geometric primitives like tetrahedra and hexahedra are commonly used to create volumetric meshes for both geometric and analytical applications. Isogeometric Analysis has revolutionized the field by providing an alternative to conventional finite element methods. By utilizing high-order spline models to describe geometry, a more straightforward and precise method is achieved. Although previous studies, such as NURBSDiff [1], have made progress in this field, they do not specifically tackle the difficulties associated with volumetric spline fitting. Conventional tensor-product splines, such as B-splines and NURBS, are not efficient in improving geometric accuracy because they do not have the ability to locally refine, resulting in a compromise between accuracy and efficiency. The objective of this study is to create a computationally efficient and precise framework for fitting volumetric CAD models that are suitable for Isogeometric Analysis (IGA) to unstructured point clouds. Truncated Hierarchical B-splines (THB-splines) utilize local refinement in tensor-product B-splines. Building upon our existing surface fitting framework [2], we have expanded the application of differentiable programming to volumetric splines, emphasizing the following key contributions. We have developed a novel differentiable THB-spline module that can be easily integrated into existing computational frameworks. This module is designed specifically for volumetric fitting. We have also conducted a thorough investigation of local refinement strategies, with a focus on optimizing them for volumetric fitting. Additionally, we have extensively tested and validated our module by applying it to 3D imaging data from biological models. Through this testing, we have demonstrated the effectiveness of our module on raw point cloud data. This work not only improves the accuracy in modeling biomedical imaging data but also makes a significant contribution to the broader field of Isogeometric Analysis by providing a more sophisticated and efficient method for volumetric CAD modeling.

ENHANCING IONIC CONDUCTIVITY IN ASSBS THROUGH OPTIMIZED SOLID ELECTROLYTE DISTRIBUTION: A COMPUTATIONAL ANALYSIS OF THE DRY MECHANICAL MIXING PROCESS

Janghyuk Moon[*1]

[1]*Chung-Ang University*

ABSTRACT

This study utilizes advanced computational modeling to refine the mechanical mixing (MM) technique for producing cathode composites in all-solid-state batteries (ASSBs). The main focus is on achieving uniform integration of solid electrolytes (SE), which is crucial for efficient ionic and electronic conductivity. By using finite element analysis, we quantitatively evaluate how MM optimizes SE distribution, outperforming traditional methods. Our computational approach not only predicts the formation of efficient ionic pathways but also assesses the structural integrity of cathodes under operational stresses. The findings suggest that the MM process is a scalable and computationally informed strategy for enhancing ASSB performance through meticulous cathode design and SE homogeneity.

ABSTRACT

Fatigue indicator parameters are a computational tool for materials design that determine the driving force for fatigue fracture and are useful in ranking deleterious microstructural features when designing engineering alloys. Many of these parameters were formulated over three decades ago (mostly for steels) using analytical models and 2D microscopy. This study revisits this development for a nickel titanium alloy using modern computational and experimental tools including computational crystal plasticity, 3D high energy diffraction microscopy (HEDM), and 3D micro-tomography. The stress state that drives fatigue fracture is shown via HEDM and mapped to fracture locations measured via micro-tomography. Computational crystal plasticity is used to elucidate the nonlinear and nonlocal mechanisms driving fatigue fracture and formulate a fatigue indicator parameter that describes fatigue fracture in a nickel titanium alloy.

A MULTISCALE MODEL FOR DISORDERED BIOPOLYMER GELS

Hashem Moosavian[*1] *and Tian Tang*[1]

[1]*University of Alberta*

ABSTRACT

Due to their unique properties, biopolymer gels find extensive use in the food industry and various biomedical applications including tissue engineering. Contrary to rubber-like materials, the constituent chains in biopolymer gels aggregate through physical, rather than covalent, cross-linking. Disordered biopolymer gels exhibit two principal regions: the disordered zone containing coiled chains, and the ordered zone manifesting in the form of ion-mediated aggregation of chain segments. The resulting network combines these two regions, where the ordered structures serve as rigid junction zones between the flexible disordered chains. While there is a wealth of macroscopic studies on disordered biopolymer gels using phenomenological models, here we present a multiscale model that bridges statistical mechanics analysis on the micro-scale and prediction of mechanical properties on the macro-scale.

The constitutive relation of disordered biopolymer gels is established by integrating the micromechanics of coil-rod structures with the well-known eight-chain network model. The coil and rod respectively represent the disordered and ordered zones, and the length of each zone can change as a result of zipping (increased ion-mediated aggregation) and unzipping (reduced ion-mediated aggregation) of the junctions. Incorporating this microscopic mechanism allows the model to reproduce a phenomenon observed in previous experiments, i.e., biopolymer gels subjected to cyclic mechanical loadings exhibit hysteresis where a residual deformation remains after complete unloading. Verification of the model is performed using experimental data for alginate gels, showcasing the model's accuracy. This multiscale formulation not only contributes to an in-depth understanding of the mechanics of disordered biopolymer gels but also establishes a foundation for modelling more advanced polymer gels in future studies.

NUMERICAL SIMULATIONS OF CHIRAL LIQUID CRYSTALS IN A LID-DRIVEN CAVITY USING THE LANDAU-DE GENNES THEORY

Isreal Morawo[1], Shancheng Li[1] and Dana Grecov[1]*

[1]*university of british columbia*

ABSTRACT

Cholesteric liquid crystals (CLCs), also known as chiral nematic LCs, exhibit a unique helical structure with a twisted axis perpendicular to the local molecular director, characterized by the helical pitch and twist sense. This study is motivated by disruptions in the local symmetry of the director field, leading to defects in CLCs, such as deviations from the ideal helical pitch, point defects, and disclinations. These defects have significant implications for the optical and mechanical properties of CLCs, affecting light transmission, reflection, and color appearance. Understanding these effects is crucial for applications in display technologies and other fields requiring precise control of optical properties.

The objective of this study is to model, simulate, and evaluate a 2D lid-driven cavity flow of chiral LCs, investigating the effects of chiral strength (Θ), Reynolds (Re) number, and viscous flow effect (Er) on the microstructure. Employing COMSOL Multiphysics, a finite element-based commercial software package, we simulate the flow characteristics of CLCs in a 2D lid-driven cavity, utilizing the Landau-de Gennes theory for various parametric studies to explore the interconnection between the micro- and macro-structure of CLCs.

Our findings show that an increase in Re at a constant high chiral strength and low Er corresponds to heightened inertial forces, affecting the chiral structure, and subsequently increasing defects and altering overall flow patterns. Elevated chiral strength results in a chiral texture with more pronounced striations and shorter pitch lengths, contributing to an augmented presence of defects. Maintaining constant chiral strength while increasing Er disrupts the chiral structure, potentially causing fracture at very high Er. The transition from low to moderate Er increases the number of defects, while a further rise in viscous flow contribution reduces defects due to destructive effects on the chiral structure. Even under exceedingly high Er, the chiral structure and its accompanying defects persist, which is attributed to the continuous existence of a vortex where the velocity at the center is relatively small; as a result, the chiral structure and defect persist in this low–velocity region. Observations at elevated chiral strength levels reveal the emergence of a hexagonal structure adorned with penta-hepta defects, aligning with expectations based on simulations depicting the coupling between flow dynamics and structural characteristics.

A LAGRANGIAN POSITION-BASED SPACE-TIME FORMULATION FOR FINITE STRAIN FREE-SURFACE FLOWS

Darcy Hannah Falcão Rangel Moreira[*1] and Rodolfo André Kuche Sanches*[1]

[1]*University of São Paulo*

ABSTRACT

Newtonian fluids have no resistance to deviatoric stresses and can deform indefinitely. That is why most researchers adopt the Eulerian description, having as main variables the velocities in the current configuration, with indeformable spatial domain. However, Eulerian description cannot be directly applied to moving boundary flows, such as free-surface flows, multiple fluid flows and fluid-structure interaction. For some free-surface flows, a Lagrangian description can be more suitable, specially if the fluid volume is enclosed and presents only finite deformations and it makes sense to consider current nodal positions as main variables. In this work, we present a position-based space-time finite element formulation for incompressible Newtonian fluid flows using total a Lagrangian description applied to free-surface flows with finite strains. Such approach uses mixed position-pressure finite elements, with Petrov-Galerking pressure stabilization. The discretization is structured in time direction, so that the space-time shape functions are given as a tensor product of the linear space shape-functions set with the quadratic shape functions set in time direction. Thus, the space-time domain is composed of space-time slabs, that can be solved progressively, with velocities and positions in the previous slab being imposed as initial conditions on the current space-time slab. The resulting formulation is tested by numerical examples, revealing to be robust and efficient for simulating free-surface incompressible flows, like sloshing and wave propagation.

ELECTRO- AND MAGNETO-MECHANICAL COUPLING MODULATES FRACTURE IN SOFT MULTIFUNCTIONAL MATERIALS

Miguel Angel Moreno-Mateos[*1] and Paul Steinmann*[1]

[1]*Friedrich-Alexander-Universität Erlangen–Nürnberg*

ABSTRACT

Smart materials are ushering in significant changes in the way humans interact with engineering devices. Numerous state-of-the-art applications are grounded in innovative methods to actuate structures that respond to various stimuli. Among these, soft dielectric electro-active elastomers (DEAP) and magneto-rheological elastomers (MREs) respond to electric and magnetic stimuli, respectively, by undergoing substantial deformations and changes in their material properties. Applications involving large deformations may lead to crack onset and propagation. In this context, the response of DEAPs to an applied electric field and the response of MREs to an internal magnetic field induced by hard-magnetic fillers with remanent magnetization can enhance the fracture behavior of such materials. Drawing on a combination of experiments and theory, we investigate the fracture behavior of an ultra-soft dielectric elastomer (~1 kPa stiffness) [1]. The application of compliant electrodes on the sides of the elastomeric samples enables the application of a high voltage during tensile deformation. Additionally, we implement a Finite Element phase-field model that addresses the multiphysics and damage evolution. The computational testbed provides a better understanding of the physical interplays driving crack onset and propagation. The results reveal that lateral Coulomb forces generate an intricate stress triaxiality state that induces beneficial crack tip blunting and reduces stress concentration. Consequently, the work to fracture increases and crack propagation is delayed. Together with the pure elastomer samples, we manufacture composite samples with BaTiO3 particles to amplify the electro-mechanical coupling. Subsequently, we examine the fracture behavior of ultra-soft MREs with remanent magnetization [2]. To achieve this, non-magnetized and pre-magnetized hMRE samples are manufactured with hard-magnetic fillers and the same ultra-soft elastomeric matrix. Here, we report crack closure due to the remanent magnetic field as a phenomenon that delays the opening of cracks. Furthermore, we introduce for the first time a bespoke multiphysics phase-field framework for fracture of hMREs. The results suggest that remanent magnetic fields induce beneficial compressive stresses in the medium, decreasing stress concentration at the crack tip.

ABSTRACT

Carbon fiber-reinforced plastics (CFRP) are widely being used as structural materials for aircraft because of their high specific strength, high specific stiffness, and high corrosion resistance. Recently, some jet engine manufactures have tried to use CFRP for fan blades of jet engines to improve the engine efficiency. Since fan blades are generally subjected to cyclic loads due to centrifugal force and aerodynamic force, it is important to investigate damage behavior of CFRP fan blades due to fatigue.

When investigating such behavior of CFRP fan blades, one has to pay special attention to “dovetails”. Dovetails are tapered parts at the bottom end of fan blades, and are attached to grooves on rotating shafts called “dovetail slots”. Thus, they are subjected to the above-mentioned loads most severely. It is revealed that CFRP dovetails can fracture by delamination [1].

Our research group has conducted elastic-viscoplastic two-scale analyses of CFRP laminates based on a mathematical homogenization theory, and revealed that the viscoplastic deformation in resin sections affects the fatigue behavior of CFRP laminates such as delamination [2].

In this study, inelastic two-scale analysis of a CFRP dovetail is conducted as a preparation of applying the fatigue life evaluation method to CFRP dovetails. To this end, a two-scale modeling method for CFRP dovetails is developed, and macroscopic and microscopic finite element models are created. In addition, the two-scale analysis method is implemented in the finite element analysis software Abaqus with its user subroutine function. The present method is then applied to the inelastic two-scale tensile analysis of a CFRP dovetail. The analysis results show that viscoplasitc deformation microscopically accumulates in the resin sections around the upper end of the contact surface between the dovetail and dovetail slot, which is in good agreement with the areas where delamination actually occurred in experiments [1].

ABSTRACT

The numerical simulation of wind turbines and wind farms aerodynamics represents an open challenge in computational mechanics. It involves multi-physics and multi-scale phenomena, turbulent flows at very large Reynolds numbers, atmospheric boundary layer features, and rotor machinery flow features and dynamics.
The geometrically resolved Computational Fluid Dynamics (CFD) [1] is renowned to be the highest-fidelity approach for wind turbine simulations but it has still a too high computational cost if employed for wind farm flow analysis. For this application, several reduced-order models have been formulated to obtain reliable results at a sustainable computational effort. Among the others, large eddy simulation (LES) with Actuator Line Model (ALM) [2] represents a valid middle-fidelity alternative for accurately simulating the wind turbine wakes dynamics and its interaction with the atmospheric boundary layer turbulence.
Most implementations of the ALM are derived for volume-based CFD solvers. In this presentation we report the implementation of this model in a Finite Element Method (FEM) framework, which allows the use of a Variational Multiscale (VMS) model [3] instead of the standard LES formulation used in finite volumes. The ALM-VMS formulation is applied to study a 15MW wind turbine rotor, comparing the results with geometrically resolved RANS solution of the same rotor.
The presentation will show performance and results of the method in terms of aerodynamic variables of main interest, such as velocity induction fields, rotor loads and aerodynamics, near and far wake features. Through this analysis we show the main strengths and weaknesses of this implementation and its reliability with respect to a model of higher fidelity.

SMOOTHED PARTICLE HYDRODYNAMICS SIMULATION OF LANDSLIDES WITH DISCONTINUITIES

Daniel Shigueo Morikawa[*1] and Mitsuteru Asai*[2]

[1]*Japan Agency for Marine-Earth Science and Technology*
[2]*Kyushu University*

ABSTRACT

Discontinuities are a major factor involving the initiation of soil disasters such as landslides. However, the simulation of discontinuities with the Smoothed Particle Hydrodynamics (SPH) method remains a great challenge, since this method is based on a continuum mechanics framework. This means that all numerical approximations are based on the assumption that all neighboring particles belong to the same continuum body, which is not the case when a discontinuity is initiated. In this context, we propose some modifications on the total Lagrangian SPH (TLSPH) in order to simulate the detachment of soil at the initiation of a landslide event.

The Smoothed Particle Hydrodynamics (SPH) is a numerical scheme in which the domain is discretized into Lagrangian particles, and the forces applied to those particles are calculated as a summation of the contributions of the neighboring particles. It has been widely used for fluid dynamics problems, but recently it has also been used to simulate landslides with reasonable success. In this work, we utilize the total Lagrangian version of the SPH method, which refers to the usage of the reference configuration to calculate the spatial derivatives. As a result, some problems such as the tensile instability can be fully overcome, and, consequently, it enables a much higher accuracy. However, using the reference configuration means that neighboring particles do not change, which is unfavorable for the simulations of discontinuities.

In this context, we propose a framework where particles at a discontinuity interface are detached from the main soil continuum, so they start to act as a separate soil body. In order to accomplish that, we applied Discrete Element Method (DEM)-inspired forces to enable self-contact between the detached soil bodies. The soil itself is simulated as a finite strain elastoplastic material using the Hencky hyperelastic model and the Mohr-Coulomb yield criteria. Then, we apply a limit on the plastic deformation to enable the fracture initiation. In this way, we developed a method where clear discontinuities can be simulated in a natural way.

GENERATIVE IMAGE MODEL FOR STRUCTURAL DESIGN CONSIDERING BOTH MECHANICAL PERFORMANCE AND STYLISHNESS

Hayata Morita[*1], Kohei Shintani[1], Chenyang Yuan[1], Frank Permenter[1] and Matt Klenk[1]*

[1]*Toyota Research Institute*

ABSTRACT

In mechanical design, shapes that combine mechanical performance and design are required. For example, in the development of a vehicle, the shape of the vehicle must combine aerodynamic performance and stylishness. However, after the designer sketches the shape design, if the shape does not meet the required mechanical performance, there is a possibility that the study will be reworked. In this study, we propose a generative image model for structural design that takes mechanical performance and stylishness. The proposed model can generate images of candidate design shapes that satisfy the mechanical performance, and is expected to streamline the designer study conducted in the early planning stages of machine design. The proposed generative image model consists of two elements. The first element is the part that generates silhouettes that satisfy the mechanical performance. In this part, the silhouette of the shape is generated by considering the relationship between design variables and cost functions used in the evaluation of mechanical performance. The silhouette uses an implicit shape representation using the Signed Distance Function, and the encoder-decoder model is used to learn the input-output relationship. The second element generates a realistic vehicle design based on the obtained silhouette. In order to generate a realistic vehicle design using the obtained silhouette as a constraint, the diffusion model with ControlNet is used. This method enables the designer to check whether the design meets the mechanical performance requirements at sketch stage, which is expected to reduce the rework of the study. The validity of this method is demonstrated using numerical examples.

SUBDOMAIN EIGENMODE-DEFLATION PRECONDITIONING FOR PARALLEL FINITE ELEMENT ANALYSIS

Naoki Morita[*1], Takumi Murai[1] and Naoto Mitsume[1]*

[1]*University of Tsukuba*

ABSTRACT

Deflation preconditioning in iterative methods is a technique that projects the linear system onto a space orthogonal to the deflation space by multiple linearly independent vectors, which are known in advance. The deflated conjugate gradient method, as proposed by Saad et al. [1], is an approach that applies deflation preconditioning to the conjugate gradient method.

In deflation preconditioning, there are numerous options for selecting the bases. The one of options is the eigenmode deflation, which is the method using the lower eigenmodes of the coefficient matrix. This method reduces the condition number of the problem by deflating the lower eigenmode components, which are a factor to the deterioration of convergence in iterative methods. However, unless the eigenmodes are already known beforehand, it is necessary to perform eigenvalue analysis before starting the iterations to acquire the lower eigenmodes required. The methods, such as Lanczos method and LOBPCG, are available for eigenvalue analysis, however the computational cost of calculating lower eigenmodes is generally significant. Bergamaschi has reviewed the behavior of iteration counts when using eigenmode deflation[2], but the paper has not considered the total computation time, including the acquisition of eigenmodes. The discussion remains focused solely on convergence.

Besides, subdomain deflation, a method that involves dividing the analysis domain into several subdomains and independently obtaining deflation bases in each of these subdomains, has been proposed. The bases obtained through subdomain deflation are expected to enhance preconditioning performance, as the dimension of the deflation subspace is larger compared to the bases obtained on the whole domain.

This study proposes subdomain eigenmode-deflation preconditioning, which applies subdomain deflation to eigenmode deflation preconditioning. The proposed method aims to reduce the computational cost of acquiring eigenmodes. The proposed method is applied to a parallel finite element analysis based on domain decomposition, utilizing the subdomains obtained from domain decomposition method as the basis acquisition areas for subdomain deflation. As a numerical example of a thin-plate shape model, the preconditioning performance and parallel performance are discussed.

A FRAMEWORK FOR LEVEL-SET BASED TOPOLOGY OPTIMIZATION WITH CONSTRAINED SHAPE UPDATES

Adrian Humphry[1], Nigel Morris[1], Adrian Butscher[1], Mehran Ebrahimi[1] and Alex Tessier[1]*

[1]Autodesk

ABSTRACT

We propose a framework for level-set based topology optimization which allows for highly constrained shape updates along a user-specified component of the shape boundary, together with conventional free-form shape updates along the remainder of the shape boundary. The possible constraints include requiring that the constrained component of the shape boundary must move in an affine manner, or must remain attached to a primitive geometric shape (e.g. plane, cylinder). This framework allows us to optimize the position, orientation or scaling of surface patches in the context of topology optimization. It provides a new aspect of control that is highly useful for engineering design problems, especially for multi-functional parts where certain components of the shape boundary may only be altered parametrically. For instance, the part to be optimized is required to include a circular aperture to accommodate a bolt hole or a pin joint. Our framework allows us to simultaneously optimize the aperture radius as well as the free-form shape and topology of the remainder of the part. Our work is related to previous work that seeks to find optimal locations for structural loads and supports [1] in topology optimization but operates in the level-set context, and allows for the imposition of more general affine constraints.

To generate shape updates we transport the level-set function of the shape with respect to a velocity field defined on the entire design domain at each iteration. We construct this velocity field using a novel constrained Hilbert space extension (C-HSE) method that expands upon existing Hilbert space extension methods [2] by incorporating the affine motion constraints into the variational problem. As a result, the C-HSE method generates a velocity field that is a descent direction for a user-specified objective function while ensuring constraint satisfaction. The C-HSE method allows multiple distinct regions to have different constraints, with many possible constraint types, e.g. combinations of translations, rotations and scalings. We show results on a variety of canonical problems with geometrically constrained boundaries.

ABSTRACT

The main goal of this work is to develop a data-driven Reduced Order Model (ROM) from high-fidelity simulation result data of a Full Order Model (FOM), in order to predict at lower computational cost, the time evolution of solutions of Fluid-Structure Interaction (FSI) problems. For some FSI applications, the elastic solid FOM (with neglected inertia) can take far more computational time than the fluid one. In this context, for the sake of performance, one could only derive a data-driven ROM for the structure and try to achieve a partitioned FOM fluid solver coupled with a solid ROM.
In this paper, we evaluate the partitioned ROM-FOM coupling on study cases with strong coupling: an incompressible 2D wake flow over a cylinder facing an elastic solid with two beams, and 3D model of the problem with a clamped solid and a nearly incompressible hyperelastic material. The accuracy and performance of the proposed ROM-FOM strategy on these cases are explored while investigating the effects of the model's hyperparameters, especially with the presence of complex/chaotic dynamics [1]. The ability to predict, not only the displacement field, but also the volumetric strain field, in the context of mixed finite elements for incompressible materials is demonstrated. In addition, we show the effect of the structural ROM on decreasing the coupling rate of convergence. To mitigate this issue, we present an additional data-driven approach, that further accelerates convergence, while implemented non-intrusively within the framework of partitioned FSI coupling and Quasi-Newton acceleration techniques [2].
We demonstrate on the considered test cases a high prediction accuracy and significant speedup achievements using our proposed strategy.

IMPROVING PERFORMANCE OF VOLUME OVERLAP CALCULATIONS FOR COUPLED MULTI-PHYSICS SIMULATIONS

Matthew Mosby[*1], Jesse Thomas[1] and Scott Miller[1]*

[1]*Sandia National Laboratories*

ABSTRACT

Many physics coupling algorithms, such as the modified Immersed Finite Element Method (mIFEM) [1], involve volume intersection calculations to weight interactions of physical quantities in the overlapped solution domains. These calculations are often expensive, involving a search for overlapping discretized cells, partial volume computations, and reductions of those partial volumes for all overlapped cells. When one or more of the computational domains employs an unstructured discretization, these operations become even more costly and can dominate the runtime of a coupled simulation. Performance improvements to these algorithms can significantly impact simulation runtime and scalability.

We present recent work to improve runtime performance of the overlap computations used in the Eulerian/Lagrangian coupling of the SABLE hydrodynamics code to SIERRA/SM explicit solid mechanics code using the mIFEM approach. We compare isolated performance of the volume overlap computations before and after the improvements, and demonstrate portability of the improved algorithms to GPU architectures that are increasingly available on commodity HPC platforms. Finally, we demonstrate the impact to overall runtime of an example coupled simulation using SABLE and SIERRA/SM.

PREDICTION OF PROCESS OUTCOMES WITH UNCERTAINTY IN LASER POWDER BED FUSION ADDITIVE MANUFACTURING

Daniel Moser[*1], Nicole Aragon[1], Michael Heiden[1], Aashique Rezwan[1], Theron Rodgers[1], David Saiz[1] and Michael Stender[1]*

[1]*Sandia National Laboratories*

ABSTRACT

Part qualification remains a key challenge to adoption of laser powder bed fusion (LPBF) technologies, particularly for high consequence applications. This work details efforts to reduce the testing burden of LPBF qualification by using physical modeling and uncertainty quantification to make process outcome predictions that account for inherent process variabilities. Beginning with detailed melt pool-scale models, LPBF machine uncertainties are estimated and propagated through a series of models to predict thermal response, melt pool morphology, porosity formation, microstructure growth, and mechanical deformation. The resulting probabilistic predictions are compared against experimental data obtained from metallography, micro-CT, EBSD, and structured light scanning measurements. Agreement with the data is assessed and gaps in modeling capabilities discussed. Potential applications are also discussed, describing how probabilistic predictive models could be used for a more agile LPBF qualification workflow.

This work was supported by the LDRD program at SNL, managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

A FUNDAMENTALLY NEW COUPLED APPROACH TO CONTACT MECHANICS VIA THE DIRICHLET-NEUMANN SCHWARZ ALTERNATING METHOD

Alejandro Mota[*1], Daria Koliesnikova[1], Irina Tezaur[1] and Jonathan Hoy[2]*

[1]Sandia National Laboratories

[2]Air Force Research Laboratory

ABSTRACT

Contact phenomena are essential in understanding the behavior of mechanical systems. Existing computational approaches for simulating mechanical contact often encounter numerical issues, such as inaccurate physical predictions, energy conservation errors, and unwanted oscillations. We introduce an alternative technique, rooted in the non-overlapping Schwarz alternating method, originally developed for domain decomposition. In multi-body contact scenarios, this method treats each body as a separate, non-overlapping domain and prevents interpenetration using an alternating Dirichlet-Neumann iterative process. This approach has a strong theoretical foundation, eliminates the need for contact constraints, and offers flexibility, making it well-suited for multiscale and multiphysics applications.

We conducted a numerical comparison between the Schwarz method and traditional methods like Lagrange multiplier and penalty methods, focusing on a benchmark impact problem. Our results indicate that the Schwarz alternating method surpasses traditional methods in several key areas: it provides more accurate predictions for various measurable quantities and demonstrates exceptional energy conservation capabilities. To address the issue of unwanted oscillations in contact velocities and forces, we explored various algorithms and stabilization techniques, ultimately opting for the naïve-stabilized Newmark scheme for its simplicity and effectiveness. Furthermore, we validated the efficiency of the Schwarz method in a three-dimensional impact problem, highlighting its innate capacity to accommodate different mesh topologies, time integration schemes, and time steps for each interacting body.

NOVEL METRICS FOR ASSESSING THE QUALITY AND COMPLETENESS OF STRESS-STRAIN DATASETS: BRIDGING THE GAP IN CONSTITUTIVE LAW DEVELOPMENT

Ehsan Motevali Haghighi[*1] and Samir Chidiac*[1]

[1]*McMaster University*

ABSTRACT

The accurate characterization of stress-strain datasets is crucial for developing robust constitutive laws for materials, essential in engineering applications. This paper introduces metrics to evaluate dataset quality and completeness, aiming for effective utilization in law development. Multiple stress-strain datasets, generated under random loading conditions, are considered, covering various material properties via the J2 constitutive law. Metrics are calculated for these datasets, and a deep neural network learns patterns within the data. The study focuses on evaluating metric accuracy by benchmarking against stress-strain datapoints collected from Finite Element Method (FEM) macro problems, for which the same metrics are also calculated. Comparing metric similarity between the benchmark problem and generated datasets, the best metric exhibits higher similarity, resulting in lower error in predicting stress-strain datapoints. In other words, the best metrics effectively capture knowledge, enriching the training database. This research establishes a standardized framework for assessing stress-strain datasets and enhances reliability in data-driven constitutive law development. The findings advance materials science and engineering practices, promoting a more systematic approach to material behavior analysis.

SIMULATION OF THE HEART USING NNFE

Shruti Motiwale[*1] and Michael Sacks*[1]

[1]*The University of Texas at Austin*

ABSTRACT

With advances in computational modeling and imaging techniques, patient-specific cardiovascular modeling for device design, disease modeling and treatment is approaching reality. However, the slow computational speed for accurately simulating the complex physiology of the heart using traditional finite-element based methods still limits their practical clinical applications. While reduced order models are used to accelerate simulations in many domains, the time savings are insufficient and can include loss of accuracy.

We have previously demonstrated the efficacy of the neural network finite element (NNFE) approach for predicting cardiac mechanics of an idealized left ventricle within clinically relevant timeframes without compromising accuracy. In the present study, we extended the NNFE approach to a realistic ovine heart left ventricle (LV) geometry to simulate the pressure-volume (P-V) active contractile behavior over the complete functional range. The finite element mesh was created from MRI scans and principal myofiber directions were prescribed using DT-MRI data, all obtained from a single ovine heart. We modeled the constitutive behavior of the myocardium using a Fung-based hyperelastic material model, and the active contraction using an additive stress based on the Hunter-McCulloch-Ter Keurs model. The NNFE approach uses neural networks (NNs) to represent the discretized displacement field, and conventional finite elements to map the NN output on the problem domain, as well as to specify the boundary conditions and perform numerical integrations. The NN was trained with a physics-based training scheme using variational principles that minimize the norm of residual force vectors. Consequentially, this approach does not rely on the existence of a potential energy formulation of the boundary value problem (BVP), and extends the NNFE approach to capture non-conservative BVPs.

The NNFE model predicted the displacement field for any P-V loop in the physiological training space with a max nodal error <1%. The NNFE model took 2-5 hours for training, and once trained the NNFE model took ~3 seconds for producing results for any loading, whereas the traditional finite element (using Abaqus) model required ~2.5 hours on average for a single loading path. Our results demonstrate a major step forward in the application of the NNFE approach for organ level simuations. We are working on extending this method to study the effects of inotropy on cardiac behavior and disease simulations.

HYBRID HIGH-ORDER METHODS FOR TIME-DEPENDENT, COUPLED ELASTO-ACOUSTIC WAVE PROPAGATION

Romain Mottier[*123], Alexandre Ern[12] and Laurent Guillot[3]*

[1]*Ecole des Ponts*
[2]*Inria*
[3]*CEA - DAM - DIF*

ABSTRACT

Owing to the complexity of geological features, the simulation of elasto-acoustic wave propagation in the Earth, is challenging. To handle efficiently this difficulty, we consider hybrid high-order (HHO) methods, which offer several attractive assets such as local conservativity, geometric flexibility through the support of polyhedral grids, and high-order precision [Di Pietro, Ern, 2014, Comput. Meth. Appl. Mech. Engrg.]. HHO methods rely on a pair of unknowns, combining polynomials attached to the mesh faces and the mesh cells. The cell unknowns can be eliminated locally using a static condensation procedure, whence an increased computational efficiency with respect to classical DG methods. HHO methods are closely related to hybridizable DG (HDG) methods [Cockburn, Gopalakrishnan, Lazarov, 2009, SINUM]. Here, we build upon previous work on HHO methods for either elastic or acoustic wave propagation in the time domain [Burman, Duran, Ern, 2022, Comm App Math Comp Sci], and devise the coupling between both HHO discretizations. A first-order formulation in time is considered, and implicit and explicit Runge--Kutta schemes are used for the time discretization. An energy balance confirming the stability of the schemes is derived. Numerical results on test cases with analytical and semi-analytical solutions show that the methods deliver optimal convergence rates. A more realistic case on the propagation of an elastic pulse in a sedimentary basin coupled to the atmosphere is presented. In accordance with what is observed in practice, we show that in such a case a significant part of the energy is captured by the sedimentary basin and then transmitted to the atmosphere.

PATIENT-SPECIFIC SURROGATE MODEL TO PREDICT PELVIC FLOOR STRETCH DURING VAGINAL DELIVERY

Rita Moura[*1], Dulce Oliveira[1], Marco Parente[2] and Renato Natal Jorge[2]*

[1]*Institute of Science and Innovation in Mechanical and Industrial Engineering*
[2]*University of Porto*

ABSTRACT

Between 6% and 40% of vaginal births may result in trauma to the pelvic floor muscles (PFM), leading to long-term consequences such as incontinence or prolapse [1]. Computational simulations can be used to biomechanically analyze the birth process; however, the integration of these simulations into clinical practice is hindered by high computational costs. To overcome this limitation, surrogate models can replace the simulations, enabling faster results. This study aims to develop an AI framework for predicting PFM stretch during vaginal delivery.

A finite element model of the PFM and fetal head was used to simulate delivery. Material properties and muscle geometry were varied to achieve patient-specific characteristics. A dataset of 5618 completed simulations was generated, with each pelvic floor node corresponding to an observation. Specifically, 49 nodes were selected near the urogenital hiatus of the PFM. The study used initial node coordinates, material properties, muscle diameters, node position, urogenital hiatus length, and time frame as training features. Decision trees (DT), random forest (RF), extreme gradient boosting (XGBT), and artificial neural networks (ANN) were selected as machine learning models. A 90/10 split was used to generate training and test sets, with the stratified shuffle split method ensuring a consistent feature distribution. Hyperparameter optimization with cross-validation was performed, and model performance was evaluated using mean absolute error (MAE).

The stretch was predicted for multiple instants of fetal descent to determine both its peak and the instant when it occurs. Preliminary results included a MAE of 0.239 mm for the DT model, 0.200 mm for the RF model, 0.544 mm for the XGBT model, and 0.397 mm for the ANN. By specifically analyzing the results obtained at each time step and node region, it was concluded that errors are higher for time steps closer to the end of the delivery and in the middle region of the muscle (corresponding to the region experiencing greater stretch).

The development of this framework consists of a preliminary step toward the implementation of patient-specific, near real-time computational simulations in a clinical setting. The ability to predict the stretch suffered on the pelvic floor immediately before or during childbirth could aid in medical decision making and in the identification of non-visible injuries.

APPLICATION OF THE HARMONIC BALANCE METHOD TO PREDICT WAVE PROPAGATION IN ONE-DIMENSIONAL NONLINEAR METAMATERIAL EXCITED HARMONICALLY

Rangel Moura Barbosa[*1] and Alberto Luiz Serpa*[1]

[1]*Universidade Estadual de Campinas - UNICAMP*

ABSTRACT

Periodicity and local resonance are features managed to achieve efficient metamaterials. In the vast majority, the latter aspect is studied through the application of linear resonators. Recently, due to dynamic characteristics provided by nonlinearity, such as the dependence of the response on the amplitude of the excitation and the transfer of wave energy to higher harmonics, nonlinear resonators have been considered.

Nonlinear behavior is typically a challenging aspect to address. It often increases complexity and must be carefully analyzed at the design stage to avoid trial-and-error approaches in the design of mechanical devices.

This requirement is pursued in this work, where the objective is to develop a computational procedure capable of capturing some nonlinear behaviors in a one-dimensional metamaterial chain, such as the emergence of higher harmonics in the response and the influence of excitation amplitude. For this purpose, the Harmonic Balance Method (HBM) is implemented with a numerical continuation, considering the steps of pseudo arc-length and Newton methods.

The implementation of the HBM method is validated for a 2-DOF system with nonlinear cubic stiffness. Subsequently, a system with 10 unit cells is analyzed, each cell composed of a main chain mass connected to a local oscillator by a nonlinear cubic spring, a linear spring, and a viscous damper. Between consecutive unit cells, there is a linear spring and a viscous damper.

By applying a harmonic force to the first unit cell, the aim is to observe the vibration transmissibility throughout the structure. By observing the harmonics that compose the response, it is possible to evaluate the energy transfer to higher harmonics and the excitation force effect due to nonlinear dependency. The results and analysis can motivate new procedures for the design of metamaterials.

A DISPLACEMENT-BASED MATERIAL POINT METHOD FOR WEAKLY COMPRESSIBLE FREE-SURFACE FLOWS

Georgios Moutsanidis[*1] and Ram Mohan Telikicherla*[1]

[1]*Stony Brook University*

ABSTRACT

We present a displacement-based material point method for simulating weakly compressible free-surface flows and fluid-structure interaction. To address volumetric locking, we employ the F-bar technique, previously developed for solid mechanics. This technique involves projecting the pressure and the dilatational part of the velocity gradient onto a lower-dimensional approximation space, eliminating complexities associated with two-field mixed formulations and operator splitting approaches. Additionally, to mitigate spurious pressure oscillations resulting from the use of a density-dependent equation of state, we enhance the framework with an artificial viscosity term. Finally, we employ higher-order spline background shape functions, resulting in a continuous representation of the velocity gradient and effectively preventing pressure jumps when material points cross element boundaries. Challenging numerical examples are provided to verify and validate our approach, demonstrating results that closely align with existing literature, exhibit reduced pressure oscillations, and are free of volumetric locking issues.

Physical models and reduced order models augmentation with data for physics-informed machine learning in real-world applications

UNVEILING BISTABLE STOCHASTIC DYNAMICS THROUGH PHYSICS-INFUSED LEARNING IN SCARCE AND NOISY DATA REGIMES

Beatriz Moya[*1], Eleni Chatzi[2] and Francisco Chinesta[3]*

[1]*CNRS@CREATE*
[2]*ETH Zurich*
[3]*ENSAM Institute of Technology*

ABSTRACT

Data assimilation and accurate identification and estimation of parameters in bistable stochastic systems pose significant hurdles. Traditional assimilation methods may struggle to capture the coexistence of multiple stable solutions and may fail to capture intricate nonlinear interactions within the system. In particular, applications such as energy harvesting, which involve mechanoelectric coupling, introduce additional complexities because of the interplay between mechanical and electrical components. On top of that, in real-world scenarios, obtaining observations for bistable systems might be limited and noisy. The scarcity of reliable data can hinder assimilation methods that heavily rely on observational information for accurate state estimation.

In response, we propose the use of deep learning for the characterization of bistable energy harvesters. The approach of Callaham et al. [1] will be complemented by the use of a penalty based on the fulfillment of the Fokker-Planck equation. The goal of this additional constraint is to combine the available noisy data with the knowledge of the system to fill the gaps of the unknowns in each separate framework and enrich the method.

Gaussian Process Latent Force Models (GPLFM) extend the concept of Gaussian processes (GPs) to include latent forces acting on the observed data. This approach is commonly used in machine learning and statistical modeling to capture complex relationships and dynamics in data, particularly in scenarios where forces or latent variables influence the observed outcomes [2]. Provided the stochastic nature of the loads triggering the dynamics of energy harvesters, this framework is used to formulate the latent forces as Gaussian Processes.

The combination of machine learning and physics-informed constraints enhances the robustness and interpretability of sensor and load characterization in complex systems with small and noisy datasets. The approach yields the reconstruction of the response surface of the dynamics under study, allowing the exploration of parameter combinations. Furthermore, an update algorithm is developed for the hybrid twin of individual energy harvesters, facilitating the continuous characterization of the mechanical properties and the stochastic load.

RETHINKING GENERATIVE INVERSE DESIGN: A GENERAL AND LIGHT-WEIGHT MACHINE LEARNING FRAMEWORK FOR ON-DEMAND NONLINEAR MATERIALS DESIGN

Haoxuan Mu[*1], Wei Zhang[1], Wei Gao[1] and Wei (Wayne) Chen[1]*

[1]*Texas A&M University*

ABSTRACT

Data-driven engineered materials design offers prospects for developing structures and systems with evolutionary material properties. In contrast to forward modeling, the inverse design process is challenging due to its intractability and non-uniqueness of potential solutions. Current data-driven inverse design methods mainly employ deep learning, which has high data demand and requires expensive training and hyperparameter tuning. In this work, we propose a light-weight, single-shot inverse design method that generates engineered materials designs with target nonlinear constitutive relations, founded on statistical inference and Markov chain Monte Carlo (MCMC) sampling. Specifically, given any machine learning model that predicts materials' nonlinear constitutive relation and its uncertainty, we can estimate the likelihood of any possible material design satisfying any given target constitutive relation. We can then sample new material designs based on the estimated likelihood. Thus, the proposed method operates as a generative model for design solutions, capturing the one-to-many relationship between the target and designs and characterizing the distribution of acceptable outcomes based on a specified design target. The method also decouples the inverse design process from the forward modeling process, leading to enhanced customizability and universality. The inverse design process does not involve model training and hence is cost-efficient. The explicit likelihood estimation indicates the probability of target satisfaction and adds interpretability to the inverse design process. We validate the performance of the proposed method on a nacre-inspired metamaterials design problem. Subsequent experiments using synthetic design data further demonstrate the method's effectiveness, providing more detailed and visually represented quantitative functional behavioral results. This work presented an alternative view to solving on-demand inverse design problems through a less data and computationally intensive approach, and laid the foundation for future advancements in engineered materials design.

PYMESOSCALE: A FRIENDLY PYTHON LIBRARY FOR GENERATING 3D CONCRETE MESOSCALE MODELS BASED ON THE LOCAL BACKGROUND GRID METHOD

Faisal Muhammad[*1] and Saheed Kolawale Adekunle*[1]

[1]*King Fahd University of Petroleum and Minerals*

ABSTRACT

Mesoscale modelling of concrete and its composites has attracted a lot of researchers over the years with the promise of establishing an accurate relationship between the mesoscopic model and the macroscopic mechanical properties of concrete. The main issues preventing such outcomes are (1) difficulty in generating a high aggregate volume fraction with control over aggregate shape and gradation. (2) computational resource consumed when generating mesoscale models, (3) realistic ITZ (Interfacial Transition Zone), (4) effective aggregate intrusion detection when placing aggregates etc. But among these issues, lies a much bigger one which is the lack of open sourcing of codes and algorithms that were implemented in research papers slowing down the speed at which research would have progressed. Researchers have to program the algorithms of previous research in order to improve or devise newer and more effective ones. Comparison between the newly developed and already existing mesoscale model generation algorithm will require programming, slowing down the pace by which important problems can be solved. Moreover, most papers do not give a complete overview of the most delicate and subtle details required to implement such algorithms leading to reading multiple papers for the implementation of a single algorithm [1,2]

pyMesoscale implements the local background method for generating 3D mesoscale models which have proved to be amongst the most effective mesoscale generation algorithm particularly with a much better aggregate intrusion detection system during aggregate placing and a high aggregate volume fraction after packing. The generated aggregates are randomly translated onto a global mesh where all the elements have been initialized as mortar. A local background grid is generated around the translated aggregate where all aggregate and ITZ identification and intrusion takes place. Python was the programming language of choice due to its smoother learning curve and beginner friendliness. Reducing implementation complexity was at the heart of its development making it approachable by both new and experience researchers to the field. Sufficient documentation in the form of Docstrings (Documentation String) have been written for easy and fast reference to users of the library. More mesoscale model generation algorithms will be added in newer versions of the library giving researchers the ability to compare and contrast between algorithms.

A TWO-WAY COUPLING FRAMEWORK FOR IMMERSED HETEROGENEOUS STRUCTURES IN FLOW WITH APPLICATIONS IN VASCULAR SYSTEMS

Chayut Teeraratkul[1] *and Debanjan Mukherjee**[1]

[1]*University of Colorado Boulder*

ABSTRACT

Immersed heterogeneous structures are prevalent in various engineering and biological applications. Examples include flow and nutrient transport into and around porous corals [1]. Within the vascular system, the blockage and fracturing of porous blood clots under pulsatile flow [2] is driven by clot-flow two-way interactions. These problems are characterized by a soft, discrete heterogeneous structure deforming under unsteady viscous flow-induced forces. Numerical simulations of the inherently multi-scale flow and flow-structure interactions of such complex structures pose a significant challenge. Using mesh conforming fluid-structure interaction methods can result in highly distorted mesh elements when structural deformation is large. Non-conforming methods such as the Immersed Finite Element Method (IFEM) [3] provide an attractive avenue for simulating an immersed continuous structure without expensive re-meshing. However, a continuum-based representation of the heterogeneous structures does not capture the inherently discrete micromechanics effectively. Additionally, modeling discontinuous phenomena, such as fracture (referred to as clot embolization), is not straightforward using a continuum-based representation. Here, we describe a method that extends IFEM by representing the structure as a series of connected mesoscopic discrete elements. Utilizing a discrete element representation allows for the direct representation of the structure's discrete properties, such as porosity, and enables modeling of discontinuous phenomena like fractures. Dynamics of the discrete elements are solved through a customized Discrete Element Method (DEM) framework. Fluid-structure interactions from each discrete element and the internal forces arising from discrete element interactions are coupled back into the background fluid flow using underlying elements of the IFEM framework. This results in a two-way coupled fluid-structure interaction framework for an immersed discrete structure. To validate the inter-element interaction aspect of the implementation, we present results from a canonical immersed two-body problem simulated using our framework. Furthermore, we compare an example problem of an immersed heterogeneous structure with an existing immersed continuous structure counterpart. Finally, we demonstrate an example application of our method by simulating the micromechanics of a porous blood clot under pulsatile flow.

OPTIMIZATION OF FUNCTIONALLY GRADED POROUS ACETABULAR COMPONENT

Ceby Mullakkara Saviour[*1] and Sanjay Gupta*[1]

[1]*Indian Institute of Technology Kharagpur*

ABSTRACT

Introduction: The mismatch of stiffness between the host bone and the stiffer acetabular components (made of ceramic or metallic alloy) causes stress/strain shielding, leading to peri-prosthetic bone resorption and eventual mechanical loosening. The functionally graded porous (FGP) design capitalizes on the benefits of porosity while maintaining mechanical strength, suggesting its superiority over the uniformly porous counterparts. Although a porous implant facilitates better tissue ingrowth, the reduced stiffness might result in higher volumetric wear of the polyethylene (PE) liner. The objective of the study was to determine the optimal design parameters of the functionally graded porous acetabular component that would result in a trade-off between volumetric wear of the PE liner and bone resorption.

Methods: The elastic properties of the porous metal-backing were determined using a numerical homogenization of the octet-truss unit cell. The multi-objective optimization problem (MOOP) was solved using a non-dominated sorting genetic algorithm. The percentage of resorbed bone mass fraction and the volumetric wear were considered as the objective functions. Porosity levels (porosity values at acetabular rim, and dome) and functional gradation exponents (radial and polar) were considered as the design parameters. The optimal functionally graded porous designs (OFGPs) 1-5 were obtained after employing a simple ranking method named Technique for Order Preference by Similarity to Ideal Solution analysis (TOPSIS) on the Pareto-optimal solutions. The sensitivity of different design parameters of FGP metal-backing on the objective functions were evaluated using multivariate analysis.

Results: The OFGP-1, having highly porous acetabular rim and less porous dome, exhibited a superior trade-off between the bone resorption and the volumetric wear of the PE liner across all OFGPs. More bone elements (~75%) were subjected to higher strains (1.1 - 1.5%) for the OFGP-1 as compared to those for the solid metal-backing. However, OFGPs exhibited an increase in volumetric wear (3-10%) compared to solid metal-backing. Based on the multivariate analysis, it was found that the objective functions were more sensitive to changes in the values of polar gradation exponent ($m\theta$) as compared to that of radial gradation exponent (mR). Statistical analysis indicated that the bone resorption and the volumetric wear of the PE liner were most sensitive to the porosity limit at the inner rim and the porosity limit at the dome, respectively.

Conclusion: The OFGP-1 appeared to be a viable alternative to the solid metal-backing. The results also indicated the superior performance of the OFGP-1 over the uniformly porous design (OFGP-5).

MODELACIÓN DE RÓTULAS PLÁSTICAS EN ELEMENTOS ESTRUCTURALES DE CONCRETO REFORZADO - REFORZADO- MODELING OF PLASTIC HINGES IN REINFORCED CONCRETE STRUCTURAL ELEMENTS

Marlyn Arantza Muñoz Moscoso[*1], Jairo Andres Paredes Lopéz*[1] *and Daniel Bedoya-Ruíz*[1]

[1]*Universidad Nacional de Colombia*

ABSTRACT

The significance of studying the behavior of plastic hinges in reinforced concrete structural elements arises from the desire to comprehend how structural design computer programs implement structural analysis in the nonlinear or deformation range, with the goal of maximizing structural integrity. However, these results remain highly generalized to the structure, prompting a deeper investigation into the stress and deformation characteristics of composite materials, such as the well-known combination of steel and concrete. Additionally, plastic hinges serve as "devices" for dissipating energy, particularly during events like earthquakes. This mechanism allows for controlled plastic deformation at the connection of a column, effectively absorbing energy.

In contemporary seismic resistant design studies, the focus has been on developing new technologies for novel constructions. Regrettably, conventional structures, which constitute the majority of Colombia's built environment, have been somewhat neglected. This underscores the necessity of probing the behavior of structures holistically, deconstructing them into finite elements possessing easily analyzable mechanical characteristics. This approach facilitates the identification of failure points, validation of plastic hinge theories, and examination of prevailing design procedures. It's important to rectify situations where creativity sometimes leads to overly rigid structures with excessive angularity, often resulting in unanticipated torsion.

To model joint development, beam-column finite elements with interior discontinuities are formulated. These elements account for damage by simulating the emergence of cracks, transverse displacements, and axial irregularities. Employing constitutive models rooted in damage mechanics and drawing from experimental tests detailed in existing literature, these finite elements encompass moment capacity, shear force, and axial force considerations, encompassing the behavior of concrete reinforced with steel. Numerical instances of reinforced concrete beams and frames subjected to damage-inducing loads are presented to illustrate the damage modeling capabilities of the developed finite elements. The load-displacement curves calculated in these numerical examples exhibit consistency with those documented in literature.

Consequently, this investigation aims to analyze the behavior of plastic hinges within a reinforced concrete portico, comprising beams and columns. Through numerical analysis, we delve into the mechanical behavior of these elements and draw comparisons with current regulations. Nonlinear analysis employs the finite element method as a computational tool, leveraging series/parallel mixture theory. Constitutive models that accurately represent the mechanical properties of each material underlie the nonlinear numerical analysis.

CFD STUDY OF PARTIAL POROUS COATING TO ENHANCE AEROACOUSTICS IN BLUFF BODIES

Jorge Munoz-Paniagua[*1], David Martínez-Aguilera[2], Javier García García[1] and Eduardo Latorre-Iglesias[1]*

[1]*Universidad Politécnica de Madrid*
[2]*Delft University of Technology*

ABSTRACT

Flow control for bluff bodies has been object of attention for many researchers for a long time. Particularly, the study of cylinders in different configurations, as they might appear in the geometry of the pantograph of a high-speed train, has been considered in [1]. The increase of train speed has resulted into a larger fluctuating contact force between the pantograph and the catenary, introducing instabilities in current collection. Nevertheless, a more significant problem in pantographs is the associated aerodynamic noise, which becomes significant at train speeds over 300 km/h. To reduce the Aeolian tones, flow control has been proposed. Among the different passive flow control techniques, covering with porous material has been applied in [2]. However, the enhancement of the aeroacoustics by this approach has also meant an increase of the drag coefficient. Besides, typically this has been studied coating the whole side of the cylinder. Only in [3] a partial covering was considered, concluding that coating 1/4 of the cylinder surface, around the detachment point, might be a good a compromise between improving the aeroacoustics and reducing the amount of porous material to be used. Here, a more complete parametric study of the position of this partial coating is proposed, ranging from 15 to 180 deg. of symmetric coating (from the stagnation point). A CFD analysis using Scale-Adaptive Simulation (SAS) turbulence model has been completed, and the results obtained show how covering the first 30 deg. let reducing both drag and fluctuation of lift coefficients, as well as sound pressure level.

STUDY OF OBJECTIVE FUNCTIONAL IN OPTIMAL DESIGN OF PHONONIC CRYSTALS FOCUSING ON BAND GAP IN HIGH FREQUENCY RANGE

Naoki Murai[*1] and Takayuki Yamada*[1]

[1]*The University of Tokyo*

ABSTRACT

Phononic crystals exhibit unusual dispersion properties such as band gap where elastic waves can not propagate to any direction because of interference or local resonance. As an attempt to take advantage of the dispersion properties of phononic crystals, vibration suppression and waveguide applications are underway, and studies on controlling heat conduction on a microscopic scale have begun. Since dispersion properties of phononic crystals depends on shape, scale, and material of the structure, effective design method is essential for the applications. Topology optimization method is studied as the design method and shown to be able to design phononic crystals with desired dispersion properties. Maximization of band gap width has been one of the most addressed cases as a benchmark. However, formulations that have been used in previous studies have difficulty optimizing the band gap in high-frequency bands where multiple modes are dense. Consideration of dispersion properties in the high-frequency band is important in the application of phononic crystals on the microscale. In this study, we propose an objective function to create and maximize the band gap in the high-frequency band and verify its effectiveness. Additionally, in the formulation of the optimization problem, connectivity of the structure and how to deal with localized modes are also be discussed.

YOGA THERAPEUTIC APPROACHES FOR THE PHYSICAL AND MENTAL HEALTH OF OLDER ADULTS: USING MOVEMENT ANALYSIS AND PSYCHOMETRIC DATA ANALYSIS

Satoko Murakami[*1], Chieko Kato[1] and Hongjie Zheng[1]*

[1]*Toyo University*

ABSTRACT

Background: Enhancing the healthy life expectancy of older adults and meeting their needs, such as purpose in life, not only helps to keep them physically and mentally healthy and improve their quality of life in their later years but also encourages active social participation and promotes the overall development and inclusiveness of the society. Objectives: Although various therapies for older adults have been proposed, the effects of yoga therapy on the physical and mental health of older adults have received extra attention. Therefore, this study was conducted to clarify the effects of yoga therapy on older adults' physical and mental health, which was verified by combining psychological data and movement analysis. Methods: A healthy older adult served as a tested participant in this study and was subjected to six yoga therapy sessions once a week with gymnastics and breathing exercises in chair yoga therapy. Yatabe-Guilford Personality Test (YG Test) and POMS-2 short version (Profile of Mood States Second Edition) were performed at the beginning and the end of the yoga therapies for before and after comparisons. In addition, we filmed the yoga therapy practice with a video camera, detected the posture of shoulder rotation movements in contact with Open Pose, and put the CSV data in chronological order. Moreover, psychometric test results and interviews about impressions of yoga therapy were included in the different studies. Results: During the first to sixth sessions, the range of motion of the shoulders, elbows, and wrists increased. In the YG test, there was an increase in scores for generally active activities; in the POMS test, there was a decrease in scores for anxiety and depression and an increase in scores for vigor. Conclusions: The possibility of visualizing yoga therapeutic movements to clarify their relevance to psychological aspects will be pursued. It is essential to consider the perspectives of older adults when considering lifelong education.

[5]Fixstars

ABSTRACT

The Finite Element Method (FEM) is a numerical method for finding approximate solutions to differential equations and is widely used in engineering. Although FEM is useful for modelling complex systems, solving very large systems is computationally demanding and requires new approaches using promising techniques such as quantum computing. With this in mind, several quantum algorithms for FEM have been demonstrated. Examples include algorithms with theoretical speed-up guarantees using fault-tolerant gated quantum computers [1] and heuristic design optimisation algorithms using quantum annealing machines [2].

In this study, a framework for FEM with quantum annealing is presented with a focus on fluid dynamics problems. In this framework, the discretised equations of FEM are mapped to a quadratic unconstrained binary optimization (QUBO) problem, which can be solved by quantum annealing. The performance of the proposed method is numerically demonstrated on a simple two-dimensional potential flow.

Furthermore, we propose QUBO to optimize the solid-fluid topology of the fluid channel on the basis of the level-set idea [3]. The combination of the proposed QUBO and classical FEM fluid analysis is used to optimize the fluid channel topology with quantum annealing.

ACKNOWLEDGEMENT

PREDICTION OF PLURAL CRACK PROPAGATION USING DISCOVERED PDE

Genki Muraoka[*1] and Yoshitaka Wada*[1]

[1]*Kindai University*

ABSTRACT

This study presents plural crack propagation prediction using partial differential equation by equation discovery. Fatigue crack growth is simulated by numerical computations considering governing laws and fracture mechanics criteria: stress intensity factor, Paris' law, and criterion of crack propagation direction. It takes much time to compute a single crack propagation case using the finite element method. In contrast, machine learning can predict interpolated crack propagation path and its rate in a much shorter time than the finite element analysis. Therefore, machine learning can efficiently evaluate a structure's integrity on a site.

A dataset is obtained from the results of crack propagation analyses using s-version FEM (s-FEM) combined with an automatic mesh generation technique. Crack propagation can be predicted by machine learning with appropriate input data design. The input parameters are coordinates of the 4 crack tips, the output data are crack propagation vectors, and the number of crack propagation cycles of 0.25 mm. Firstly, the coordinates of each crack tip are given to the predictor. Secondly, the propagation rate and direction are predicted by machine learning. Finally, the next crack coordinate is calculated. A series of these procedures are iterated to predict the crack propagation. The loss is defined by the weighted sum of the prediction loss and the partial equation loss. The definition of two losses is called as physics informed neural networks. The advantage of the loss definition is accelerating of train. PDEs are discovered by evolutionary algorithms. The PDE are composed by 1st and 2nd order partial derivatives of the input and output parameters. It is expected that the loss of PDE as regularization will accelerate training, improve prediction accuracy and minimize loss more rapidly.

The important thing is that the PDE, which can be minimized with less iterations of training, should be appropriately specified using an equation discovery technique. We'd like to discuss how machine learning can be applied to actual engineering problems to generate accurate predictions with less iterations.

ABSTRACT

Elasticity imaging involves probing the deformation of tissue non-invasively using a standard imaging technique like ultrasound, magnetic resonance imaging, or optical coherence tomography. This yields a noisy and incomplete measurement of the deformation field inside the tissue in response to an excitation. The goal is to use this deformation field and the knowledge of the physics of deformation to determine the spatial distribution of its mechanical properties. This is a challenging and ill-posed inverse problem where prior information about the tissue plays a significant role. In this talk, we will describe the use of conditional generative models to solve this problem in a probabilistic setting. This approach provides us with an estimate of the tissue properties as well as the uncertainty associated with this estimate. Applications include imaging the mechanical properties of the inner eye and that of tumor spheroids growing in a soft medium.

MULTISCALE TOPOLOGY OPTIMISATION FOR NONLINEAR ELASTIC STRUCTURES

Ryan Murphy[1], Dilaksan Thillaithevan[1], Robert Hewson[1] and Matthew Santer[1]*

[1]*Imperial College London*

ABSTRACT

In this presentation, a multiscale structural optimization framework capable of efficiently designing two-scale structures with prescribed displacements in the nonlinear elastic regime is presented. In contrast to previous multiscale structural optimization frameworks, which are founded upon the assumptions of linear elasticity, the present framework is capable of efficiently operating within the nonlinear elastic regime. At the core of the present framework is a parameterized microscale geometry (or metamaterial), which through the straightforward manipulation of the microscale parameters provides direct access to both positive and negative Poisson's ratios. The microscale model is concurrently coupled to the macroscale model, such that only the microscale parameter space traversed by the optimizer is resolved during the optimization procedure, leading to a significant reduction in the computational expense of analysis. To demonstrate the capability of this framework, two prescribed deformation profiles are targeted by two distinct optimization procedures. In both instances, the deformation profile is successfully targeted. To verify the accuracy of the optimized structures, high-fidelity single-scale simulations are performed. In each case, excellent agreement is noted between the high-fidelity simulations and the corresponding optimized macroscale displacement fields, with errors of less than 10\%.

ASSESSMENT OF MINING TAILINGS SPILL IMPACTS WITH THE WEAKLY COMPRESSIBLE MPS METHOD

Herman Siaben Musumari[*1] and Ahmad Shakibaeinia*[1]

[1]*Polytechnique Montréal*

ABSTRACT

Accidents causing sudden failures of mining industry tailing dams and subsequent toxic material spills have been extensively documented. The consequences of such incidents pose long-term threats to surrounding environments and ecosystems. It is therefore crucial to develop effective models for assessing the potential impact of these flows and formulating comprehensive response and management plans. The initial release of tailings, being marked by significant deformation and fragmentation, poses a serious challenge to traditional mesh-based numerical methods. Moving particle semi-implicit model (MPS) due to its fully Lagrangian nature offers a unique opportunity to handle such complex physics and is flexible enough to accommodate their non-linear behaviors.

In this study, we employ a three-dimensional (3D) multiphase weakly compressible moving particle semi-implicit (MPS) model to simulate overland flows and evaluate the impact of the material spread within the area of interest. The model incorporates the enhanced represented polygons boundaries (ERP) instead of traditional ghost particles to accurately represent real topography, enabling large-scale applications. To address the non-linear behavior of tailings, Bingham plastic and Herschel-Bulkley rheologies are adopted. The model is applied to simulate the Brumadinho tailings and a hypothetical dam breach at the Copper Mountain tailings dam in British Columbia, anticipated to be the second largest after extension. Simulation scenarios include a single-flow mixture and a multiphase flow with a tailings pond capping the mixture. Numerical results demonstrate the capability of the method to capture the dynamic of the flow and both its scale and intensity with reasonable accuracy.

POWER DISSIPATION MODELLING IN ROLLING CONTACT

Andrzej Myśliński[*1] and Andrzej Chudzikiewicz*[2]

[1]*Systems Research Institute*
[2]*Kazimierz Pulaski University of Technology and Humanities in Radom*

ABSTRACT

This paper deals with the estimation of power dissipation due to friction and simulation of the wear evolution in rolling contact problems including Coulomb rather than Hertz friction model as well as the frictional heat flow. The displacement and stress of the rail in contact are governed by the coupled elasto-plastic and heat conductive equations. We focus on power dissipation modelling rather than contact stresses as in [1]. This work develops new approach to estimate numerically power dissipation and wear modelling in wheel – rail contact problems and provides new insights into the research of these problems. The wear is computed for wheel – rail contact for elasto-plastic material model rather than elastic material model only. Wear estimation is based on combined power dissipation and Archard models rather than Archard model only [2,3].
Numerical model is solved using generalized Newton method rather than Fastsim or Contact software methods. The update finite element mesh algorithm related to the worn material volume rather than general type algorithm is used. The obtained numerical results indicate that the obtained contact patches are characterized by longer zones and lower stress intensity than in the elastic case. For relative small increase of temperature the contact patches are slightly longer than for plasto-elastic model. The power dissipated as well as the wear rate are strongly dependent on the friction coefficient, i.e. they increase when the friction coefficient increases.

COADJOINT ORBITS FLUID IMPLICIT PARTICLES

Mohammad Sina Nabizadeh[1], Ritoban Roy-Chowdhury[1], Hang Yin[1], Ravi Ramamoorthi[1] and Albert Chern[1]*

[1]*University of California, San Diego*

ABSTRACT

Incompressible fluids enjoy particle relabeling symmetry, giving rise to Kelvin's circulation conservation. Throughout the past two decades researchers have been actively developing methods that mimic this continuous property of fluids in the discretized simulations. From a computational fluid dynamics (CFD) viewpoint, these discrete models resemble finite difference or finite volume schemes, which unfortunately have limited stability conditions, despite alluring benefits of structure preservations. Thus non-structure-preserving (but more-stable) semi-Lagrangian, fluid-implicit-particle (FLIP), and particle-in-cell (PIC) schemes are still the dominating numerical methods in applied fluid simulations.

We propose a new approach to structure-preserving discrete fluids. This approach results in discrete models that resemble the mainstream FLIP or PIC methods, but with much more geometric structures.

By incorporating isogeometric analysis techniques (i.e. mimetic interpolation), a staggered grid velocity interpolates into a smooth divergence-free vector field. Furthermore, instead of only moving the positions of the particles by this interpolated velocity field, we let both the positions and the momenta be acted by this field in a symplectomorphic manner. This symplectomorphic group action therefore induces a momentum map, from the particles' position-momentum space to the dual space of velocities. We argue that this canonical map should be taken as the particle-to-grid information transfer. Since momentum maps are Poisson structure preserving, Hamiltonian flows of particles will map into a coadjoint orbit in the dual Lie algebra of divergence-free velocities. In particular, our method preserves Casimirs such as 2D enstrophy and 3D helicity.

Our method, named Coadjoint Orbits FLIP (CO-FLIP), undergoes the following transformation from the traditional FLIP method: The grid-to-particle transfer becomes a mimetic interpolation, the particle motion becomes a symplectomorphic action, and the particle-to-grid transfer becomes the momentum map. Each of these components are informed with each other. We showcase traditional simulation methods benefit from structure-preserving techniques by producing higher fidelity vortical structures, without the need of having prohibitively high resolution computation grids.

ABSTRACT

ABSTRACT
Currently, Standard Topological Optimization tools are able to propose an optimal material distribution for the component, but when small topological details are required the computational cost becomes excessive. In order to overcome this drawback, the present work proposes a two-level topology optimization method in three main steps. The first one subdivides the whole component in cells and generates a coarse optimized low definition material distribution through the well-known SIMP method [1]. The second step uses an equilibrating technique [2] that provides tractions continuity between adjacent cells,. Finally, each cell is optimized at fine scale taking as input data the densities and the equilibrated tractions obtained from the coarse problem via the SIMP method again [3]. Thus quasi-ensuring the material inter-cell continuity after the cells optimization process.
Even if this 2-level approach allows to decrease the computational cost with respect to the full scale problem, the topology optimization processes at each cell, must be performed. Considering that each topology of a given cell could be parametrized with the input data (i.e. loads and density), an strategy based on the measurement of the distances in that parametric space is developed. This measurement is used in combination with a Machine-Learning tool to decrease the number of iterations in the topology optimization process in each cell by proposing a quasi-optimal initial topology in the optimization loop of each cell.

[4]*Sandia National Laboratories*

ABSTRACT

Recent advances in mechanics focuses on coupling nonlocal models with classical local models. This coupling is motivated by the goal of reducing the high computational costs associated with high fidelity models like nonlocal equations, which are used in modeling and simulating complex material behaviors in materials science. Nonlocal models provide a more thorough depiction of certain phenomena that classical Partial Differential Equations (PDEs) cannot sufficiently represent. Such phenomena include the fractures and cracks [1]. In this context, various coupling methods, such as the Variable Horizon Coupling Method (VHCM) and matching displacements or stresses in overlapping regions, have been proposed [2]. This study introduces an innovative machine learning-based approach for automating the classification between local and nonlocal regions within the coupling process. This identification process takes various factors into account, including load functions, boundary conditions, and material geometry. The dataset includes diverse load conditions, such as loads with or without discontinuities. These loads are then preprocessed using the windowing approach, which proves highly effective in handling load functions with varying numbers of discontinuities and other conditions. This approach enables the examination of individual data points within the load. Utilizing window-based techniques, we formulate the problem as a node-wise classification approach. By applying window configurations around each data point, we segment the load effectively, facilitating a focused and precise classification strategy at each point. For the classification, we employ a Convolutional Neural Network (CNN)[3] as a deep learning algorithm that takes windows as input and assigns a label to the window's central node. The resulting output consists of labels assigned to central nodes, indicating either LM for the nodes located in the local region or NLM for the non-local region. The model exhibits exceptional performance, achieving an accuracy of 0.98 and an F1-score of 0.97. These results underscore the potential of our approach to significantly enhance coupling processes, leading to more accurate and computationally efficient designs in material science.

APPLICATION OF XFEM USING CONTINUUM SHELL ELEMENTS TO DAMAGE PROPAGATION ANALYSES OF CFRP LAMINATE

*Toshio Nagashima**[1]*

[1]*Sophia University*

ABSTRACT

Due to high specific strength and stiffness, carbon fiber-reinforced plastics (CFRP) have been widely used in aviation industries in recent years. However, CFRP laminate is susceptible to out-of-plane load, leading to complex damage such as delamination, matrix crack, and fiber breakage. Because the damage may cause a decrease in compressive strength, CAI (Compression After Impact) strength is important in designing CFRP laminate structures.

This study applies an extended finite element method (XFEM) to damage propagation analyses of CFRP laminate. An eight-node quadrilateral interface element and an eight-node hexahedral continuum shell element enriched with only the Heaviside function are used to model delamination and matrix cracks, respectively. In addition, the zig-zag cohesive zone model is employed for delamination and matrix cracks to perform the implicit analysis successfully.

In this presentation, the implicit static method is used to perform damage propagation analyses of CFRP test specimens. It was shown that the proposed XFEM using continuum shell elements is an effective method for damage propagation analysis of CFRP laminates.

A MACHINE LEARNING APPROACH TO PREDICT IN VIVO SKIN GROWTH

Matt Nagle[1], Hannah Conroy Broderick[1], Adrian Buganza Tepole[2], Michael Fop[1] and Aisling Ní Annaidh[1]*

[1]*University College Dublin*
[2]*Purdue University*

ABSTRACT

Skin growth through tissue expansion is an important process for many modern reconstructive surgeries including breast reconstructions and skin defect repair. When a tissue expander is inserted underneath the surface of the skin and inflated, the skin is held in a stretched position which triggers skin growth. Unfortunately, the procedure can have significant complications for patients, for example 8.9% of breast reconstruction patients have been reported to experience skin necrosis [1]. These complications are often the result of thin poor-quality skin and/or overexpansion.

Our previous research has shown that elastic wave measurements may be a suitable method for inferring in vivo skin tension [2]. As such, our goal is to use simulated data from a finite element (FE) model to train a machine learning (ML) model to determine in vivo material properties and predict future growth from measurements of elastic wave speed.

Abaqus was used to develop a 3D FE model to simulate in vivo human skin during the tissue expansion and wave propagation procedures. A custom user defined material was used to model the growth of the skin during tissue expansion [3].

The FE model was run for 1,000 unique sets of human-like material parameters sampled using a Latin hypercube technique. In each case, the skin material parameters, the growth field after 7 days and the waveform (displacement of a node 5mm from the origin of the surface wave) was stored. Using this dataset, an artificial neural network (ANN) was trained to predict growth and material properties.

The ANN was found to have excellent predictive performance for all target variables. The R2 value computed between the true FE outputs and the predicted ANN outputs were found to be 0.94 ± 0.03, 0.98 ± 0.06, 0.86 ± 0.03 and 0.98 ± 0.02 for the growth field, stiffness, growth rate and natural pre-stretch respectively.

Principal Contributions:

Currently, no method exists to non-invasively quantify in vivo skin growth. Thus, a model of the kind presented in this work, once validated, could result in a major advance for reconstructive surgeries. Surgeons could obtain non-invasive measurements of future growth, reducing overexpansion and complications for the patient. Furthermore, this framework could be used to explore different expander geometries/textures, subject specific inflation procedures etc.

ABSTRACT

In this talk we review recent developments of isogeometric analysis in LS-DYNA with particular focus on crashworthiness. We discuss the reason for and the importance of supporting a versatile set of geometric representations. Finally, we provide a glimpse into the latest industry trends and the challenges encountered as production-grade industrial deployment of the technology progresses.

THE “CHICKEN-EGG” ALGORITHM, A MULTIPHYSICS METHODOLOGY TO JACOBIAN TRIANGULARIZATION

Christopher Nahed[*1]*

[1]*French Atomic and Alternative Energies Commission*

ABSTRACT

The role of non-dimensional ratios in engineering and physics is ubiquitous; but applied mathematicians sometimes overlook the utility of non-dimensional analysis. Notably, in the multiphysics modelling community, coupling methods are often discussed and developed without consulting the various non-dimensional ratios of the various inter-physics coupling terms. However, it is evident that the varying strengths of the coupling terms in a multiphysics model of N physics modules will influence either the convergence rate, the stability of the coupling scheme and the program execution speed. In fact, the analysis performed by Huang [1] explicitly showed that the “ordering” of the predictor physics modules is primordial to the performance characteristics of the multiphysics coupling scheme. However, the question of “how to order” (who came first, the chicken or the egg?) the N physics modules remains vaguely posed. In fact, physics ordering is generally based on the scientist’s experience or on problem specific stability analyses performed on academic computational configurations (see computational FSI and conjugate heat transfer literature). In the case of generic multiphysics coupling, where volume, interface and/or surface coupling terms can manifest, the optimal ordering of the physics modules may strongly vary along simulation time (for the same application) and/or across applications. Motivated to find an approximate measure that does not resort to cumbersome and problem specific stability analyses, we borrow the concept of non-dimensional analysis from physics and apply it to the algebraic systems that manifest in multiphysics computational models. The “chicken-egg” algorithm is based on a non-dimensional methodology that serves to “triangularize” the full Jacobian matrix of an exact Newton-Raphson implicit scheme. The method poses a non-dimensional preconditioner that estimates the different strengths of the various coupling terms found in the multiphysics application. The elimination of the small non-dimensional entries $\phi_{ij}<1$ and the row reordering of the preconditioner represents the now triangularized and “ordered” Jacobian of the multiphysics model. The “chicken-egg” algorithm estimates at every given time step the order of magnitude of ϕ_{ij} and correspondingly orders the N partitioned physics modules (automatically). This algorithm is tested for the first time on a thermo-hygro-corrosive multiphysics model and shows promising results. Compared to a classic sequential block-diagonal algorithm, the first numerical tests show over a 2-fold improvement in program calculation time.

CLUSTER-BASED CONTROL IN HIGH-DIMENSIONAL FLOW SYSTEMS THROUGH CONVOLUTIONAL AUTOENCODER

Aditya Nair[*1], Nitish Arya[1], Khalid Rafiq[1], Jayesh Dhadphale[2] and Sujith Ri[2]*

[1]University of Nevada, Reno
[2]Indian Institute of Technology, Madras

ABSTRACT

We introduce an innovative architecture for cluster-based control of complex flows using high-dimensional data, addressing the limitations of traditional sensor-based methods. Traditional flow control strategies, whether model-free [1] or model-based [2], have relied on limited sensor measurements, leading to control laws that are often specific and lack generalizability across different features. We propose a novel methodology that fully leverages high-dimensional datasets to enhance control mechanisms. By employing a convolutional autoencoder, we compress the vast data into a manageable form, producing a low-dimensional embedding that captures the critical nonlinear dynamics of the system within latent space vectors. The subsequent clustering of the latent space informs a feedforward neural network, facilitating a direct mapping between the latent space vectors and key system quantities like the drag coefficient. This creates a clear interpretability of the clustered states, a significant advancement in understanding complex flow dynamics. We construct a cluster-based network model [3] to serve as a transition propagator between centroids in response to control inputs. This model informs the creation of a feedback control law that guides the latent space trajectory toward a desired cluster state. The control law is then decoded and applied as a forcing input, steering the high-dimensional system toward a targeted low drag state, particularly over an airfoil at a high angle of attack. The inherent speed and efficiency of our model stem from its foundation in low-dimensional latent space vectors, allowing it to encompass the full spectrum of high-dimensional system characteristics. Notably, the model demonstrates versatility, controlling multiple attributes simultaneously without extensive reconfiguration. This architecture signifies a leap forward in flow control, marrying full data utilization with rapid operational capability. It promises to reshape the way we approach control laws for complex systems, with potential applications extending beyond aerodynamics into various fields where flow dynamics play a crucial role.

MATERIAL POINT METHOD MODELING OF CRACK PROPAGATION FOR INTERACTING AND INTERSECTING EXPLICIT CRACKS

John Nairn[*1] and Yamina Aimene*[2]

[1]*Oregon State University*
[2]*University of the West Indies, Ecofog*

ABSTRACT

Numerical crack propagation modeling of multiple, explicit cracks requires methods that can resolve interacting, and potentially intersecting, cracks as well as methods to calculate crack-tip parameters with sufficient accuracy for predicting when and where cracks will grow. The material point method (MPM) can solve interacting crack problems using the CRAMP method (for cracks in MPM), but J integral calculations needed to predict crack propagation have to be modified whenever other cracks intersect the J contour for the propagating crack. If the tip of an intersecting crack is inside the J contour, the contour has to be adapted to avoid that tip. This talks will describe robust J calculations for interacting and intersecting cracks. Several examples show that the revised J methods are accurate even when J contours are intersected. Selected crack propagation examples show the new methods have sufficient accuracy for interacting crack propagation calculations. The calculations work with a regular background MPM grid without any need to remesh or to highly refine crack-tip regions.

MULTISCALE STRUCTURAL OPTIMIZATION USING MACHINE LEARNING SURROGATE MODELS FOR SECOND-ORDER HOMOGENIZATION

Ahmad Najafi[*1] and Nolan Black*[1]

[1]*Drexel University*

ABSTRACT

Multiscale structural optimization considers the simultaneous design of both the macroscale (observable) structure and its microscale constituents. In this work, microstructures with intricate features are used to control local structural properties. Driven by advancements in additive manufacturing, the introduction of complicated microarchitectures in the microscale design space can produce superior structures for high strength-to-weight and energy absorption applications. Numerical homogenization techniques that have traditionally been used to incorporate microarchitecture mechanics into multiscale design, however, fail to capture local physical phenomena. The deliberate integration of these microarchitectures into the greater structure must also include both microscale and macroscale design variables. To address these challenges, numerical homogenization is typically used to estimate the local response of the microarchitecture, while design parameterization is used to limit the multiscale design space.

This presentation seeks to extend the homogenization approach to design using machine learning. As in traditional topology optimization, we implement a surrogate for parameterized homogenization to model the micro-to-macro transition. As a surrogate, we explore the deep neural network (DNN) for its ability to efficiently model high-dimensional and nonlinear functions. In addition, we build the DNN's training dataset using finite element simulations of second-order numerical homogenization. The second-order homogenization method incorporates a strain gradient into the microstructural analysis, increasing the information exchange between the macro- and microscales and addressing problems of scale separation. The model is applied to evaluate the local stress amplification caused by spatially varying microarchitectures. Through numerous examples, we show how a model can be used to efficiently evaluate hierarchical structures in stress-constrained design.

ENERGY STABLE RELAXATION-FREE RUNGE-KUTTA SCHEMES

Mohammad Reza Najafian Zadeh Najafabadi[*1] and Brian C. Vermeire*[1]

[1]*Concordia University*

ABSTRACT

Exact solution of the governing equations of physical phenomena often enforces auxiliary admissibility criteria, e.g., conservation of entropy or conservation of energies. Often referred to as invariants, these auxiliary admissibility criteria are typically not enforced via conventional discretization techniques. Ultimately, this leads to non-physical solutions, loss of accuracy, and loss of stability.

Over the past several decades, significant attention has been placed on low-order entropy or kinetic energy conservative spatial discretizations. These frameworks then have been extended to high-order discretizations, including discontinuous Galerkin (DG) and flux reconstruction (FR). For example see the work of Chan [1]. However, less attention has been given to the role of time integration on conserving invariants.

Recently, Ketcheson [2] demonstrated the relaxation Runge-Kutta (RRK) schemes can be used to enforce energy conservation, subsequently extended to entropy conservation by Ranocha et al. [3]. These introduce a time step relaxation parameter to enforce global conservation. In contrast, the incremental direction technique (IDT) can used to maintain a constant step size, but yields a loss of order of accuracy. Hence, existing techniques are disadvantageous, requiring dynamic variation of the step size, or loss of accuracy.

Here we introduce relaxation-free Runge-Kutta (RFRK) schemes, enforcing conservation while maintaining both a constant time step size and equivalent or greater order of accuracy than the base Runge-Kutta scheme. Implementation complexity is similar to that of RRK and IDT schemes and, under smooth solutions, performance converges to that of the base RK scheme. We demonstrate energy conservation for a range of example applications, and propose that these schemes are a suitable replacement for RRK and IDT schemes, alleviating the limitations of both previously proposed approaches.Exact solution of the governing equations of physical phenomena often enforces auxiliary admissibility criteria, e.g., conservation of entropy or conservation of energies. Often referred to as invariants, these auxiliary admissibility criteria are typically not enforced via conventional discretization techniques. Ultimately, this leads to non-physical solutions, loss of accuracy, and loss of stability.

MULTI-FIDELITY MODELING FOR UNCERTAINTY QUANTIFICATION OF A RATCHETING MECHANISM

David Najera[*1] and Robert Kuether[2]*

[1]*ATA Engineering, Inc.*
[2]*Sandia National Laboratories*

ABSTRACT

Complex mechanisms containing gears, springs, and movable pawls are common in mechanical systems and are critical for the correct function of components that rely on subsystem kinematics to operate (e.g., mechanical watches). These systems involve contact interactions between various piece-parts during operation, which complicates their analysis because linearization of these systems is often infeasible. An approach to evaluate the performance of these mechanisms under relevant dynamic environments is to perform detailed, high-fidelity finite element analysis considering frictional contact. However, these types of simulations are very computationally intense and are often intractable when it comes to evaluating the performance of the structure over long periods of time, such as random vibration. Alternatively, simplified models and reduced-order models are efficient in terms of the computation times due to their lower-fidelity but may be limited in how accurate they are in terms of representing the physics. This work explores the use of a multi-fidelity machine learning surrogate model to combine multiple physics-based model fidelities to obtain a predictive model that achieves accuracy comparable to high-fidelity simulations with increased efficiency even when compared to a low-fidelity model. The proposed approach makes use of a Bayesian neural network to account for epistemic and random uncertainty, and the surrogate is used to study the mechanism’s response to varying inputs and parameters. The approach is demonstrated on a ratcheting gear mechanism that is relevant to industrial applications. SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

CONSTRAINED PROBABILISTIC MODEL CALIBRATION GIVEN SUMMARY STATISTICS

Habib Najm[*1], Tiernan Casey[1], Pieterjan Robbe[1] and Mohammad Khalil[1]*

[1]Sandia National Laboratories

ABSTRACT

Uncertainty quantification in computational models relies on probabilistic characterization of uncertain model inputs and parameters, which is effectually arrived at by the solution of a statistical inverse problem given available data. In this talk, we address specific challenges with the computational solution of statistical inverse problems in a Bayesian setting, related to missing data. In many practical situations, actual data is simply not available, and one is limited to available data summaries, in the form of statistics, such as nominal values and conditional/marginal bounds, on the quantities of interest or functions thereof. Maximum entropy methods are useful for inference employing constraints, rather than data. We describe our computational implementation of the maximum entropy principle employing approximate Bayesian computation methods, to enable inference of uncertain parameters given summary statistics that define a constraint on the data conditioned on all available information. We present illustrations of the performance of this construction in model application problems.

[2]*National Tsing Hua University*

ABSTRACT

2D layered lead-halide perovskite material has been the focus of intensive investigation in recent years due to its superior stability against the elements compared to the 3D counterparts, which is a consequence of intercalation of large organic hydrophobic spacer cations within its structure solving the degradation issue. Spacers induced quantum and dielectric confinement leads to different exciton binding, and hence, band gap values for different number of perovskite layers between the intercalating bulky organic molecules, thus enabling the tuning of the optoelectronic and photovoltaic properties in devices employing 2D perovskite material. To this day the theoretical studies of this material have been limited to density functional theory, and hence, several hundred atoms due to lack of reliable potentials which would enable the insight into the properties of the 2D perovskites observable in larger scale. In this study we developed quantum accurate machine learning enabled inter-atomic force-field based on the spectral neighbor analysis potential (SNAP) scheme applicable to most studied intercalating spacers butylammonium (BA) and phenylethylamonium (PEA). Our resulting SNAP potential reproduces the energies of the reference structures with high fidelity, while at the same time exhibits excellent stability in molecular dynamics simulations. We employed our machine learning enabled force-field to study layer distribution in 2D perovskite material including both of the aforementioned spacers by employing hybrid Monte Carlo approach. Our results from large scale Monte Carlo simulations are in good agreement with available experimental findings confirming non-uniform perovskite layer distribution between the intercalating cations. Furthermore, our results indicate that the non-uniform distribution is more energetically favorable compared to the uniform one which is a consequence of intricate balance between spacer and perovskite layer content which predominantly influences lead-halide bond properties. In addition, our simulations confirmed both temperature and spacer layer distribution dependence as predicted by the reference experimental study. Hence, presented multiscale simulations demonstrate that machine learning enabled models can be successfully employed to extract the microstructure of the complex perovskites and its impact on the underlying properties of the material.

COMMUNICATION-COMPUTATION OVERLAPPING FOR PARALLEL MULTIGRID METHODS

Kengo Nakajima[*1]*

[1]*The University of Tokyo, RIKEN Center for Computational Science*

ABSTRACT

Preconditioned iterative methods based on the Krylov subspace technique are widely employed in various scientific and technical computing. When utilizing large-scale parallel computing systems, the communication overhead tends to increase with the growth in the number of nodes, making its reduction a crucial challenge. In parallel finite element methods (FEM) and finite volume methods (FVM), halo communication and computation overlapping (CC-Overlapping) are commonly employed, often in conjunction with the dynamic loop scheduling feature of OpenMP. This approach has been primarily applied to sparse matrix-vector products (SpMV) and explicit solvers. Previous studies by the author have proposed reordering techniques for applying CC-Overlapping to processes involving global data dependencies, such as the Conjugate Gradient method preconditioned by Incomplete Cholesky Factorization (ICCG). Successful implementations on massively parallel supercomputers demonstrated high parallel performance, but the application of CC-Overlapping was limited to SpMV. In the present work, the author propose a method to apply CC-Overlapping to the forward and backward substitutions of the IC(0) smoother of the parallel Conjugate Gradient method preconditioned by Multigrid (MGCG). Using up to 4,096 nodes on Wisteria/BDEC-01 (Odyssey) with A64FX, performance improvements of approximately 40+% was achieved compared to the original implementation, while improvement was 20+% on Oakbridge-CX system with Intel Xeon CPU's.

Multiscale computational homogenization for bridging scales in the mechanics and physics of complex materials

[1]*Tohoku University*

ABSTRACT

This study proposes a surrogate homogenization model of elastopolasic composites within the finite deformation framework using a Radial Basis Function (RBF) interpolation.
Although various homogenization methods have been developed so far, conventional methods, such as coupled and decoupled schemes, face challenges of high computational cost and complicated macroscopic constitutive model, respectively. In an attempt to overcome these problems, data-driven multiscale methods were developed by incorporating mechanistic machine learning technologies [1]. In this context, we have developed a data-driven method for two-scale analysis of elastoplastic composites under small deformation problem [2]. Specifically, the surrogate model was created by performing RBF interpolation for a constitutive database of macroscopic behavior of elastoplastic composite to replace the microscopic analysis in the two-scale analysis. However, it needs to be extended to the finite deformation framework to properly capture the multiscale mechanics of composite structures in practical problems. For that purpose, we changed the variable setting of the RBF interpolation from the infinitesimal strain and Cauchy stress to the macroscopic right stretch and the Second Piola-Kirchhoff stress. By employing these variables instead of the deformation gradient and First Piola-Kirchhoff stress, we can eliminate the influence of rigid body rotations in the proposed model. Also, we employ the right stretch tensor to define the history-dependent variables.

Representative numerical examples are presented to discuss the validity of the proposed method. As the first step, a series of numerical material tests are carried out on a representative volume element model composed of multiple elastoplastic materials to generate a constitutive dataset. To demonstrate the material flame-indifference of the presented method, we confirm the response of the model subjected to the large deformation involving rotation. Then, RBF interpolation is performed to the obtained dataset to create a surrogate homogenization model. Next, a macroscopic finite element analysis is conducted using the obtained model. Finally, localization analysis is performed using the macroscopic deformation gradient history at a certain computation point of the macroscopic structure.

A DEM-BASED SURROGATE MODEL FOR POWDER MIXING

Hideya Nakamura[*1], Naoki Kishida[1], Shuji Ohsaki[1] and Satoru Watano[1]*

[1]Osaka Metropolitan University

ABSTRACT

In many industries, powder mixing is an important operation. Numerical simulations based on the discrete element method (DEM) have been widely used for the analysis of the powder mixing process. However, high computational cost is one of the current limitations of DEM simulation. Recently, approaches combining machine learning models and numerical simulations have attracted considerable attention. However, high-speed computing methods that consider individual particle motions for powder mixing have not been investigated. Here, we present an original DEM-based surrogate model employing machine learning, namely, a recurrent neural network with stochastically computed random motion (RNNSR), which enables long-time scale powder mixing simulation with low computational cost and high accuracy. The RNNSR is designed to learn individual particle dynamics with periodicity from short-term DEM simulation results and predict powder mixing for a longer period of time. The RNNSR combines a recurrent neural network and a stochastic model to predict both convective and diffusive mixing. The simulation results obtained using the RNNSR were quite similar to those obtained using the DEM in terms of the degree of powder mixing, particle velocity, and granular temperature. It was also demonstrated that the RNNSR has the capability of ultrafast computation in powder mixing simulations. In conclusion, we have demonstrated the effectiveness of the RNNSR for ultrafast computation of the powder mixing process.

DATA ASSIMILATION-INTEGRATED MULTI-PHASE-FIELD SIMULATION OF SOLIDIFICATION IN SUS316L STAINLESS STEEL IN ADDITIVE MANUFACTURING

Shoichiro Nakamura[*1], Masahiro Kawasaki[1], Masahito Segawa[1] and Akinori Yamanaka[1]*

[1]*Tokyo University of Agriculture and Technology*

ABSTRACT

Additive manufacturing (AM) is a powerful method to produce an industrial part with arbitrary shape and superior mechanical properties. In the AM process, extremely high cooling rates and thermal gradients cause formation of unique solidification microstructures. Since the unique solidification microstructures are formed very rapidly, it is challenging to observe their details experimentally[1]. Therefore, a numerical simulation is effective method to understand the mechanism of unique solidification microstructure formation in the AM process. The authors have recently developed the non-equilibrium multi-phase-field (NEMPF) model[2] coupled with the CALPHAD-based thermodynamic database to simulate the solidification behaviours in SUS316L stainless steel during the AM process. The NEMPF model describes the evolution of solidification microstructure and the partitioning of solute atoms at the solid-liquid interface in the non-equilibrium condition. However, the NEMPF model requires material parameters which are difficult to be identified and largely unknown. To solve the issue, Bayesian data assimilations (DA)[3] are effective because DA can estimate unknown material parameters and unobservable states through integration of simulation results and experimental data. In this study, we develop a new simulation methodology that couples the Bayesian DA with the NEMPF simulation of solidification in Fe-C-Cr-Mn-Mo-Ni alloys during the poder bed fusion (PBF) AM process. The numerical experiments called twin experiments are performed to validate the estimation accuracy of solidification state and material parameters obtained by the proposed method. The results of twin experiments show that the DA can accurately estimate the solidification state and material parameters (e.g., phase-field mobility) from only solidification microstructures. In order to obtain the accurate DA results, we reduce the computational cost of the NEMPF simulation by replacing the CALPHAD-based thermodynamic calculation with the machine learning method where the neural network estimates the Gibbs free energy and chemical potential from temperature and chemical composition at the solid-liquid interface region.

AN INCREMENTAL TWO-STEP SOLUTION METHOD FOR SOLVING NONLINEAR DYNAMIC PROBLEMS

Zihai Shi[1] and Masaaki Nakano[2]*

[1]Pioneering Science
[2]R&D Center, Nippon Koei Co., Ltd.

ABSTRACT

The two-step solution was originally proposed for analyzing the cracking behaviors of concrete dams during strong earthquakes. 1) This paper reports an incremental two-step solution method for solving general types of nonlinear dynamic problems 2) A dynamic response problem in association with a time-dependent energy input is defined by four functions: the target function, T(x,y,z); the excitation function, E(t); the force function of T(x,y,z), FT(x,y,z,t); and the deformation function of T(x,y,z), DT(x,y,z,t). A nonlinear dynamic problem is expressed as $T(x,y,z) \times E(t) = FT(x,y,z,t)|NL \times DT(x,y,z,t)|NL$ (1)

The two-step approach suggests obtaining the force function FT (x,y,z,t)|L first by a linear response analysis, then an approximate nonlinear deformation function D*T(x,y,z,t)|NL is derived based on FT(x,y,z,t)|L by a static nonlinear analysis. This transforms the time history analysis from dynamic analysis to static analysis.

However, for a general type of nonlinear dynamic problem, the effect of nonlinearity in the deformation function DT(x,y,z,t)|NL on its dynamic response may be evaluated by the two-step solution at each time increment Δt during numerical computations, as

$T(x,y,z) \times E(ti + \Delta t) = FT(x,y,z,ti+\Delta t)|L \times DT(x,y,z,ti+\Delta t)|L$ (2)

$T(x,y,z) \times E(ti + \Delta t) \approx FT(x,y,z,ti+\Delta t)|L \times D^*T(x,y,z,ti+\Delta t)|NL$ (3)

Based on the solution of Eq.(2), the approximate nonlinear deformation function D*T(x,y,z,ti+Δt)|NL can be derived.

Note that the newly obtained incremental nonlinear features should be updated to the target function and the dynamic results should also be adjusted accordingly for subsequent analyses. This paper will show the effectiveness of this new method in solving dam crack problems.

DEVELOPMENT OF A MIXED REALITY VISUALIZATION SYSTEM USING A LOCATION-BASED METHOD FOR THE UNDERWATER OBJECTS

Ryodai Nakaso[1], Kazuo Kashiyama[1] and Tsuyoshi Kotoura[2]*

[1]Chuo University
[2]Penta-Ocean Construction Co.

ABSTRACT

Recently, the use of visualization based on MR (Mixed Reality) have been increasing in the several stage of construction work, such as planning, design, construction, maintenance and management. MR is effective in terms of safety because both hands are free and this feature is extremely effective in field use. We have developed a MR visualization system for the underground structures using marker-based method [1]. Although this method allows for highly accurate superimposition, it is necessary to set the marker at the correct position. On the other hand, the location-based methods using GNSS (Global Navigation Satellite System) receivers have been attracting attention in recent years. This method is particularly effective for visualization in open-sky environments or when there are no reference points around the objects, such as at the sea.

This paper presents the development of a MR visualization system using a location-based method for underwater objects. To obtain location information, GNSS receivers are used, which can obtain highly accurate location information by network RTK positioning at open-sky environment. The Microsoft HoloLens 2 is employed for the MR device. The system is capable of superimposed 3D models into real space accurately and automatically. The present system is applied to the visualization of underwater objects and flow simulation results in order to check the validity and effectiveness.

ABSTRACT

Topology optimization is a mathematical method that optimizes material distribution within a prescribed design space to maximize a desired performance while satisfying given constraints. For more practical applications, topology optimization methods that incorporate multiple materials have been developed. While solution frameworks based on density methods or level set methods that solve problems implicitly have been used for multi-material topology optimization conventionally, Zhang et al. established an approach for explicit multi-material topology optimization based on moving morphable components (MMC) method [1]. In MMC solution framework, a set of morphable components are used as building blocks to represent the structural topology explicitly. The optimal structure is obtained by optimizing the geometry parameters of these components such as widths, lengths, inclined angles, and locations. The advantage of this method is that the direct relationship between optimized structures and computer aided design (CAD) systems can be formed unlike the implicit way. However, in the MMC based method, there is an issue that fixed and input boundaries in the design domain are not connected by solid materials during the optimization process, which has a negative effect on its stability. To solve the disconnection issue, Zhu et al. proposed a single-material MMC based method that use moving wide Bezier components with constrained ends [2]. In this method, control points and widths of the Bezier curves are optimized, and their ends are constrained based on the boundary conditions.

Here, we propose a multi-material explicit topology optimization using moving wide spline curves with constrained ends. The key concept of this method is M kinds of level set functions are constructed explicitly by using a set of wide spline curves. These level set functions are used to represent M material domains and void domain without overlap. To maintain connectivity during optimization, the ends of certain wide spline curves are constrained according to prescribed boundary conditions. In addition, minimum length scale control can be easily achieved without imposing additional constraints by setting the lower bound of widths of spline curves. We show our proposed method’s validity via numerical examples from several optimization problems.

ANTHROPOPHOBIC TENDENCY AND SUBJECTIVE WELL-BEING

Hinata Nanya[*1] and Chieko Kato*[1]

[1]*Toyo University*

ABSTRACT

Research suggests that Anthropophobic Tendency tends to increase over time. Another research revealed a negative correlation between well-being and perceived stress. And stress studies have shown that interpersonal relationships are stressors for the mental health of children and students. These findings suggest that the impact of interpersonal stress is an important issue in educational situations. We hypothesised that coping with stress would improve mental health and well-being. Therefore, the hypothesis of this study was that good coping with interpersonal stress would reduce anthropophobic tendency. The scales used were the Anthropophobic Tendency Scale (ATS), the Subjective Well-Being Scale (SWBS), and the Interpersonal Stress-Coping Inventory (ISI)'. ATS to see what kind of worries interpersonal phobia you have, SWBS to see what kind of cognitive and emotional aspects of subjective well-being you have, ISI to see what kind of positive attitude you have towards the stressful event, self-reflection and positive relationship coping. This involves taking positive actions to establish, improve and maintain positive relationships, including taking care of the other person who caused the stress, not getting involved with the other person, not talking to them, etc., and negative relationship coping, which is coping in which the person actively abandons or does not talk to the other person. Positive relationship coping, which is coping in which the person acts to establish, improve and maintain positive relationships, including being considerate of the other person, and negative relationship coping, which is coping in which the person actively abandons or disrupts the relationship, including not engaging with and not talking to the other person. The selection was made to see which of the following types of coping were more common. Postponing resolution coping is where the stressful events caused by the relationship are downplayed and avoided as a problem, such as not caring or thinking they can manage the problem by themselves. The results of an analysis of covariance using the data from those responses showed that positive relational coping had a positive effect on subjective well-being, and that subjective well-being had a negative effect on the anthropophobic tendency of the group. In this study, the relationship between subjective well-being, interpersonal stress coping and anthropophobic tendency was examined and it was found that learning positive relational coping in an educational setting and increases well-being and reduces anthropophobic tendency.

EFFICIENT DERIVATIVE-FREE OPTIMIZATION OF STRUCTURES OPERATING IN COUPLED FLUID-SOLID ENVIRONMENTS

Aditya Narkhede[*1], Noah Eilers[1], Kevin Wang[1] and Xingsheng Sun[2]*

[1]*Virginia Tech*
[2]*University of Kentucky*

ABSTRACT

The bottleneck for optimizing mechanical structures operating in a fluid-solid coupled environment is often the fluid subsystem, due partly to the extensive degrees of freedom required to delineate the system. The objective however is to define the structure's geometry, material, or topology to maximize performance based on specified constraints. Coupling between fluid and solid subsystems relies on communicating the state variables at the domain intersection. Hence, substituting a surrogate fluid model that preserves the crucial flow feature – such as the interaction of shock waves with the structure – like, linear regression, Reduced Order Method, Neural Networks, etc., for a full-order fluid dynamics model to predict the interface state variables would provide a significant speed-up. This surrogate model could be trained in an offline-online framework where the database is created by sampling the design space uniformly, randomly, or in a greedy manner. However, this adds an expensive overhead to the optimization process.

We leverage these facts along with the data-based nature of derivative-free methods like Genetic Algorithm, Particle-Swarm, etc., to train an adaptive machine learning model on the fly and reduce computational costs. The database is dynamically created during optimization by storing the state variables such as pressure and displacement, at the material interface in a tree-type data structure and labeling these as ground truth. A simple mesh-free radial basis interpolation approach is adopted to predict the interface pressure showcasing the effectiveness of the proposed framework. During design iterations, an active learning-based classification model adaptively identifies new design points that can be evaluated using interpolated fluid pressure instead of pressure computed by the fluid dynamics solver. This model is chosen as it offers accurate predictions using limited training instances through interactive queries in regions of uncertainty. The proposed framework is versatile and applicable to any coupled problem involving an interface boundary condition.

To demonstrate this nested analysis and design framework, we investigate the weight reduction of blast mitigation chambers through geometry and wall-thickness optimization. The shock-dominated multi-phase FSI problem is simulated using the open-source finite element solver, AERO-S, and finite volume solver, M2C. Details of simulating strong shocks and their interaction with lightweight chambers capable of undergoing large plastic deformations will be discussed, along with optimization results.

A COMPREHENSIVE BENCHMARK FOR MYOCARDIAL MECHANICS

Anastasia Nasopoulou[*1] and Pablo Lamata*[1]

[1]*King's College London*

ABSTRACT

Introduction
As cardiac biomechanical models are reaching maturity, and in anticipation of their wide use bedside, novel computational methods are being developed to increase model fidelity or computational efficiency. This process requires the validation of these methods and the comparison of their accuracy to established techniques. However, the lack of a real “ground truth” presents a problem and colleagues often revert to, either employing oversimplistic analytical paradigms, or, to computational phantoms where the effects of the computational methods choices employed in the phantom and the inherent numerical errors, may confound results. To address these needs, in this contribution, we present a series of analytically derived data sets for benchmarking myocardial mechanics and motion tracking.

Materials and Methods
We generated in silico datasets based on two axisymmetric geometries, traditionally used to model cardiac mechanics: a thick walled cylinder and a thick walled sphere. These reference geometries are subjected to a series of volume preserving, homogeneous deformations: (i). passive inflation, (ii). stretch and (iii). torsion, assuming quasistatic conditions. Adopting an incompressible, hyperelastic material description, we provide solutions for popular material models used in cardiac mechanics. The analytical solutions are implemented in MATLAB R2021b (MathWorks, Natick, MA, USA).

Results
We developed a benchmarking data set that can accommodate different needs raised by the community. The user is requested to select the reference geometry of the data set, the material description and deformation, and our code provides the continuous kinematics & dynamics, the corresponding boundary conditions, as well as estimates of work and energy. An additional functionality can provide meshes of the reference and deformed geometries with user specified resolution and interpolation schemes. Alternatively user specified meshes can be used as input.

Discussion and Conclusions
Through this work we make publicly available a benchmark for cardiac biomechanics based on analytical solutions of baseline problems in nonlinear mechanics. The resulting data set allows the user to test their methods against benchmarks of increasing geometrical and deformational complexity, which should aid them to locate the problematic areas in their code in a systematic manner. This data set, despite its simplicity, represents the primary modes of deformation in myocardial mechanics (inflation, torsion) – a significant improvement from previously used analytical benchmarks used in the community.

Theory and application of provably-robust and efficient high-order methods for high-fidelity computational fluid dynamics

PROVABLY-STABLE PARTITIONED ALGORITHM FOR CHT PROBLEMS

Sarah Nataj[1], David Del Rey Fernandez[1] and David Brown[2]*

[1]*University of Waterloo*
[2]*Ansys Inc.*

ABSTRACT

In this work, we design and analyze a novel provably-stable partitioned algorithm for the conjugate heat transfer (CHT) problem. In the monolithic approach, a single numerical solver is developed to solve for all unknowns simultaneously. In contrast, a partitioned approach applies two separate solvers in each of the sub-domains, which are sequentially solved. Monolithic solvers are computationally efficient and robust but need to be designed for each new multi-physics problem, while partitioned schemes can take advantage of existing solvers. On the other hand, many partitioned schemes may encounter stability issues. As a model, we consider a CHT problem consisting of linear advection–diffusion and heat equations coupled at an interface and design a partitioned SBP-SAT scheme in each subdomain. In the proposed approach, the separate SBP-SAT schemes for each sub-problem are explicitly and weakly coupled at the interface. We proved that the resulting fully discrete scheme is conditionally stable dependent on specific range of SAT parameters.

WORKING TOWARDS A MODULAR, FULLY-COUPLED PHASE FIELD FRACTURE MODEL INTEGRATING ELASTICITY, PLASTICITY, AND DAMAGE

Chiraag Nataraj[*1] and Andrew Stershic*[1]

[1]*Sandia National Laboratories*

ABSTRACT

Many phase field fracture models that have been implemented to date are opinionated regarding the choice of elastic model, plastic model, damage model, etc. While this enables easier development of the formulation itself, the resulting model is inflexible and often only applies to a subset of problems of interest. Further, if a change in model is desired, it may be required to redo much of the derivation and implementation. This work aims to develop and implement a generalized, variational, fully-coupled, and modular phase field fracture formulation capable of handling a diverse range of problems. The choices of elastic model, plastic model, damage model, rate-(in)dependence, degradation functions, and tension-compression split are all modularized with well-developed interfaces, enabling the development of solver infrastructure independent from the particular choices of models. While this approach brings its own challenges, it also enables classes of models which were previously tedious to implement, thus allowing the exploration of more complex problems.

In this presentation, we detail this modular approach from analytical derivations through to implementation in SIERRA, a robust multi-physical finite element code developed at Sandia National Laboratories. The approach will be demonstrated for several canonical model forms, including elastic and elastic-plastic fracture mechanics.

Sandia National Laboratories is a multi-mission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy’s National Nuclear Security Administration under contract DE-NA0003525.

HIGH-ORDER IMPLICIT SHOCK TRACKING FOR TIME-DEPENDENT FLOWS

Charles Naudet[*1] and Matthew Zahr*[1]

[1]*University of Notre Dame*

ABSTRACT

Shock tracking aims to generate a mesh such that element faces align with shock surfaces and other non-smooth features to perfectly represent them with the inter- element jumps in the solution basis, e.g., in the context of a finite volume or discontinuous Galerkin (DG) discretization. These methods lead to high-order approximations of high-speed flows and do not require nonlinear stabilization or exten- sive refinement in non-smooth regions because, once the non-smooth features are tracked by the mesh, the high-order solution basis approximates the remaining smooth features. High-Order Implicit Shock Tracking (HOIST) recasts the geometrically complex problem of generating a mesh that conforms to all discontinuity surfaces as a PDE-constrained optimization problem. The optimization problem seeks to determine the flow solution and nodal coordinates of the mesh that simultaneously minimize an error-based indicator function and satisfy the discrete flow equations. A DG discretization of the governing equations is used as the PDE constraint to equip the discretization with desirable properties: conser-vation, stability, and high-order accuracy. By using high-order elements, curved meshes are obtained that track curved shock surfaces to high-order accuracy. The optimization problem is solved using a sequential quadratic programming method that simultaneously converges the mesh and DG solution, which is critical to avoid nonlinear stability issues that would come from computing a DG solution on an unconverged (non-aligned) mesh [1] .
In this work, the HOIST method is further extended to simulate time-dependent, inviscid flows for higher dimensions. We use a space-time formulation of the governing equations and perform shock tracking over a space-time slab [2]. In the two-dimensional space and time setting we generate a three- dimensional mesh by extruding a spatial mesh of quadrilateral elements into hexahedral elements. We also introduce robustness measures for hexahedral element collapses, as well as a method to leverage information from previous time-slabs to improve the initial guess for our mesh on the current slab.

ABSTRACT

Although viruses may seem to be infinitesimal biological entities, harmless for the future of the human species, SARS-CoV2 has put the whole of humanity in check, causing millions of deaths. In such a situation, it is worth considering the possibility of developing new methods for disabling or deactivating the viral structures.

In the field of structural engineering, vibration frequencies are determined so that structures such as bridges do not collapse. But the opposite approach could also be considered, i.e.: calculating the vibration frequency for which a structure such as a virus could collapse by resonance. If the natural vibration frequencies of a molecular structure were known, a device could be constructed that would cause the virus enter into resonance until its collapse, as if it were the old Tacoma Narrows bridge.

In the framework of the VirionBreak project, developed by the GMNI with funding from the Instituto de Salud Carlos III (ISCIII), a formulation was proposed that allows the definition of the mass and stiffness matrices in a structure with intramolecular bonds, which is the first step in the calculation of the vibration frequencies of the structure [1]. The proposed formulation allows the analysis of any three-dimensional structure with the characteristic bonds that are considered in the molecular dynamics field, i.e., stretch, angular and dihedral type bonds, including their possible degenerate configurations [2].

The formulation has been applied to a series of molecules, comparing the results obtained with theoretical and experimental values from different sources, obtaining a good fit in all the cases analyzed [3]. The formulation can also be applied to the calculation of vibrational frequencies of arbitrarily large complex structures, such as viruses, where the intramolecular bonds considered are the causes of structural integrity.

The strategies for solving these particular type of computational dynamics problems are discussed.

STABILIZATION STRATEGIES FOR THE 3D CARTESIAN GRID DISCONTINUOUS GALERKIN METHOD (CGDG)

Héctor Navarro-García[1], Ruben Sevilla[2], José Manuel Navarro-Jiménez[1], Enrique Nadal[1] and Juan José Ródenas[1]*

[1]Universitat Politecnica de Valencia
[2]Swansea University

ABSTRACT

Simulating the propagation of waves through a complex domain involves significant computational challenges. High order finite element methods have proven to be one of the best simulation alternatives, capable of providing accurate and efficient solutions. However, robust techniques for automatically generating the curved meshes required for these analyses still remain challenging.

The Cartesian grid discontinuous Galerkin finite element method (cgDG) [1] represents an advancement in this regard. The method's main features include the use of high order discretizations within Cartesian meshes independent of the geometry, together with the formulation of the weak form of the problem following the discontinuous Galerkin (DG) approach. As a result, the meshing process becomes trivial, computation times can be significantly reduced, and the solution approximation retains the properties of conventional high-degree methods. The strategy was introduced for the 2D case in [1] and applied with great success to solving problems related to electromagnetic scattering.

This work presents the extension of cgDG to the 3D context. Generalizing the method requires refining the strategies developed for the 2D case, such as element overlap and domain reassignment. The method is implemented to solve the Maxwell equations in the temporal domain, and its performance is evaluated in a series of reference problems.

ABSTRACT

The choice of implant material at the fracture site has an influence on the fracture healing not only from the biological perspective but also from the mechanical perspective. Biodegradable implants such as magnesium (Mg) and zinc (Zn) have shown to fasten the secondary bone healing process as compared to that of bioinert implants such as titanium (Ti). In general, this benefit of Mg was seen mostly only from biocompatibility perspectives. However, the advantage of Mg is also there in terms of mechanical perspectives.

We studied the effect of Ti and Mg as base materials for implants from mechanical perspectives in the initial phase of bone healing. The focus was on the displacements at the fracture site of the tibia and their influence on the stimulus for bone healing. Claes tissue differentiation theory was used to evaluate the conditions for secondary healing at the callus. In addition, the stress distribution in the implant determined in order to quantify the change in the stress shielding conditions. In comparison, Mg implants have minimal stress shielding problem than Ti, which led to better mechanical stimulus at the fracture site. The conditions for secondary bone healing were better when Mg implants were used. The study illustrates the benefits of Mg for osteological implants from mechanical perspectives and the potential to replace Ti for fracture treatment in the future.

Constitutive modeling of complex materials with machine learning and artificial intelligence

DIFFERENTIABLE FEM FOR NEURAL CONSTITUTIVE MODELING OF COMPLEX MATERIALS

Hanfeng Zhang[1], *Priyambada Nayak**[1], *Tengfei Luo*[1] *and Jianxun Wang*[1]

[1]*University of Notre Dame*

ABSTRACT

Understanding and predicting the constitutive behavior of materials with complex microstructures pose significant challenges in materials science, primarily due to the resultant nonlinear macroscopic properties, which are further complicated by mechanisms like viscoelasticity, plasticity, and damage at the sub-scale level. Traditional constitutive models, evolving since their inception in the early 19th century, have gradually incorporated complex physics but often fail to address the intricate interplay of microstructural behaviors effectively. The application of machine learning, specifically neural networks, for constitutive modeling has emerged as a promising avenue in the past decade. These approaches offer a paradigm shift from conventional physics-based and phenomenological models, providing a novel perspective for learning complex material behavior from data. However, existing neural network-based models are critically dependent on the availability of extensive, high-quality datasets of direct measurements, largely limiting their practical applicability. Furthermore, the integration of neural networks with traditional numerical solver, especially for indirect data management, presents the technical challenge of propagating essential intermediate gradients for a holistic optimization. Physics-informed learning approaches, e.g., PINN, while addressing some of these limitations, are constrained by their training and convergence challenges in many complex scenarios. In response to these challenges, this study introduced a novel neural differentiable modeling framework that seamlessly integrating deep neural network with differentiable FEM solver to effectively learn and discover the constitutive laws of complex materials from indirect data, offering a robust and scalable solution to the longstanding challenges of modeling complex material behaviors.

A QUALITY BY DIGITAL DESIGN (QBD2) FRAMEWORK FOR THE DEVELOPMENT OF INTENSIFIED CRYSTALLIZATION SYSTEMS

Monika Neal[*1], Tesia Janicki[2], Zoltan Nagy[1] and Rekha Rao[2]*

[1]Purdue University
[2]Sandia National Laboratories

ABSTRACT

Crystallization is an important unit operation in solid products manufacturing as it acts as not only a purification step but also a process control step for influencing crystals critical quality attributes (CQAs) such as crystal size, shape, and polymorphic form1. Efficient crystallization is prioritized for intensified manufacturing processes with high impact in the manufacturing of solid products for various industries, including energetic, pharmaceutical, food and fine chemicals. The integration of digital twins and digital design frameworks enhances and streamlines this process by providing a virtual representation of the crystallization process, allowing for detailed simulation and optimization across the design space. Resveratrol, a dietary supplement chosen as a model material for energetic substances, shares a similar chemical makeup to some traditional energetic materials and offers a safer alternative. A modular autonomous crystallization system (MACS) with a model-free Quality-by-Control (mfQbC) approach minimizes required experiments while utilizing feedback control to enhance the understanding of the system2. An automated design of experiments (DoE) through an in-house LabVIEW platform called Omnibus streamlines data collection. This DoE involved 6 heating-holding-cooling experiments with various cooling rates and seeding amounts to gain insights on crystallization mechanisms, such as primary nucleation, secondary nucleation, the metastable zone width tendencies, and nucleation rate. Direct nucleation control (DNC) and supersaturation control (SSC) experiments were applied to further improve the understanding of attainable regions and design space for the system and to generate data for model identication.1 Process analytical technology (PAT) tools collect in-situ data that can be translated into crystal size, concentration, and polymorphic form. Based on this information a process model was developed to include the mechanisms occurring, allowing for parameter estimation to then develop a digital twin using two-dimensional population balance modeling (PBM). This digital twin facilitates in silico investigation of the design space as well as the digital design of the crystallization process to achieve the desired CQAs. The results illustrate a systematic quality-by-digital-design (QbD2) framework for the understanding and development of optimized crystallization processes.

PRATT TRUSS CHARACTERISTICS FOR OPTIMAL WEIGHT

Arturs Neiburgs[1]*

[1]*Latvia University of Life Sciences and Technologies (LBTU)*

ABSTRACT

In recent years, two main trends can be observed in the research on topology optimizations. One is focused on optimization results, intended for additive manufacturing, while the other is oriented towards traditional construction production. Optimizations fitted for additive manufacturing holds great potential for the future and is approved topic among researchers. Optimization solutions contributing to traditional construction production, can provide immediate benefits for the industry. Pratt truss can be considered as specific subset from the ground structure domain. There can be found more efficient truss topologies than Pratt truss, but it is widely used and suitable for traditional production.

This study focuses on finding correlation between various Pratt truss characteristics and the truss weight. Aim is to define truss geometry based on certain parameters, that would give its weight close to optimal or optimal. Several parameters are set to analyze truss behavior within established model. Some of the characteristics are based on geometry, others are based on the principles of Force Density Method. Correlation is explored by using the advantages of parametric design and machine learning. The resulting data are obtained by calculating significant number of trusses using parametric model and Finite Element Method. Steel trusses with span $L \in \{12\ m \leq x \leq 25\ m\}$ and height $H \in \{1\ m \leq y \leq 3.55\ m\}$ are studied. For each truss case constant roof load is applied and two types of supports selected. To explore member profile impact on characteristics, they were defined as continuous and discrete variables. The obtained data are processed and analyzed using machine learning algorithms and by visually observing generated graphs and animated calculation process.

Data analysis revealed non-linear correlations between the selected parameters and truss weight. Approach for the profile choice affects correlation and the possibility of predicting the weight of the truss. Better understanding of the truss topology can reduce the time needed to obtain optimal solutions. Dataset displayed some outcomes that did not fit within the rest, revealing different behavior of the specific trusses compared to other. These distinct cases are planned to be studied in more detail in the future research.

MODELLING COUPLED SURFACE-BULK VISCOUS FLOWS IN ANIMAL CELLS WITH UNFITTED FINITE ELEMENTS

Eric Neiva[*1] and Hervé Turlier*[1]

[1]*Centre interdisciplinaire de recherche en biologie - CNRS UMR7241 - Collège de France*

ABSTRACT

The shape of animal cells is governed by the surface mechanics of its actomyosin cortex: a network of cross-linked polymer filaments stirred by active motors and lying beneath the plasma membrane [1]. In large animal cells, cortical actomyosin flows can drag cytoplasmic flows in the cell bulk, and vice versa [2]. These surface-bulk hydrodynamic couplings serve a myriad of biological functions, such as contributing to the establishment of PAR-polarity in the C. Elegans zygote, the even distribution of syncytial nuclei in Drosophila embryos or the asymmetric positioning of the spindle in mouse oocytes. However, they have been so far little investigated, due to a lack of appropriate numerical tools.

In this talk, we will describe our efforts to shed light onto this matter with mathematical modelling and numerical simulations with unfitted Finite Element (FE) methods [3]. Together with biophysical measurements, they can test current hypotheses, formulated by biologists and physicists, on the mechanisms ruling interactions between the cortex and the cytoplasm. The mathematical model considers the dynamics of surface-bulk viscous flows on general and smooth closed surfaces with an active term on the surface, representing active tensions generated by the activity of myosin motors. For the numerical discretization, we have considered a first-of-its-kind approach, coupling trace FE formulations for the surface physics with aggregated FE formulations for the bulk physics. We will provide details on our coupled formulation and its numerical behaviour, performance aspects of the computer implementation, and some numerical examples, including qualitative experimental validation.

TOPOLOGY OPTIMIZATION FOR FIBER ORIENTATION IN FRACTURED CONCRETE

Andre Luis Ferreira da Silva[1], Luís A. G. Bitencourt Jr.[1] and Emilio Carlos Nelli Silva[1]*

[1]Universidade de São Paulo

ABSTRACT

Concrete is widely used in civil engineering due to its compression strength. However, it is prone to cracking under tension, necessitating reinforcements to mitigate this vulnerability. The addition of fibers in the concrete has been used to improve the concrete resistance under tension solicitation after cracking occurrence. However, the orientation of these fibers plays a crucial role in the structure's mechanical behavior, making it possible to reduce the amount of fibers used to reinforce the concrete. The optimized fiber orientations are addressed in this work using the Topology Optimization.

The concrete behavior is simulated using a Continuum Damage Mechanics Theory (CDMT)-based model with a rate-independent formulation, distinguishing between tensile and compressive responses.

The methodology integrates an implicit-explicit integration scheme to improve computational efficiency. By focusing on the fracture mechanics model, we seek to minimize structure compliance, indirectly extending the lifespan of the reinforced concrete. We present the methodology, results, and conclusions, highlighting contributions to the field of concrete reinforced with fibers.

INCORPORATION AND EVALUATION OF PARAMETRIC WIND AND RAINFALL MODELS FOR COMPOUND FLOODING IN A DISCONTINUOUS GALERKIN STORM SURGE FRAMEWORK

Suranjan Nepal[*1], Ethan Kubatko[1] and Aaron Sines[1]*

[1]*The Ohio State University*

ABSTRACT

Accurate meteorological data, encompassing wind, pressure, and rainfall, are crucial inputs to hurricane-related storm surge forecasts and hindcasts. These meteorological fields can be generated using simple parametric storm models, which are functions of a small number of key storm parameters like storm track, maximum winds, and radius of maximum winds. While the National Hurricane Center's advisory (for forecasts) and best-track (for hindcasts) data are routinely used to inform parametric wind and pressure fields in storm surge models, the inclusion of rainfall is typically omitted, resulting in an incomplete flood assessment during hurricanes, which are often accompanied by extreme precipitation. We aim to address these gaps in storm surge modeling through incorporation of a parametric rainfall model (known as R-CLIPER), enabling accurate and efficient modeling of the meteorological drivers of compound flooding events. In this talk, I will discuss our efforts to improve simulations of compound flooding events due to both surge and rainfall through incorporation of the parametric rainfall model into a discontinuous Galerkin shallow water equation model (DG-SWEM). Evaluations of multiple enhanced storm surge simulations for hurricanes with varying intensities of accompanying rainfall will be presented.

A MULTI-QUERY MODEL REDUCTION FRAMEWORK FOR NONLINEAR DYNAMICS SIMULATIONS WITH MULTIPLE NON-PARAMETRISED LOADING CONFIGURATIONS

Alexandre Daby-Seesaram[1], Amélie Fau[1], Pierre-Etienne Charbonnel[2] and David Néron[*1]*

[1]ENS Paris-Saclay
[2]CEA

ABSTRACT

Predicting the service life and assessing hazards for a complex structure under various loadings poses a recurrent challenge, particularly pronounced when evaluating the risk of structural failure due to seismic hazards, which often entails numerous computationally intensive simulations. For example, when constructing fragility curves, the nonlinear damageable behavior of structures needs careful consideration, necessitating dynamic response computations for a broad spectrum of potential ground motion inputs.

In such scenarios, model reduction techniques emerge as powerful strategies, leveraging computational similarity to expedite the sequence of calculations. The LATIN-PGD method proves instrumental in efficiently handling the nonlinear aspects of the problem. Simultaneously, the efficient management of parametric problems is achieved by constructing a reduced-order basis applicable across all scenarios.

This research extends the application of the LATIN-PGD method to dynamic problems and introduces an innovative approach for efficiently addressing cases where loadings cannot be easily parameterized. To address this, a space-frequency PGD is introduced for solving the dynamics aspect of the history-dependent nonlinear problem, thereby combining the effectiveness of model-order reduction with the numerical advantages of frequency computations. Additionally, a novel approach is introduced to handle multi-query aspects, enabling a highly efficient linkage of computations. The resulting computational cost is significantly reduced compared to the cumulative expense of independently executing various scenarios.

CONSERVATION PROPERTIES OF EMBEDDED FINITE-ELEMENT METHODS FOR FLOW IN FRACTURED POROUS MEDIA

Maria Giuseppina Chiara Nestola[*1], Patrick Zulian[1], Marco Favino[1] and Rolf Krause[1]*

[1]*Università della Svizzera italiana*

ABSTRACT

Numerical simulations of Darcy flow in fractured porous media rely on hybrid- or equidimensional fracture models. The former considers fractures as lower-dimensional manifolds, while the latter treats them as objects of the same geometrical dimension as the porous matrix. Embedded strategies are widely used simulation approaches that remove the inherent difficulties in mesh generation for fractured media, as they employ two different and possibly non-conforming meshes.

Among all possible embedded approaches, we focus on strategies that rely on the Lagrange multiplier method and are discretized within a Continuous Galerkin (CG) finite-element framework [1]. From a theoretical perspective, we analyze the conservation properties [2] of embedded discretizations based on non-conforming meshes. Following that, we present a computational analysis for both hybrid and equidimensional models of fractures, considering established benchmarks for flow in porous fractured media.

The numerical results confirm that embedded discretizations are conservative on subdomains consisting of unions of elements.

URBAN MULTI-PHYSICS CFD MODEL TO ACCESS THE COOLING POTENTIAL OF TREES IN A TYPICAL NORTH AMERICA NEIGHBORHOOD

Clément Nevers[1], Aytaç Kubilay[2], Jan Carmeliet[2] and Dominique Derome[1]*

[1]*Université de Sherbrooke*
[2]*ETH Zurich*

ABSTRACT

In a world strongly affected by climate change, understanding complex urban climate phenomena by explicit Computational Fluid Dynamics (CFD) modeling stands out as a crucial pursuit. Since cities are heating up, research studies need to address appropriate heat-mitigation solutions to enhance thermal comfort relying on comprehensive analysis of urban environment. Among other mitigation measures, trees can reduce the ambient heat by providing shading and transpirative cooling. However, trees also come with potential negative effects such as ventilation reduction by impeding incoming wind, the increase of relative humidity due to the moisture release by leaves, or the sky view factor reduction, ultimately reducing thermal comfort.

This complexity warrants CFD studies to understand the cross-effects of trees towards an optimal balance. This study assesses the overall contribution of urban trees on pedestrian comfort according to different vegetation scenarios. To explore the urban complexity, the study uses a homemade CFD-based coupled solver developed by authors called urbanMicroclimateFoam, based on OpenFOAM. This urban microclimate model solves successively fluid motion with realizable k-ε RANS, heat and moisture (HAM) transport in porous media, and radiative exchanges including multiple diffuse reflections, in three distinct sub-domains with their respective meshes. Regarding temporal coupling, for each steady RANS time step performed, transient HAM simulations are conducted with adaptive timesteps using Picard iterative scheme.

Downscaling from results obtained through mesoscale meteorological model WRF, time-varying boundaries conditions are established. To reduce gravity wave reflection, blending layers are imposed on lateral boundaries where velocity and temperature are relaxed.

The study relies on a model of a typical neighborhood in Montreal representing six lots for a total study zone of 250m x 300m. One major challenge is managing a wide urban model with different sub-meshes while maintaining acceptable precision and computational cost.
