Universal Thermal Climate Index (UTCI) combining air temperature, mean radiant temperature, velocity and relative humidity at a given position documents outdoor thermal comfort. Analysis demonstrates that trees in ventilation corridors, aligned with the primary wind, reduce the mean pedestrian comfort by wind blocking despite the shade generated. On the other hand, trees in private gardens, or in crosswind corridors, can enhance both the local thermal comfort and the overall mean pedestrian comfort over the entire neighborhood, thereby improving overall walkability. As a final aim and based on those findings, the

present study will propose an ideal vegetation configuration maximizing cooling potential and pedestrian comfort.

TRANSPORT OF MICROCAPSULE IN FRACTURED MEDIA USING COUPLED CFD-DEM METHODS

Pania Newell[*1] and Xiaoming Zhang*[1]

[1]*The University of Utah*

ABSTRACT

Geothermal energy presents a promising solution to address our energy crises and environmental concerns. However, challenges such as production temperature, flow rate, and thermal breakthrough time impact its efficiency. In this presentation, we propose an innovative solution involving the injection of polymer-based microcapsules into fractures to modify permeability and prevent preferential flow, ultimately mitigating thermal breakthrough. Utilizing coupled computational fluid dynamics and discrete element method (CFD-DEM), we investigated scenarios considering microcapsule size, concentration, and fracture roughness. Our findings reveal that in smooth fractures, small microcapsules easily traverse, while larger ones do so at lower concentrations, and a mixture of sizes tends to seal the fracture. In rough fractures, microcapsule transport complexity increases due to interactions with rough walls. The results suggest that complex fracture surfaces enhance sealing behavior, and this effect could be alleviated using smaller and lower concentrations of microcapsules.

DISCONTINUOUS GALERKIN METHODS FOR HYPERSONIC FLOWS

Ngoc-Cuong Nguyen[1], R. Loek Van Heyningen[1], Dominique Hoskin[1], Jordi Vila-Perez[1], Wesley Harris[1] and Jaime Peraire[1]*

[1]*Massachusetts Institute of Technology*

ABSTRACT

In recent years, high-order discontinuous Galerkin (DG) methods have emerged as an attractive approach for numerical simulations of compressible flows. We present an overview of the recent development of DG methods for compressible flows with particular focus on hypersononic flows. We describe various shock capturing methods to deal with strong shock waves in hypersonic flows. We discuss r-adaptivity techniques to refine meshes for hypersonic boundary layers. We present a few examples to demonstrate the ability of high-order DG methods to provide accurate solutions of hypersonic laminar flows. Furthermore, we present direct numerical simulations of hypersonic transitional flow past a flared cone at Reynolds number 10.8×10^6, and hypersonic transitional shock wave boundary layer interaction flow over a flat plate at Reynolds number 3.97×10^6. These simulations run entirely on hundreds of graphics processing units (GPUs) and demonstrate the ability of DG methods to directly resolve hypersonic transitional flows, even at high Reynolds numbers, without relying on transition or turbulence models.

THE ROLE OF SURFACE DEFECTS IN DYNAMIC DUCTILE FAILURE: AN EXPERIMENT AND NUMERICAL STUDY

Thao Nguyen[*1], Saryu Jindal Fensin[1] and Darby Luscher[1]*

[1]*Los Alamos National Laboratory*

ABSTRACT

In this work, we study the role of surface defects on ductile damage evolution during dynamic loading process on polycrystalline copper. The surface defects of different shapes and locations were manufactured on the surface of the target specimens subjected to impact experiment. The velocity history of each experiment was recorded for diagnostic purposes. In addition, the target specimens were sectioned after the experiments for microstructure analysis. The resulting velocity signals and the microstructures (of the loaded specimen) shows a strong effect of the defect shape and location. The experiments were modeled with a calibrated set of a viscoplasticity model of Preston-Tonks-Wallace (PTW) and ductile damage model (Tepla). The simulations successfully capture the trend of surface defect dependence on both the velocity signal and the resulting microstructure. Examination of the evolving stress field within the target material under loading reveals the mechanism behind this surface defect dependence.

Industrial applications of IGA

ISOGEOMETRIC ANALYSIS AND THE DIGITAL TWIN

Clint Nicely[*1] and Stuart Taylor*[1]

[1]*Raytheon*

ABSTRACT

The Digital Twin represents a new digital frontier in industry, theorized to improve quality, improve efficiency in the product lifecycle, and open up new avenues for revenue and customer satisfaction. Product Digital Twins represent a particular product or assembly which is identified as the single source of truth however the design process of today currently does not align with the vision of utilizing that single source of truth. In many approaches to analysis of design, derivatives of the product design are produced to understand the impact of environmental requirements. This approach, with disparate or disconnected geometric derivatives, does not create a path towards the realization of the vision of the Digital Twin. Isogeometric Analysis is in a unique position to allow a direct connection to the singular ‘source of truth’ during the analysis process. It can be shown that IGA satisfies the Digital Twin’s direct connection to CAD or representative physical geometry. In addition, IGA has shown promise as the solution method for future designs that would include complex geometries produced by optimization methods and generative design. Also, a discussion on other technologies that are required to further enable the vision of the Digital Twin as it relates to mechanical simulation.

CAUSAL SPATIAL STENCIL LEARNING: CAUSAL DYNAMICS IN COMPLEX SPACE-TIME SYSTEMS

Jake Nichol[*1,2] and Michael Weylandt*[3]

[1]*Sandia National Laboratories*
[2]*University of New Mexico*
[3]*Baruch College*

ABSTRACT

Discovering causal relationships is one of the foremost endeavors in science. With an ever increasing need to address anthropogenic climate change, understanding the etiologies of our climate's systems is essential. However, climate datasets are typically extremely high-dimensional, consisting of hundreds of variables measured across thousands of grid locations, which poses extreme difficulties for existing causal discovery algorithms. To escape this high dimensional regime, prior applications of causal discovery algorithms in climate science typically perform extreme spatial dimension reduction; this spatial dimension reduction, however, impairs the interpretability of the discovered relationships, and is particularly problematic when studying transient phenomena with rapidly changing spatial structure, such as volcanic eruption plumes. To address these issues, we present Causal Spatiotemporal Stencil Learning (CaStLe), a novel algorithm for discovering local dynamics in spatiotemporal systems. By projecting individual grid cells to a relative coordinate structure, CaStLe leverages implicit spatial replicates to identify uniform local dynamics, thereby eliminating the high dimensionality and reducing the sample complexity of the causal discovery task. We demonstrate the advantages of CaStLe through a comprehensive simulation study and application to a large-scale Earth system model. CaStLe achieves state-of-the-art results for discovering causal spatiotemporal dynamics and enables characterization of a wider range of climate dynamics.

3D MULTI-PHYSICS SIMULATION OF HIGH TEMPERATURE INDUCED THERMO-HYGRAL FRACTURE OF CONCRETE

Elia Nicolin[1], Maddegedara Lalith[1], Kohei Fujita[1] and Tsuyoshi Ichimura[1]*

[1]*The University of Tokyo*

ABSTRACT

When exposed to fire, concrete is liable to fracture and spalling owing to thermo-hygro-mechanical phenomena. It is challenging to gain a deep and systematic understanding of high temperature induced cracking in concrete due to the interplay of several physical phenomena, some of which are non-linear. In particular, spalling is widely considered to be highly dependent on the migration, evaporation and condensation of internal moisture content. Numerical modelling may be the only viable method for studying high temperature concrete fracture phenomena, as the real time observation of moisture propagation, evolution of vapour content and induced pore pressure, and mechanical strain in 3D are difficult or infeasible to obtain by experimentation.

The model presented in this study simulates thermal conduction, multi-phase moisture diffusion, and the induced mechanical deformation and fracture owing to thermal gradients and build-up of pore pressure. Studies in this area are usually limited to 1D or 2D problems, despite the fact that cracking is inherently a 3D phenomenon. PDS-FEM was used as the numerical method since it provides a numerically efficient treatment for simulating crack propagation in large 3D models. The model was validated against experimental data [1] by comparing with the measured pressure and temperature at varying depths, where good qualitative agreement was met.

Using the validated model, a full 3D simulation was conducted in order to explore and compare the simulated fracture pattern with available visual data [2]. As a result of the observed results, we speculate that a build-up of moisture inside the macro-cracks may be a key mechanism responsible for spalling. Therefore, we also introduce a mechanism by means of an additional boundary condition for the release of moisture into the opened cracks. This has laid the groundwork for estimation of the additional macroscale pressure exerted on the concrete skeleton inside the cracks themselves.

MANIPULATION OF CONTACT ANGLE HYSTERESIS AT ELECTRIFIED IONIC LIQUID-SOLID INTERFACES

Pengcheng Nie[*1], Xu Zheng[1] and Dongshi Guan[1]*

[1]*Chinese Academy of Sciences*

ABSTRACT

Room-temperature ionic liquids (RTILs) are intriguing fluids that have drawn much attention in applications ranging from tribology and catalysis to energy storage. With strong electrostatic interaction between ions, their interfacial behaviors can be modulated by controlling energetics of the electrified interface. In this work, we report atomic-force-microscope measurements of contact angle hysteresis (CAH) of a circular contact line (CL) formed on a micron-sized fiber, which is coated with a thin layer of conductive film and intersects a RTIL-air interface. The measured CAH shows a distinct change by increasing the voltage U applied on the fiber surface. Molecular dynamics simulations were performed to illustrate variations of the solid-like layer in the RTIL adsorbed at the electrified interface. The integrated experiments and computations demonstrate a new mechanism to manipulate the CAH by rearrangement of interfacial layers of RTILs induced by the surface energetics.

Theory and application of provably-robust and efficient high-order methods for high-fidelity computational fluid dynamics

HIGH-ORDER FINITE DIFFERENCE METHOD FOR INCOMPRESSIBLE NAVIER-STOKES EQUATIONS IN COMPLEX GEOMETRY

David Niemelä[*1]

[1]*Uppsala University*

ABSTRACT

We solve the incompressible Navier-Stokes equations in complex geometry using a multi-block high-order finite difference scheme with summation-by-parts (SBP) properties. The work is a continuation of the work in [2], with the continuation of curvilinear multi-block geometries. Using the Projection method [1] for interface and wall boundary implementations the boundary conditions are imposed strongly, as separate from the usual weak imposition of the Simultaneous-Approximation-Terms (SAT) boundary method commonly seen in SBP schemes. Something shown in [2] to improve the detail of near boundary effects, such as vortices. Using SBP operators the well-posedness analysis of the discrete scheme can be directly related via the Energy method to the continuous well-posedness analysis, showing energy conservation of the system. Stability for the scheme is proven using the Energy method for the curvilinearly transformed equations and convergence of expected order is shown for the analytic Taylor-Green vortex problem on complex coupled multi-block geometries. Classical benchmark problems, such as cylinder in flow are also solved.

EXAMINING SEA-ICE FORMATION WITHIN THE CANADIAN ARCTIC ARCHIPELAGO USING DEMSI

Svetoslav Nikolov[1], Kara Peterson[1], Adrian Turner[2] and Devin O'Conner[1]*

[1]*Sandia National Laboratories*
[2]*Los Alamos National Laboratory*

ABSTRACT

High resolution (sub-kilometer - 1 km) models are required to accurately resolve sea-ice formation within the Canadian Arctic Archipelago (CAA) due to the large density of islands and tortuous channels which surround them. To build these high resolution models we rely on a unique PCA-based data fusion methodology that leverages both active (synthetic aperture radar, SAR) and passive (thermal-infrared, TIR) satellite sensor data to accurately initialize sea-ice simulations. This data fusion procedure is integrated into the Discrete Element Method for Sea-Ice (DEMSI) code, which is a Lagrangian particle method capable of naturally handling the non-linear/discontinuous sea-ice behavior during fracture. Using these SAR-TIR data infused DEMSI simulations we examine how sea-ice growth progresses in Queen Elizabeth islands during the fall months. A comparison with coarser 20 km arctic basin DEMSI models and raw SAR/TIR data is provided.

DEVELOPING A NOVEL LAYERWISE THEORY TO ANALYZE NONLINEAR FREE VIBRATION OF THERMALLY POST-BUCKLED FG-GRC THIN-WALLED STRUTS

Seyed Farzad Nikrad[1], Zengtao Chen[1], Hamid Akbarzadeh[2] and Mahdi Hamidinejad[1]*

[1]*University of Alberta*
[2]*McGill University*

ABSTRACT

The influence of local buckling on the performance of slender structural elements subjected to compressive loads has been a significant focus within the industry. Specifically, for thin-walled sections, local buckling leads to a marked decline in axial compressive stiffness, which in turn considerably diminishes their load-bearing capacity. One of the main objectives of this paper is to examine the possible enhancements in fundamental frequencies and post-local buckling responses of polymeric composite laminated thin-walled struts, such as channel sections, under thermal conditions, through the use of multi-layer graphene sheet reinforcements. Owing to the graphene volume percentages variations in each layer constituting the webs and flanges of thin-walled structures, a piecewise functionally graded distribution is observed through their thicknesses. To precisely and efficiently analyze the nonlinear compressive behavior of these structures, a novel layerwise theory based on the third-order shear deformation theory by incorporating von Karman geometrical nonlinearity has been introduced. Laminated plate theories, commonly employed for plate and shell analysis, can be broadly categorized into two types: the equivalent single layer (ESL) theory and the layerwise theory. In both cases, the 3D elasticity problem is simplified into a two-dimensional (2D) problem. However, it is important to note that the ESL theory has certain limitations, particularly in accurately predicting stress and strain distribution in thick composite laminates or in situations involving dissimilar material layers, such as FG-GRC, where thermomechanical properties vary throughout the laminate's thickness. This limitation arises due to the assumption of constant transverse shear stresses throughout the thickness direction. To address these challenges and provide an accurate estimation of the post-local-buckling response of FG-GRC laminated channel section struts, this paper employs the layerwise theory in conjunction with the TSDT. To verify the accuracy of the results obtained based on the LW-TSDT and to evaluate its computational efficiency, a three-dimensional (3D) finite element model is also developed using ABAQUS for comparative analysis. An extensive analysis of nonlinear stability is performed on functionally graded graphene-reinforced composite (FG-GRC) laminated thin-walled struts to determine the optimal material distribution that raises both the critical buckling temperature and the pre/post- buckled fundamental frequencies.

ABSTRACT

We propose a deep generative model for 3D shapes that incorporates structural mechanics parameters and a dataset of about 10,000 3D shapes created by topology optimization and Eulerian elastoplastic simulation using Cartesian mesh. Our model is based on DeepSDF, a decoder-type neural network that implicitly represents shapes as signed distance functions (SDFs). We extend DeepSDF to condition the shape generation on structural mechanics parameters, such as strain energy, load direction, volume, and dimension. We also introduce positional encoding to improve the spatial resolution of the model. Our dataset consists of various 3D shapes generated by a linear topology optimization method and Eulerian elastoplastic simulation based on the building-cube method (BCM), suitable for large-scale and high-resolution problems. We use the strain energy as a quantitative indicator of the structural performance of the shapes. We train our model on the dataset and evaluate its ability to reconstruct and generate 3D shapes that reflect the structural dynamics parameters. Our numerical results indicate that our model can produce 3D shapes with high fidelity and diversity and achieve an average reconstruction accuracy of 88.8% for the test shapes. We also show that our model can generate novel 3D shapes that satisfy the desired structural performance by manipulating the structural mechanics parameters and the latent vector. Our model and dataset open up new possibilities for 3D shape generation and structural design using deep learning.

DERIVING INTERVERTEBRAL DISC FEM MODELS FROM MRI IMAGE SEGMENTATION IN LARGE COHORTS

Kati Nispel[1], Tanja Lerchl[1], Gabriel Gruber[1], Hendrik Moeller[1], Veit Senner[1] and Jan S. Kirschke[1]*

[1]*Technical University of Munich*

ABSTRACT

Patient-specific intervertebral disc (IVD) models for Finite Element Analyses (FEA) struggle to achieve high fidelity. Limited soft tissue segmentation methods contribute to inaccuracies in numerical models, especially in modeling IVD and vertebra contact surfaces. As a result, interindividual stress distributions and deformations are can be imprecise. In automated pipelines, which are inevitable for analyzing back pain in large cohort studies, model fidelity is even more compromised. [1]

To address this, our team has developed an innovative pipeline for automatically deriving high-fidelity Finite Element Method (FEM) models of patients' IVDs from MRI scans. This pipeline is a product of an interdisciplinary effort among medical professionals, IT specialists, and mechanical engineers. Here, we focus on the pipeline parts from the segmentation mask to the FEM model, while the segmentation method is described in detail elsewhere [2]. Based on the segmentation, surface meshes of the vertebrae and IVDs were created using the marching cubes algorithm. For this, we implemented separate smoothing pipelines for vertebrae and IVDs, which include multiple distinct steps while preserving the anatomical geometries. IVD smoothing is parted in three steps, which are (I) overall preprocessing, (II) selective smoothing and (III) postprocessing. In (II), we remesh the nodes of the IVD mesh to match the nodes of the adjacent vertebral endplate surface, ensuring the contact surface to be perfectly aligned. After smoothing, IVD surface meshes are transformed to volumes using surface reconstruction. Volumes are meshed uniformly with tetrahedral elements. We rated the performance of our pipeline by examining (I) the average processing time per IVD in 30 patients with full spine MRIs (=220 IVDs) taken from the German National Cohort (GNC) and (II) the quality of the meshes based on their aspect ratios.
On average, less than 2 minutes were needed to create one IVD model from the segmentation file. The average aspect ratio of tetrahedrons was 1.62 for all models, ensuring a suitable mesh quality for simulation.

Our pipeline enables simulation studies with varying loads in large cohorts and paves the way to creating more complex, heterogeneous IVD meshes.

ERROR ESTIMATES FOR DYNAMICAL LOW RANK APPROXIMATIONS OF RANDOM PARABOLIC EQUATIONS

Fabio Nobile[*1], Eva Vidlickova[1] and Thomas Trigo Trindade[1]*

[1]*Ecole Polytechnique Federale de Lausanne (EPFL)*

ABSTRACT

Dynamical Low Rank (DLR) approximation for time-dependent problems with random parameters can be seen as a reduced basis method, in which the solution is expanded as a linear combination of a few well-chosen deterministic functions with random coefficients. The distinctive feature of the DLR method is that the spatial basis is computed on the fly and is free to evolve in time, thus adjusting at each time to the current structure of the random solution. In this talk, we consider the DLR approximation for a random parabolic equation discretized by a stochastic collocation finite element method and advanced in time by a projector-splitting scheme. Similarly to the continuous DLR approximation, our fully discrete scheme is shown to satisfy a discrete variational formulation. By exploiting this property, we derive a priori and residual-based a posteriori error estimation for a linear parabolic problem with random parameters. The error estimates consist of four terms controlling the finite element error, the time discretization error, the stochastic collocation error, and the rank truncation error. The a posteriori error estimator can be used to drive an adaptive choice of the four discretization parameters.

A LOW DIFFUSION VERIFIED CONFORMING TRANSIENT H-R UNSTRUCTURED ADAPTIVE MESH REFINEMENT (CTHRUAMR) METHOD FOR COUPLED INTERFACE PROBLEMS

David Noble[*1]*

[1]*Sandia National Laboratories*

ABSTRACT

Enriched finite element methods are powerful tools for coupled multiphase and multimaterial problems with moving interfaces. To capture the discontinuities across interfaces, these methods introduce some form of enrichment of the degrees of freedom. Additional unknowns are assigned to the mesh entities (elements, nodes, sides, or edges) that are associated with these interfacial elements, and additional equations are formulated.

In CDFEM[1], level sets are used to describe the domain of each material or phase. Nodes are added at the intersection of each level set surface with the edges of the input mesh, and a conforming mesh is generated automatically. This allows the weak and strong discontinuities across the interfaces to be captured using standard finite element methods.

In recent work, a new strategy has been developed for automated interface conforming tetrahedral mesh generation, which produces higher quality discretizations than CDFEM techniques. The Conforming Transient h-r Unstructured Adaptive Mesh Refinement (cThruAMR) method uses a combination of h-adaptivity and r-adaptivity to generate high quality meshes that conform to a moving interface. The term h-adaptivity is used for refining or cutting the mesh. CDFEM uses interface-conforming h-adaptivity to capture dynamic topology problems. The term r-adaptivity is used for moving the nodes of the mesh to capture a desired feature. By combining h and r adaptivity, cThruAMR can produce high quality meshes even for dynamic topology problems. The method is closely related to the Conforming to Interface Structured Adaptive Mesh Refinement (CISAMR) method but employs a general unstructured mesh and is developed for transient moving interface problems. A new, low diffusion, cThruAMR method has been developed that has lower error than earlier implementations of the method.

This focus of this talk is the description of cThruAMR for coupled interface problems including the strategies employed for r-adaptivity, level set advection, dynamic DOF handling, and interfacial boundary conditions. The method is verified using multiple benchmark problems and is shown to produce optimal convergence rates. The discretization is shown to have better conditioning and much better mesh quality compared to CDFEM.

A STUDY ON THE STRUCTURAL SYSTEMS WITH TAPERED HARDENING-TYPE HYSTERESIS DEVICES

Aguri Noda[*1], Toshio Maegawa[1], Soma Mitsui[2] and Masamichi Sasatani[2]*

[1]Kumagai Gumi Co., Ltd.
[2]Tokyo Denki University

ABSTRACT

Japanese seismic design allows for the formation of plastic hinges at the ends of beams in the event of a major earthquake. These plastic deformations in the structure increase its seismic energy absorption capacity and help prevent the building from collapsing.
However, in cases where seismic motion exceeds expectations, the seismic energy surpassing the structure's absorption capacity may cause partial destruction, ultimately leading to building collapse. Allowing for the plastic deformation of structural members may result in a lengthening of the building's natural period due to repetitive seismic motion. In such instances, prolonged seismic motions could unexpectedly damage buildings.
For this background, a structural system with hardening-type hysteresis was proposed to enhance building durability. This system consists of a moment frame connected to displacement control devices with hardening-type hysteresis. The devices prevent excessive deformation of the building in the event of seismic motion exceeding the expected level and provide the building with a margin of safety. This paper carries out experiments and analysis on the device with hardening-type hysteresis.
The device consists of steel rods, disc springs, a pair of tapered members, and a pair of up-thrust members. Specifically, the tapered and up-thrust members are connected by steel rods fastened with disc springs. It has low stiffness up to a defined displacement when compressive and tensile forces are applied. It becomes highly stiff when further forces are applied.
Firstly, to verify the fundamental properties of the device, loading tests were conducted using various specimens with different taper angles and combinations of disc springs. As a result, two levels of stiffness were obtained as expected.
Subsequently, a finite element analysis was performed under the same conditions as the experiment. The results of this analysis broadly aligned with the experimental results, confirming the capability of the finite element analysis model to replicate the experiments.
We designed a hardening-type hysteresis based on these results. The hysteresis model was applied to a multi-story steel-frame structure and subjected to seismic analysis to confirm the effects of the reduction of acceleration and deformation on the building.

EXPLORATION OF MICROSTRUCTURES WITH NEGATIVE THERMAL EXPANSION COEFFICIENTS USING TOPOLOGICAL DERIVATIVES

Masaki Noda[*1] and Takayuki Yamada*[1]

[1]*The University of Tokyo*

ABSTRACT

The application of topological derivatives in topology optimization has been a focal point in various studies. Particularly, research in multi-material topology optimization methods has progressed, yet attempts to derive microstructures with negative thermal expansion coefficients based on topological derivatives are scarce. In this study, we present topological derivatives related to thermal expansion, i.e., topological derivatives that take into account the deformation of the structure due to thermal stress at a uniform temperature change. We employ these derivatives in creating microstructures with negative thermal expansion coefficients. To derive the optimal multi-material structure, we utilize the multi-material topology optimization method previously proposed by the authors [1]. This research applies existing theories of topological derivatives [2] to a novel context, exploring new possibilities in topology optimization.

SIMULATING OVERTURNING MOMENTS AND PILE RESISTANCE CAPACITY IN TSUNAMI-EXPOSED REINFORCED CONCRETE BUILDINGS WITH MPS METHOD

Rose Noggle[1], Tibing Xu[2], Seiichi Koshizuka[1] and Tsuyoshi Koyama[2]*

[1]*Univeristy of Tokyo*
[2]*University of Tokyo*

ABSTRACT

Overturning moment and foundation resistance capacity are interesting in the design of reinforced concrete (RC) buildings which are overturned by the force of a tsunami wave impact, as occurred in the 2011 off the Pacific coast of Tohoku Earthquake. Before this event, RC buildings were considered to be tsunami- and earthquake-resistant because of their large self-weight and strong outer walls. Overturning of RC buildings in Onagawa-cho, Miyagi Prefecture was determined by Nakano et al. [1] to be caused by tsunami wave overturning moment exceeding the resisting moment from the building self-weight (accounting for buoyancy) and foundation pile pull-out strength.

In our study, algorithms for computing the overturning moment, uplift moment, and resistance capacity from pile foundations, resulting from the impact of a collapsing water column on a rigid block in a two-dimensional moving-particle semi-implicit method- (MPS-) based simulation [2] are presented. The MPS method used in this study, both fluid particles and wall particles have variables of pressure to enable accurate calculation of fluid particle acceleration due to pressure gradient when in the vicinity of rigid walls. These algorithms use the pressure values from the wall particles of the rigid block to approximate combined hydrostatic and hydrodynamic pressure of the fluid on the block and the pore water pressure increase in the underlying soil. These pressure values provide a convenient simplification of both uplift and pile pull-out capacity calculations unique to the MPS method by eliminating the need for complex seepage flow simulation in the determination of water pressure in the underlying soil.

The simulation was verified using two benchmark tests: one of hydrostatic conditions and the other based on the dam break experiment by Lobovský et al. [3]. The pressure output showed good agreement with both the pressure data from that experiment and the analytical solution of hydrostatic pressure.

MULTIPHYSICS-INFORMED NEURAL NETWORKS FOR NON-DESTRUCTIVE STRUCTURAL HEALTH MONITORING IN THERMOMECHANICAL SYSTEMS

Hong-Kyun Noh[*1], Myeong-Seok Go[1] and Jae Hyuk Lim[1]*

[1]*Jeonbuk National University*

ABSTRACT

This study introduces a model utilizing Multiphysics-informed neural networks (MPINNs) to predict full-field temperature, displacement, and stress of silicon wafers regarding thermomechanical problems. Traditional methods relied on numerous temperature sensors to detect wafer operation and defects; however, they were insufficient for monitoring the temperature, displacement, and stress fields across the entire wafer. While recent advancements in deep learning models have led to approximate models predicting outputs based on input data, there are limitations in accuracy for untrained domains due to the low precision of extrapolation of data-driven approaches. Although PINNs offer high prediction accuracy even in data-absent areas due to their integration of physical knowledge; they require retraining when boundary conditions or loads change. To overcome these challenges, this study incorporated temperature data from a limited number of sensors into the input layer of existing MPINNs and trained them under various loading conditions. Consequently, it was observed that using this sparse temperature data alone accurately predicted the temperature, displacement, and stress across the entire domain. Furthermore, various techniques such as sequential training and model parameter sharing were quantitatively analyzed to enhance the convergence of MPINNs.

MULTI-TRACK AND MULTI-LAYER SIMULATION METHODOLOGY FOR POWDER BED FUSION PROCESS BY LATTICE BOLTZMANN AND MULTI-PHASE FIELD METHODS

Sukeharu Nomoto[1], Jun Katagiri[1], Masahiro Kusano[1], Tomonori Kitashima[1] and Makoto Watanabe[1]*

[1]*National Institute for Materials Science*

ABSTRACT

A three dimensionally integrated numerical framework using lattice Boltzmann method and multi-phase field method is proposed for simulating melting and solidification of metal alloy in laser powder bed fusion process. Modified lattice kinetic scheme that is a kind of lattice Boltzmann method is applied to simulate fluid flow consisting of atmosphere gas and melt liquid with free surface. Melting and solidification of metal alloy are modelled by multi-phase field method with consideration of grain interface anisotropy. Conserved Allen-Chan equation, which is also transformed to the modified lattice kinetic scheme formulation, is adapted to track the liquid-solid free surface moving dynamics. Thermal equation with heat source of traveling laser beam is solved by coupling fluid flow and melting / solidification analysis. Highly parallelized computational program is developed by using MPI and OpenMP hybrid method. A three-dimensional model of powder bed fusion additive manufacturing of Ni alloy is built by consisting of atmosphere gas, base plate, and powder regions. The base plate is modelled with multi-grains generated by Voronoi tessellation method, of which crystalline directions are randomly distributed. Ni alloy powder, of which particle assumed sphere, is set by discreet element method. Seamlessly analysis from melting to solidification is performed in condition of two laser beam tracks and two powder layers. Solidification microstructure constructed with epitaxially multi-grain growth is formed. The obtained result is qualitatively compared with experimental measurement. It is confirmed that the present numerical framework gives us high speed and robust method for large scale model of powder bed fusion process.

ON THE NEED FOR THE INERTIAL EFFECTS FOR EVALUATING THE MITIGATION PERFORMANCE OF THE COASTAL TREES IN 2D UNSTEADY TSUNAMI FLOW SIMULATIONS

Reika Nomura[*1], Shuji Ishizawa[1], Shuji Moriguchi[1] and Kenjiro Terada[1]*

[1]*Tohoku University*

ABSTRACT

2D nonlinear shallow water (SW) simulation is a common way to evaluate tsunami propagation and inundations in the fields of coastal engineering. There are many open-source software or in-house codes that can simulate how tsunamis propagate from offshore to onshore, and how they are prevented/attenuated from the coastal structures, such as seawalls or vegetation. For evaluating such the resistance effects of coastal vegetation, the source terms, which represent the resistance forces against the flow, are generally inserted into the momentum equations of 2D SW equation. Although many researchers model the source term based on the idea that the resistance effects are mainly caused by the non-inertial, so-called drag effects only, Suzuki et al. 2019[1] insisted that the inertial effects would become larger inside the coastal trees. Indeed, modeling only the drag effects seemed to have a discrepancy in expressing the instantaneous amplifications of the tsunami impact as reported by Aburaya et al. 2002[2]. That is, they are required to employ a much larger drag effect parameter only in the very short term during the wavefront reaches the structures. Therefore, we shall consider the effects of inertial force in the evaluations of the mitigation performance of the coastal vegetation.

In this study, we aim to investigate how the inertial forces due to the presence of trees ultimately influence disaster mitigation performance. We first set up a 2D nonlinear SW momentum equation considering the inertial effects due to the presence of the trees in addition to the drag effect. To identify the parameter appearing in the formulation of drag/inertial forces, we preliminary carry out the 3D numerical flow tests with the open channel domain, and the tree geometry generated by the L-system[3]. From implementing the resultant parameters and the established momentum equations, we simulate the 2D unsteady flows. The comparison with 3D flow simulations with direct tree resistance provides the discussion for the necessity of the inertial effects.

STABILIZATION OF LARGE DEFORMATION ANALYSIS FOR A NONRECIPROCAL GEL UNDER CYLINDRICAL INDENTATION

Shoma Nonogaki[*1], Seishiro Matsubara[1], So Nagashima[1] and Dai Okumura[1]*

[1]*Nagoya University*

ABSTRACT

A nonreciprocal gel is a uniform composite consisting of oriented nanosheets embedded in a hydrogel [Wang et al., 2023. Mechanical nonreciprocity in a uniform composite material, Science 380, 192–198]. This material exhibits mechanical nonreciprocity owing to buckling of nanosheets. Mechanical nonreciprocity has many potential engineering applications in energy conversion and biological manipulation [Sun and Kang, 2023. A mechanically one-way material, Science 380, 135].
In the previous study, plane-strain finite element analysis for cylindrical indentation of the nonreciprocal gel was performed to clarify the deformation mechanism. The nonreciprocity of the gel was modeled by extending the framework of orthotropic linear elasticity. Relative material constants were nonlinearized by line approximations as functions of applied strains based on experimental data, i.e., the nonreciprocity was explicitly introduced into the constitutive model. Numerical results elucidated the relationship between the nonreciprocity and the asymmetric response of the gel. It was, however, found that severe large deformation drastically degrades the robustness of the computation. Asymmetric deformation occurs due to both nonreciprocity and large compressive deformations, especially in the region just below the cylinder. It was further found that hourglass deformation modes arising in the severe deformation elements lead to this vulnerability [Nonogaki et al., 2023. Large deformation analysis of a nonreciprocal gel under cylindrical indentation. Japan Society for Computational Methods in Engineering 23, 123–128].
In this study, we demonstrate that the introduction of artificial viscosity and hourglass control stabilizes the large deformation analysis of the nonreciprocal gel. The artificial viscosity allows us to complete the computation even under severe large deformations. The hourglass control also prevents hourglass deformation modes. We study the effects of these parameters on the computational accuracy and efficiency. Using larger values of two parameters increases computational efficiency but decreases computational accuracy. Parametric studies reveal the proper range of two parameters where computational efficiency is compatible with accuracy.

FSI SIMULATION WITH IMPOSED DISPLACEMENTS USING TRIOCFD ON A SCALE-RELEVANT MOCKUP OF A NUCLEAR FUEL ASSEMBLY

Raksmy Nop[1], Maria Adela Puscas[1] and Guillaume Ricciardi[1]*

[1]CEA

ABSTRACT

Investigating the behavior of fuel assemblies under mechanical solicitation in a fluid flow is of key importance for the safety of nuclear pressurized water reactor (PWR) in case of seismic events. In this context, experiments have been conducted with 1:2 scale fuel assembly mockups that were forced to vibrate in an ascendant fluid flow [1]. To have a better understanding of fluid-structure interactions in such a configuration, we aim at numerically simulating the setup, and the first step for this is to develop a fluid modeling with moving boundaries. This communication presents the first fluid-structure simulation on a large and complex geometry with imposed displacements using TrioCFD [2], the open-source CFD code of CEA, and how it was modeled.

The turbulent fluid flow is modeled with a standard k-ε RANS (Reynolds-Averaged Navier-Stokes) approach. In order to reduce the computational cost, the complex geometry of the spacer grids is modeled with a porous medium where an anisotropic pressure loss is defined. In the axial direction, the latter has been calibrated to reproduce the pressure drop experimentally measured throughout the entire assembly and in the transverse direction, a larger pressure loss is imposed to mimic the displacement of the fluid due to the spacer grid structure. The moving boundaries are handled by the Arbitrary Lagrangian-Eulerian method [3] implemented in TrioCFD.

After a static computation to initialize the fluid velocity field, the dynamic computation is then realized with an imposed displacement of the assembly. This displacement mimics the first vibration mode of an Euler-Bernouilli pinned-pinned beam, with an amplitude of 1mm and a frequency of 5 Hz. The calculation of about 18 periods using a 70 million tetrahedral element mesh needed the use of about 50,000 CPU hours. This reasonable computational cost as well as the first analyses that we will present display a glimpse of a wide potential of physical parametric studies.

SENSITIVITY ANALYSIS FOR TURBULENT FLOWS

Nathalie Nouaime[1], Bruno Després[2], Maria Adela Puscas[1] and Camilla Fiorini[3]*

[1]*CEA Saclay*
[2]*Sorbonne University*
[3]*CNAM*

ABSTRACT

Our work focuses on sensitivity analysis for the RANS equations more precisely the k− ε model, using the Polynomial Chaos Method (PCM) [1]. PCM is a probabilistic method consisting in the projection of the model output on a basis of orthogonal stochastic polynomials in the random inputs. The stochastic projection provides a representation of the model output variability with regard to the inputs.

PCM has been used for Uncertainty Quantification in many domains. It offers significant advantages in various engineering applications with turbulent flows, despite being a highly challenging problem. Due to the difficulty of applying the PCM to the k − ε [3], we first used it for the Navier-Stokes equations, which is easier to perform.

First, the first-order sensitivity of the Navier-Stokes equations using the PCM is computed. A Finite Element-Volume (FEV) [2] numerical scheme for the Navier-Stokes equations is proposed. This discretisation is integrated into the open-source industrial code TrioCFD, promoted by the CEA. The FEV method is a widely employed discretisation technique for partial differential equations. It ensures local mass conservation, which is essential for some physical issues.

Second, the first-order sensitivity Navier-Stokes equations are discretised according to the FEV. However, the most significant and original point is the discretisation of the non linear term. Then, a stability estimate for continuous and discrete Navier-Stokes equations is established. The PCM provides an estimate of the mean and the variance of the solution of the Navier–Stokes equations when there are uncertain parameters, and this estimated variance is used to compute confidence intervals.

Some numerical tests are presented to evaluate the polynomial chaos method and to compare it to the Monte Carlo and Taylor expansion methods.
Finally, we show that the standard PCM is not directly applicable to the k − ε equations but some novel works are in progress to extend this method to the turbulent flows and the first results are promising.

GENERATION AND QUANTIFICATION OF SYNTHETIC POROUS MEDIA

C. A. Suarez-Afanador[1], Stephane Urcun[1], Thomas Lavigne[1] and Anas Obeidat[1]*

[1]University of Luxembourg

ABSTRACT

Firstly, we introduce an innovative pipeline for the generation and permeability evaluation of synthetic porous media. Addressing the unpredictability in natural porous materials, our approach focuses on creating controlled synthetic media, essential in diverse fields such as biomechanics, industrial applications, and medical science. We explore the complexities of porous microstructures and fluid-structure interactions, employing advanced technologies like CT and micro-CT for accurate 3D microstructure analysis.

Secondly, we address the continuum biological hydrodynamics simulation in complex geometries, by utilising the Entropically Damped Artificial Compressibility (EDAC) solver for The Discretisation-Corrected Particle Strength Exchange (DC-PSE). The solver is coupled with Brinkman penalisation to add a layer of robustness when dealing with such stochastic complex geometries. The Entropically Damped Artificial Compressibility (EDAC) formulation equations are solved using the DCPSE.

Finlay, we extract RVE’s from the simulated porous medium where the the averaged permeability is evaluated under vorticity criterion.

Our pipeline facilitates enhanced research in fluid movement, heat transfer, and targeted therapeutic interventions by mimicking natural tissue conditions. This work provides a novel tool for synthetic media generation and for robust computation of permeability in porous structures, contributing significantly to technological development and medical advancements.

CONDITIONAL DIFFUSION MODELS FOR SOLVING PHYSICS-BASED INVERSE PROBLEMS

Assad Oberai[*1], Agnimitra Dasgupta[1], Javier Murgoitio-Esandi[1] and Harisankar Ramaswamy[1]*

[1]*University of Southern California*

ABSTRACT

Conditional generative models aim to sample from a conditional distribution given samples from the joint distribution, which makes them particularly suitable as tools for solving inverse problems in a Bayesian setting, especially when solving the forward problem is efficient. Thus, a significant body of work exists on utilizing conditional generative models for solving inverse problems. Diffusion models—a type of generative model—are responsible for significant advances in generative artificial intelligence. This work explores the use of conditional score-based diffusion models for solving physics-based inverse problems. Using multiple challenging applications in computational mechanics involving synthetic and experimental data, this work explores the efficacy of conditional score-based diffusion models in solving large-scale physics-based inverse problems. It also contrasts their performance against conditional generative adversarial networks, another class of popular generative models. It also explores the effect of various sampling and model-related hyperparameters on performance, and the behavior of these models in different limits.

MULTI-FIDELITY MODELING VIA THE DATA GRAPH LAPLACIAN

Assad Oberai[*1] and Orazio Pinti*[1]

[1]*University of Southern California*

ABSTRACT

Low-fidelity data is typically inexpensive to generate but inaccurate, whereas high-fidelity data is accurate but expensive. To address this, multi-fidelity methods use a small set of high-fidelity data to enhance the accuracy of a large set of low-fidelity data. In this talk, this is accomplished by constructing a graph Laplacian from the low-fidelity data and computing its low-lying spectrum. This is used to cluster the data and identify points closest to the cluster centroids, where high-fidelity data is acquired. Thereafter, a transformation that maps every low-fidelity data point to a multi-fidelity counterpart is determined by minimizing the discrepancy between the multi- and high-fidelity data while preserving the underlying structure of the low-fidelity data distribution. The method is tested with problems in solid and fluid mechanics. By utilizing only a small fraction of high-fidelity data, the accuracy of a large set of low-fidelity data is significantly improved. A Bayesian version of this approach, which allows for the quantification of uncertainty in the multi-fidelity model is also described.

A NEW NUMERICAL METHOD FOR SCALAR EIGENVALUE PROBLEMS IN HETEROGENEOUS, DISPERSIVE, SIGN-CHANGING MATERIALS

Martin Halla[1], *Thorsten Hohage*[2] *and Florian Oberender**[2]

[1]*Johann Radon Institute for Computational and Applied Mathematics*
[2]*Georg-August Universität Göttingen*

ABSTRACT

In this talk we consider time-harmonic scalar transmission problems between nondispersive and dispersive materials with generalized Lorentz frequency laws. For certain frequency ranges such equations involve a sign-change in their principle part. Due to the resulting loss of coercivity properties the numerical simulation of such problems is demanding. Furthermore, the related eigenvalue problems are nonlinear and give rise to additional challenges. We present a new finite element method for such problems, which is based on a weakly coercive reformulation of the PDE. The new scheme can handle C^1 interfaces consisting piece-wise of elementary geometries. Neglecting quadrature errors the asymptotic convergence of the method follows straightforwardly. For our implementation we apply a simple, but nonstandard quadrature rule. We present computational experiments in 2D and 3D for source and eigenvalue problems, which confirm the stability and convergence of the new scheme.

MODEL VALIDATION VIS À VIS PREDICTIVE CAPABILITY

William Oberkampf[*1]

[1]*W. L. Oberkampf Consulting*

ABSTRACT

Simulation is becoming the primary tool in predicting the performance, reliability, and safety of engineered systems. Terminology such as “virtual prototyping,” “virtual testing,” and “full physics simulation” are extremely appealing when physical testing, budgets and schedules are highly constrained. When pressure from competitors or upper management is added, project managers are persuaded to rely heavily on simulation for decision making. Many contend that higher fidelity physics modeling, combined with faster computers, is the path forward for improved predictive capability of systems. However, when you examine the rate of increase in physical complexity, computational requirements, and system information requirements when finer scales of physics are included in modeling, the argument for increasing predictive capability is questionable.

This presentation takes the perspective of the decision maker, project manager, or regulatory authority who is accountable for their decisions on engineered systems. It is pointed out that this perspective is in sharp contrast to a researcher or academic involved in developing mathematical models and computational methods for simulation. I use the concept that model validation is the assessment of model accuracy determined by comparison with experimental measurements. I define predictive capability as the estimation of the total uncertainty in any system response quantity of interest, regardless of whether it relates to system performance, reliability or safety. Predictive capability is the emerging field attempting to capture all aspects of uncertainty in order to foretell the response of a system for conditions where no experimental data are available. I argue that estimation of predictive capability is the most constructive and prudent path forward from the perspective of the decision maker or regulatory authority. In contrast to traditional uncertainty estimation, specifically Bayesian estimation, predictive capability attempts to capture all potential sources of uncertainty. These include model input uncertainty, model form uncertainty, and numerical solution error, as well as uncertainty in the environments and scenarios to which the system could be exposed. This talk will briefly review uncertainty quantification approaches that have been developed in fields such as nuclear power reactor safety, civil engineering and nuclear weapons. An important distinction is made between uncertainties that are random (aleatory uncertainties) and those that are due to lack of knowledge (epistemic uncertainties). I argue that imprecise probability approaches offer the most appropriate description to represent the total predictive uncertainty for a decision maker. This presentation also points out the organizational/customer resistance to improved estimation of predictive capability.

MODELING SEA ICE DYNAMICS WITH A DISCRETE ELEMENT METHOD: AN OVERVIEW OF THE DEMSI PROJECT

Devin O'Connor[1], Kara Peterson[1], Adrian Turner[2] and Svetoslav Nikolov[1]*

[1]*Sandia National Laboratories*
[2]*Los Alamos National Laboratory*

ABSTRACT

The Arctic has undergone significant changes in recent decades, with substantial reductions in sea ice extent and multiyear ice, leading to thinner ice that is susceptible to breakup [1]. As sea ice deforms it can fracture and create areas of open water called leads. The opening of leads exposes ocean water to the atmosphere, providing an opportunity for ocean-atmosphere energy exchange. When thermodynamic conditions are right, the water in a lead can refreeze and when compressed the ice can create a pressure ridge. These local processes, while difficult to describe, are important components of sea ice models and Earth System Models (ESM) and are challenging to reproduce with continuum sea ice models. In this talk we present a new discrete element model for sea ice (DEMSI) and discuss an overview of some of its main features including a bonded particle model, pressure-ridging contact model, particle interpolation and remapping, and sea ice thermodynamics [2]. Sea ice simulations of the Arctic Basin using DEMSI will be presented as well as a regional scale example in the Beaufort Sea north of Alaska. Simulated ice motion results will be compared with satellite observations and discussed.

CORNER SUPPORTED THICK LAMINATED COMPOSITE PLATES

Ali Odeh[*1], Husain Al-Gahtani[1] and Madyan Al-Shugaa[2]*

[1]King Fahd University of Petroleum and Minerals
[2]Onaizah Colleges

ABSTRACT

In this study, a Ritz method-based solution of the corner supported thick Laminated Composite plate under uniform loading is presented. The flexural and shear behavior of thick laminated plates is described by five coupled partial differential equations, derived based on the “Rissener-Mindlin plate theory”. These equations have been analytically solved by many researchers for specially stacked laminated plates with simple boundary conditions and geometries. Especially for the case of arbitrary stacked thick laminated plates, the form of governing equations is too difficult to be solved by classical methods. The difficulty of the solution is further increased if boundary conditions involve free edges and corner supports. Therefore, this research is destined to develop a robust method to handle such a complicated problem. The proposed method is based on an automated Ritz method capable of yielding accurate solutions for a uniformly loaded corner-supported thick laminated composite rectangular plate having a general stacking sequence. In the proposed approach, Ritz method is cast in a matrix form and an automated symbolic integration procedure is used to allow the use of many approximating polynomial terms as required for convergence. The accuracy of the proposed method is validated by comparing the results obtained against those finite element method (FEM) solutions generated using the commercial software COMSOL Multiphysics.

HIERARCHIC REISSNER-MINDLIN SHELL FORMULATIONS FOR EXPLICIT DYNAMIC ANALYSES

Bastian Oesterle[1], Rebecca Thierer*[2], Lisa-Marie Krauß[2] and Manfred Bischoff[2]*

[1]*Hamburg Universtity of Technology*
[2]*University of Stuttgart*

ABSTRACT

The hierarchic concept for structural element formulations has been developed within the group of the authors with a focus on shear deformable Reissner-Mindlin shell formulations, as can be seen for instance in [1, 2]. Via reparametrization of the kinematic variables, these formulations possess distinct primary variables for transverse shear. This directly results in element formulations that are intrinsically free from transverse shear locking. That is, transverse shear locking is avoided a priori, independent of the utilized discretization scheme.

In addition, the hierarchic structure can be exploited towards an intrinsically selective mass scaling (ISMS) scheme [3]. That is, the high shear frequencies, which usually limit the critical time step in explicit analyses using shear deformable shell elements, are scaled while the low bending frequencies remain mostly unaffected. This stands in contrast to conventional rotational mass scaling for shear deformable elements with rotational degrees of freedom, where the total rotational inertia is scaled and, therefore, also bending frequencies and angular momentum are manipulated.

In this contribution, we present recent investigations on ISMS for hierarchic plate and shell formulations. We discuss the effects of transverse shear parametrization in several transient problems with respect to efficiency and accuracy.

ATOMISTIC SIMULATION OF CHEMICAL ORDERING IN MEDIUM ENTROPY ALLOYS DRIVEN BY NEURAL NETWORKS: FORMATION KINETICS AND IMPACT ON MECHANICAL AND DIFFUSION PROPERTIES

Shigenobu Ogata[*1]*

[1]*Osaka University*

ABSTRACT

The formation of local chemical order in medium-entropy alloys and high-entropy alloys (MEAs/HEAs) has been strongly suggested in recent experimental observations and theoretical studies. Since chemical order can lead to changes in mechanical and functional properties, tailoring of chemical order is a promising approach for further improving those properties of MEAs and HEAs. However, details regarding the atomic structure of the chemical order and its formation kinetics remain unclear. In the present study, utilizing the newly developed ANNP (artificial neural network potential)-driven atomistic simulation, such as artificial-neural-network-accelerated kinetic-Monte-Carlo (ANN-kMC) vacancy diffusion simulations for vacancy jump, we first precisely depict the genuine chemical ordering structures relative to annealing temperature and duration in CrCoNi MEA. Following this, we analyze its impact on deformation/strength and interstitial/vacancy diffusion in CrCoNi MEA using ANNP-driven molecular dynamics and ANN-kMC simulations, revealing a clear link between the degree of chemical ordering and the strength and diffusion kinetics.

NUMERICAL ANALYSES OF COUPLED THERMAL-HYDRAULIC-MECHANICAL-CHEMICAL PROCESSES WITHIN FRACTURED ROCKS BASED ON EXPLICIT FRACTURE MODELS

Sho Ogata[*1]*

[1]*Osaka University*

ABSTRACT

For investigating the capability of a geological disposal facility for high-level radioactive waste (HLW), long-term alteration in the permeability distribution within the rock mass that work as the natural barrier, must be predicted by using the numerical simulation.
Within the natural barrier, the rock fracture generation during the excavation of the disposal cavity bring about the enhancement of permeability around the excavated cavity. And afterwards, permeability of generated fractures during excavation, may be changed by the influence of coupled processes between the various physical/chemical phenomena induced by rock fracture network, such as heat transfer, fluid flow, stress/deformation, solute transport, and the geochemical reactions of minerals and groundwater (e.g., pressure dissolution, free-face dissolution/precipitation) after disposal of HLW into the excavated cavity. Therefore, both of the rock fracture generation process and the subsequent coupled thermal-hydraulic-mechanical-chemical (THMC) processes on the generated fractures, must be resolved realistically. To resolve such processes as realistically as possible, the numerical simulator should be based on explicit fracture models. However, the most of the existing coupled THMC simulators handle the rock fractures based on the implicit fracture modeling and they cannot resolve the details of fracture generation and coupled THMC processes acting on generated fractures.
Thus, in this study, we proposed a novel coupled THMC simulator based on explicit fracture models to resolve the details of the processes from fracture generation to subsequent coupled THMC interactions. Then, the proposed simulator was validated by replicating the results of in-situ experiments such as observed trends of rock fracture generation during cavity excavation and measured permeability evolution around cavity with time after excavation. Subsequently, the simulator was applied to predict the long-term change of the permeability distribution within the natural barrier when implementing geological repository of HLW.

PROPOSAL OF A MULTI-MATERIAL TOPOLOGY OPTIMIZATION FOR MICROSTRUCTURES USING THE ALTERNATING ACTIVE-PHASE ALGORITHM

Shun Ogawa[1], Kazuo Yonekura[1] and Katsuyuki Suzuki[1]*

[1]*The University of Tokyo*

ABSTRACT

This paper introduces a method for optimizing microstructures of multiple materials through topology optimization. With a focus on lightweight and enhancing strength in mechanical structures, recent attention has turned to material design, especially in composite materials. However, designing structures with multiple materials, each having distinct properties, poses challenges, particularly when dealing with small-scale objects and complex mechanical behaviors. To address this, we present a multi-material topology optimization approach tailored to material design challenges. Specifically, it optimizes the arrangement of multiple materials in the microstructure using an isotropic elastic model and tackles the synthesis maximization problem of the macrostructure composed of these microstructures. A decoupling multi-scale analysis is applied in topology optimization to integrate microstructure and macrostructure.

While there are numerous reports on multi-scale topology optimization methods [1] using a single design variable, such as single-material or two-phase material approaches, challenges arise when dealing with multi-material topology optimization involving three or more phases. The complexity of managing multiple design variables and interpolating material property functions makes extending conventional topology optimization systems difficult. This complexity is further heightened in multi-scale topology optimization that couples microstructures and macrostructures.

To overcome these challenges, we apply the Alternating active-phase algorithm [2], an extension of the framework of the conventional two-phase material density method, as the topology optimization algorithm. This algorithm sequentially selects two phases from multiple materials, solving subproblems based on the topology optimization of conventional two-phase materials. Applying this operation to all materials allows us to leverage the established conventional two-phase material topology optimization system. This not only enables us to reuse insights from established methods but also provides the advantage of constructing a concise topology optimization system for complex microstructures.

The paper presents the problem formulation, sensitivity analysis, and algorithm for multi-material topology optimization based on the Alternating active-phase algorithm. Finally, several numerical examples are provided to demonstrate the effectiveness of the proposed method and highlight future works.

NUMERICAL ANALYSIS OF CRACK PATH INSTABILITY UNDER THERMAL LOADING

Sayako Hirobe[1] and Kenji Oguni[1]*

[1]Japan Agency for Marine-Earth Science and Technology

ABSTRACT

Predicting crack growth remains a significant challenge in the field of fracture mechanics. A simple experiment firstly performed by Yuse and Sano (1993) [1] has attracted many attentions due to well-controlled quasi-static crack propagation in glass plates. In their experiment, a thin glass plate was moved from a hot heater to a cold water bath at a constant velocity. At this time, an initial crack placed on the bottom of the glass plate propagated under thermal stress. The crack paths exhibited transitions of straight, oscillating, and branching cracks depending on factors such as quenching speed, temperature difference between the heater and the water bath, and/or the width of the glass plates. Despite the simplicity of the experiment, the mechanism behind the transition of crack paths remains unexplored.

This research focuses on simulating crack path transitions in quenched glass plates to analyze the relationship between the thermal stress field and crack path instability. We implemented a technique to incorporate the thermal stress field into Particle Discretization Scheme Finite Element Method (PDS-FEM) for thermal crack analysis. In the simulations, we prepared 2D analysis model and varied quenching speed and width of the glass plate. Our simulation results successfully reproduced the transitions of the crack paths, including straight, oscillating, and branching cracks. Also, we show interactions between changes in the thermal field and the crack growth. We ensure that these results will contribute to an understanding of the mechanism of the mechanisms behind crack path instabilities.

SYMBOLIC REGRESSION BASED ON BAYESIAN INFERENCE AND ITS APPLICATION TO ADDITIVE MANUFACTURING

Hongsup Oh[1] and Jacob Hochhalter*[1]

[1]*The University of Utah*

ABSTRACT

Symbolic regression (SR) has gained attention in scientific research due to its intrinsic interpretability. SR commonly employs genetic programming (GP) to explore the model search space. GP serves as a global optimization technique designed to prevent convergence to local optima but faces challenges, including equation bloat, overfitting to sparse or noisy datasets, and convergence speed. To address these challenges, SR has incorporated Bayesian inference. In this study, we introduce Markov chain Monte Carlo Symbolic Regression (MCSR), where SR integrates the Markov chain Monte Carlo (MCMC) method. In MCSR, we use the categorical distribution to represent the likelihood of selecting mathematical operators at each node within an acyclic graph. MCMC functions as the evolution algorithm in MCSR, aiming to discover the optimal categorical distribution that accurately depicts the training dataset. The MCSR algorithm comprises five consecutive steps. (1) an initial population of weight tensors is generated using the standard normal distribution, (2) candidate weight tensors are generated using the Gaussian distribution, (3) categorical distributions are calculated, and acyclic graphs are sampled from these distributions, (4) the population of the next generation is selected between the current and candidate weight tensors using rejection sampling, and (5) the second to fourth steps are iterated until any weight tensor in the population satisfies the user-defined threshold. The robustness of MCSR to overfitting given noisy datasets will be demonstrated through various benchmark problems. Lastly, we illustrate the utility of MCSR in scientific or engineering research. For instance, we demonstrate how MCSR can be applied to construct a surrogate model for topology optimization. Additionally, we will demonstrate that MCSR can be utilized to learn a mathematical model representing the relationship between the cooling rate and input values in additive manufacturing, such as laser power and velocity.

VORTEX GENERATION IN THE FEED SLOT DURING SLOT COATING

Sangho Oh[1] and Jaewook Nam*[1]

[1]*Seoul National University*

ABSTRACT

Slot coating is a major technique employed during the coating of battery slurry electrodes, necessitating a uniform and stable product. Preventing various defects that may arise during the slot coating process is crucial. In particular, vortex formation in the feed slot can lead to critical defects. Vortices in the feed slot can cause unpredictable flows due to the coagulation of slurry particles or the leakage of large particles, resulting in the unevenness of the final product.

This study focuses on quantifying the vortex generated in the feed slot during slot coating and analyzes how its location and size change under varying process conditions. The trends were examined by altering geometry and process parameters, comparing the effects of two types of fluids – Newtonian and Carreau fluid - for analyzing the impact of shear-thinning characteristics. Finite Element Method-based computational simulations were employed for flow simulations, and clustering techniques were applied to stream function data for vortex quantification.

The analysis of the influence of geometry parameters revealed that, in comparison to the coating gap, an increased feed slot height tends to promote the generation of feed slot vortices. From a process parameter perspective, it was observed that higher substrate speeds relative to the flow rate result in the enhanced formation of feed slot vortices. Lastly, the study confirmed that shear-thinning characteristics inhibit vortex formation. The findings provide insights into optimizing the coating process and mitigating issues about the vortex.

MULTISCALE MODELING OF LOCALIZED DAMAGE IN CERAMIC MATRIX COMPOSITE STRUCTURES WITH THE GENERALIZED FINITE ELEMENT METHOD

Bryce Mazurowski[1], Patrick O'Hara[2] and Armando Duarte[1]*

[1]University of Illinois Urbana-Champaign
[2]Air Force Research Laboratory

ABSTRACT

Ceramic Matrix Composites are showing promise as a structural material in high-speed aircraft. These materials have excellent strength-to-weight ratios and are resilient in the extreme environments encountered with high-speed structures. High-speed structures have complicated loading and structural features that shrink the structural length scale. CMCs bring several relevant length scales considerably larger than traditional metals, especially when modeling material failure. As the structural and material length scales approach each other, fundamental assumptions of homogenization theory are no longer valid. This requires a more rigorous, and significantly more expensive, analysis of the structure. However, this convergence of length scales typically occurs in localized areas of the structure: around sharp loads, high-gradient temperature profiles, connections, material interfaces, etc. A multiscale method based on the Generalized Finite Element Method with global-local enrichment functions (GFEMgl) is used to incorporate the local structural features, relevant material microstructure, and nonlinear constitutive behavior at these hot spots into global structural behavior on the fly. The proposed method can make use of homogenized material models throughout the majority of the structure, where there is sufficient separation of length scales. A damage model formulated to capture CMC failure modes at an intraply level is used to capture the nucleation and progression of damage in structural hot spots where homogenization theory is not valid. The method is shown to capture damage nucleation and progression accurately and efficiently in CMC structures when compared against industry-standard methods.

INFLUENCE EVALUATION OF FLOW DIVERTER STENT PARENT VESSEL COVERAGE ON CEREBRAL ANEURYSM THROUGH THE CFD-DEM COUPLING SIMULATION

Yoshio Ohkura[*1], Dai Watanabe[1], Ryo Taniguchi[1], Soichiro Yamani[1] and Hiroyuki Takao[2]*

[1]*Shibaura Institute of Technology*
[2]*The Jikei University School of Medicine*

ABSTRACT

A cerebral aneurysm is a type of cerebrovascular disorder characterized by the development of a balloon-like bulge in a part of the brain's arteries. When it ruptures, it can lead to subarachnoid hemorrhage, and due to the high mortality rate following onset, treatment must be initiated before the cerebral aneurysm ruptures.

To address this, the Flow-diverter Stent (FDS) placement has been developed specifically for large cerebral aneurysms. In this procedure, a device known as FDS, consisting of a cylindrically woven metal wire, is utilized. The FDS is placed in the neck of the cerebral aneurysm from within the blood vessel using a catheter for treatment. The embolization process gradually reduces the blood flow velocity entering the cerebral aneurysm, and endothelial cells invade the surface of the FDS, eventually closing the gaps between the struts and occluding the cerebral aneurysm.
Ensuring effective treatment outcomes in cerebral aneurysm treatment with FDS requires precise placement of the FDS. Improper placement may result in increased blood flow velocity and Wall Shear Stress (WSS) within the cerebral aneurysm or elevated pressure inside the aneurysm. Such phenomena suggest a potential risk of rupture, especially in the case of giant aneurysms.
Considering these circumstances, in this paper, we evaluated the impact of FDS placement on cerebral aneurysms by creating multiple FDS placement models with varying proximal and distal positions within the aneurysm. Subsequently, we conducted fluid-structure coupled analysis using the Particle Finite Element Method (PFEM) for the blood and the Discrete Element Method (DEM) for the FDS, comparing the behavior of blood and evaluating WSS and pressure inside the cerebral aneurysm based on the placement of FDS. The results of these analyses are presented.

NUMERICAL ANALYSIS OF WRINKLE TRANSFORMATION DUE TO WATER SURFACE TENSION

Rikuto Ohta[*1], So Nagashima[1], Seishiro Matsubara[1] and Dai Okumura[1]*

[1]*Nagoya University*

ABSTRACT

Electrocapillary deformation of soft solids has received growing attention in both fundamental research and technological applications [1]. Recently, researchers have experimentally observed capillary-induced transformation of wrinkles in bilayers composed of a thin film on a soft substrate [2]. When a water droplet comes into contact with a pre-wrinkled hydrophilic surface, water filaments instantaneously develop around the contact line. This transformation results in the emergence of folds that resemble biological patterns. Since film–substrate bilayers are ubiquitous in organisms where water is a major constituent, the capillary-induced wrinkle transformation could be exploited to help rationalize morphogenesis. However, the underlying mechanisms have not been fully elucidated.

In this study, we numerically investigate the water-induced morphological transformation of wrinkles to folds in film–substrate bilayers. Finite element analysis was performed under plane strain conditions using a model composed of a linear elastic film on an incompressible neo-Hookean hyperplastic substrate. Point loads corresponding to the forces generated by the surface tension of water were applied to the wrinkles to induce the transformation into folds. The critical conditions for the occurrence of the transformation and the resulting fold geometry were explored. In particular, the effects of the wrinkle aspect ratio (amplitude/wavelength), elastic modulus ratio between the film and substrate, film thickness, and surface wettability were investigated. Our results show that as the surface hydrophilicity and the wrinkle aspect ratio increase, water filaments are more likely to be generated. Furthermore, the spacing between the resulting folds can be controlled by adjusting the values of the aforementioned factors. These findings would help better understand the mechanisms of the capillary-induced wrinkle transformation.

DATA-DRIVEN MODELS IN VISCOELASTIC FLUID FLOWS

Cassio Oishi[1], Steven Brunton[2] and J. Nathan Kutz[2]*

[1]São Paulo State University
[2]University of Washington

ABSTRACT

Viscoelastic fluids, characterized by a combination of viscous (liquid-like) and elastic (solid-like) attributes, are an important class of non-Newtonian materials. Their complexity properties find applications across various domains, leading to widespread use of computational methods to address viscoelastic fluid flows. These computational approaches have significantly contributed to our understanding of non-Newtonian mechanics. Despite advances in scientific computing for modeling and simulating viscoelastic fluid flows, many problems remain computationally challenging, such as resolving viscoelastic instabilities and elastic turbulence. Therefore, it is essential to develop enhanced numerical schemes for non-Newtonian fluid mechanics based on machine learning algorithms and data-driven strategies.

This work leverages the Sparse Identification of Nonlinear Dynamics (SINDy) algorithm to develop interpretable reduced-order models for viscoelastic flows. In particular, we explore a benchmark oscillatory viscoelastic flow on the four-roll mill geometry using the classical Oldroyd-B fluid. The chosen flow scenario encompasses canonical challenges associated with non-Newtonian flows, featuring transitions, asymmetries, instabilities, and bifurcations arising from the interplay of viscous and elastic forces.

Our approach first showcases the effectiveness of the data-driven surrogate model in predicting transient evolution and accurately reconstructing the spatial flow field for fixed flow parameters. After this, we develop a fully parametric, nonlinear model capable of capturing dynamic variations as a function of the Weissenberg number (Wi) which is related to the elastic contribution in the flow. While the training data predominantly focuses on a limit cycle regime for moderate Wi, our results demonstrate that the parameterized model can effectively extrapolate, accurately predicting dominant dynamics even in scenarios with high Weissenberg numbers.
The proposed methodology represents an initial step in the field of reduced-order modeling for viscoelastic flows with the potential to be further refined and enhanced for the design, optimization, and control of a wide range of non-Newtonian fluid flows using modern machine learning and reduced-order modeling techniques.

DRAG REDUCTION EFFECT OF STREAMWISE TRAVELING WAVE WITH SPANWISE PHASE SHIFT IN A TURBULENT CHANNEL FLOW

Kyohei Oishi[1], Yusuke Nabae*[2] and Koji Fukagata*[1]

[1]*Keio University*
[2]*Tokyo University of Science*

ABSTRACT

Streamwise traveling wave of wall deformation has a high potential for friction drag reduction [1]. Among others, Nabae and Fukagata [2] optimized the parameters of the spanwise-uniform streamwise traveling wave using the Bayesian optimization and achieved 60.5% drag reduction in a direct numerical simulation (DNS) of a turbulent channel flow under a constant pressure gradient (CPG) condition. However, the resultant flow in their study was unstable in the sense that laminarization and re-transition to turbulence are repeated in time. In this study, to obtain a stable and high drag reduction effect, we propose a streamwise traveling wave with a spanwise phase shift. We examine its performance by DNS of a turbulent channel flow under a CPG condition at the friction Reynolds number of Re_tau = 180. By introducing such spanwise variations to the streamwise traveling wave, we expect that the flow reversal in the near-wall region that triggers re-transition can be mitigated. We consider eight different amplitudes of the spanwise phase shift, x_off. The DNS results show that the flow remains unstable for relatively small phase shift (x_off < 63); however, for x_off > 63, the flow is stabilized, while retaining a large drag reduction effect. The maximum drag reduction rate attained is 49.7% in the case of x_off = 141, which corresponds to a half of the streamwise wavelength of the traveling wave. According to the analysis of the Reynolds shear stress (RSS) in the case of x_off = 141, the turbulent RSS is significantly suppressed compared to not only the uncontrolled case but also the maximum drag reduction case in Nabae et al. [3]. Visualization of the vortical structures reveals that quasi-streamwise vortices are concentrated at specific spanwise locations, while they are substantially suppressed in other regions.

POSITIVE PART BASED LEVEL SET METHOD FOR OPTIMAL DESIGN PROBLEMS

Tomoyuki Oka[*1]

[1]*The University of Tokyo*

ABSTRACT

In this talk, we shall discuss level set methods for optimal design problems. Typically, a method combining Hamilton-Jacobi equations with the shape derivative is well-known, as well as a method combining reaction-diffusion equations with the topological derivative. In the so-called diffusion-based level set methods with material representations via characteristic functions, the issue of sensitivities remains in terms of differentiability, at least in gradient descent methods. In this talk, positive parts of level set functions are devised as a formulation to avoid this issue, and numerical examples for optimal design problems are introduced by employing a numerical algorithm based on nonlinear diffusion equations.

LINEAR ELASTIC FRACTURE MECHANICS ANALYSIS USING S-VERSION ISOGEOMETRIC ANALYSIS - CONDITIONS FOR GUARANTEE THE ACCURACY OF EVALUATES STRESS INTENSITY FACTOR

Yusuke Sunaoka[1], Yuhi Tsuchiyama[1], Takashi Kurosawa[1], Yuto Otoguro[1] and Hiroshi Okada[1]*

[1]Tokyo University of Science

ABSTRACT

In the presentation, the formulation and the numerical implementation of the s-IGA (S-version Isogeometric Analysis, see [1] for IGA) for linear elastic fracture mechanics problem are presented. S-IGA follows the idea of s-FEM (s-version finite element method [2]). IGA patches for the structure/solid as whole and for local features such as cracks are generated separately. Then, they are superposed. It is noted that modeling local features such as cracks are not an easy task in the applications of IGA because the patch structures are always hexahedrons. S-IGA enables us to build models for the structure as whole and those for local features such as crack separately. Hence, the generations of computational model with such local features became much more tractable than the IGA alone. In a similar way of the thoughts, technique such as X-IGA which is the IGA version of X-FEM was proposed (see, for example, De Luycker et al. [3]). In this paper the equation formulation of S-IGA, computations of stiffness matrices including the coupling stiffness matrix, the singular patch method that can reproduce the so-called square root singularity and the numerical implementations of J- and interaction integral methods that are suited to the IGA are introduced. Then, the condition to guarantee the accuracy of evaluated stress intensity factors are presented.

A COMPUTATIONAL FRAMEWORK FOR OPTIMIZING PERSONALIZED LOW DOSE METRONOMIC THERAPY

Lois Okereke[*1], Ernesto Lima[1], Anna Sorace[2] and Thomas Yankeelov[1]*

[1]The University of Texas at Austin
[2]University of Alabama-Birmingham

ABSTRACT

Low dose metronomic therapy (LDMT) is the frequent administration of cytotoxic drugs at low doses over prolonged periods without extended breaks. LDMT has emerged as a promising cancer treatment strategy for enhancing patient's overall quality of life, due to its potential to maximize progression free survival while minimizing adverse effects. However, optimizing LDMT on a patient-specific basis remains a challenging problem. Towards this end, we are developing mathematical models to characterize the main effects of cytotoxic drugs on both tumor growth and toxicity. More specifically, we include the therapeutic effects of different modes of drug delivery, as well as directly account for treatment induced toxicity. Using these models we identified (theoretically) patient-specific regimens that can effectively induce and maintain tumor stability (in the sense of the Response Evaluation Criteria in Solid Tumors, RECIST) while keeping treatment induced toxicity below a desired threshold. We found that LDMT requires lower steady state drug concentration when compared to regimens designed for tumor eradication. For tumors with a pre-treatment volume to carrying capacity ratio (i.e., proliferation saturation index) between 0.1 and 0.2, LDMT can yield up to a 34.6% reduction in total dose. Furthermore, we used in silico experiments to illustrate the therapeutic effects of the treatment regimens identified by our models. The simulation results show that tumor control is sustained. The tumor size remains bounded between 34.3% and 172.8% of the pre-treatment volume, with toxicity maintained below the desired threshold at all times. Our study generates hypotheses that can be directly tested in experimental settings, thereby providing a computational approach for rigorously designing personalised therapeutic regimens that balance efficacy and toxicity

OPTIMAL SENSOR PLACEMENT FOR STRUCTURAL HEALTH MONITORING

Knut Morten Okstad[*1], Adil Rasheed[1], Trond Kvamsdal[1] and Daniel Menges[2]*

[1]*SINTEF Digital*

[2]*Norwegian University of Science and Technology*

ABSTRACT

Efficient structural health monitoring (SHM) relies heavily on strategically placing sensors to optimize associated costs related to sensors, data collection, transfer, and processing. Precise sensor positioning at critical points within a structure not only ensures accurate data collection but also minimizes redundancy in measurements. This strategic placement facilitates the development of computationally efficient online anomaly detection systems.

In this study, we explore the application of compressed sensing techniques for full order reconstruction from sparse measurements. Compressed sensing involves solving an under-determined system, assuming the signal to be reconstructed is either sparse or can be sparsified through transformation. Typically, a generic basis is used for representing the sparse signal, requiring the solution of an L1 optimization problem, see [1]. However, when we possess system understanding or prior information, a customized basis can be created, simplifying the optimization problem.

Our focus here is on a simply supported plate problem subjected to dynamic loads. Utilizing proper orthogonal decomposition of snapshots from numerical simulations, we create a custom basis. A QR decomposition of the matrix formed by this custom basis identifies optimal sampling locations for data collection. The results demonstrate promising outcomes, highlighting the method's ability to accurately reproduce dynamic responses with acceptable precision using a minimal number of sensors. In the domain of structural health monitoring, the meticulous positioning of sensors is paramount, directly influencing the system's capacity to safeguard infrastructure integrity. This research contributes to advancements in structural engineering and risk mitigation by emphasizing the critical role of sensor placement in enhancing monitoring capabilities.

REAL-TIME FORWARD AND INVERSE SIMULATIONS OF TIME-HISTORY DYNAMIC STRUCTURAL RESPONSES USING PINNS AND AR VISUALIZATION

Toko Okuda[*1] and Mayuko Nishio*[1]

[1]*University of Tsukuba*

ABSTRACT

Real-time simulation to structural responses with use of extended reality (XR) technologies to visualize results of numerical calculations is expected to realize more interactive applications of digital twins. However, some numerical calculations including the time-history analysis of structural dynamic response increase difficulties of realizing real-time performance due to computational cost of numerical integration. In this study, authors focus on the application of physics-informed neural networks (PINNs) to overcome those difficulties on a real-time structural vibration analysis. PINNs incorporate physical laws represented by partial differential equations (PDE) into the loss function, allowing for synergistic integration of physical models and data-driven methods, and it can be applied to both forward and inverse problems. This paper shows predictions of dynamic displacement and bending moment of a cantilever beam in synchronization with real-world phenomena by applying the PINNs. Here, the inputs of neural network (NN) are time and beam coordinates, and the outputs are the displacement and bending moment of the cantilever beam. The loss function includes not only the mean square error term of observation data but also those for satisfying the equation of motion of damped free vibration of a continuous beam and their boundary/initial conditions. A sequential PINNs were then developed to realize the real-time simulation. PINNs trainings and predictions are performed at each time interval close to the vibration period, and the NN weights obtained for prediction in the previous time interval are carried over to the training in the next time interval. The outputs of PINNs, displacements and bending moments through the axial coordinate of the beam at time t, were converted to color contours for intuitive understanding, and then displayed in the augmented reality (AR) on the real beam. In addition, PINNs can make unknown properties included in the PDE prediction parameters at the same time in the training process. The verification for the free vibration of a cantilever beam, whose bending stiffness changes in the beam axis direction, was conducted to verify effectiveness of the sequential PINNs to simultaneously predict displacements and bending moments (forward analysis) and estimate the bending stiffness (inverse analysis). The study suggests possibility of real-time data assimilation, which might contribute to the development of digital twin technology in the future.

PHASE-FIELD SIMULATION OF SOLUTE SEGREGATION IN A RAPIDLY SOLIDIFIED HASTELLOY-X NI-BASED SUPERALLOY DURING LASER POWDER-BED FUSION

Masayuki Okugawa[*1], Kenji Saito[1], Haruki Yoshima[1], Katsuhiko Sawaizumi[1], Yuichiro Koizumi[1] and Takayoshi Nakano[1]*

[1]*Osaka University*

ABSTRACT

Additive manufacturing (AM) technologies have attracted considerable attention as they allow us to build three-dimensional parts with complex geometries easily. Among the wide range of available AM techniques, powder-bed fusion (PBF) has emerged as a preferred technique for metal AM. In particular, PBFed Ni-based superalloys are desired to be applied to aerospace industries. However, solute segregations become remarkable during the process [1] and increase the susceptibility to cracking [2]. Therefore, an understanding of solute segregation is essential for the fabrication of reliable PBF-fabricated parts while avoiding cracks. In the present study, we simulated solute segregation in a conventional solid-solution hardening-type Hastelloy-X Ni-based superalloy under the PBF process by a multi-phase field (MPF) simulation using the temperature distributions obtained by a computational thermal-fluid dynamics (CtFD) simulation.

The single-track laser-beam irradiation CtFD simulation of HX was performed using a 3D thermo-fluid analysis software (Flow Science FLOW-3D® with Flow-3D Weld module). The dimensions of the computational domain of the numerical model were 4.0 mm × 0.4 mm × 0.3 mm. The beam power and scanning speed were set to 300 W and 600 mm/s, respectively. Then, two-dimensional MPF simulations with the temperature distributions obtained by the CtFD simulation were performed using the Microstructure Evolution Simulation Software (MICRESS) with the TQ-Interface for Thermo-Calc. The simulation domain was 5 × 100 μm, and the grid size Δx and interface width were set to 0.025 and 0.1 μm, respectively. The model was solidified under the temperature field distribution obtained by the CtFD simulation. The concentration distribution and crystal orientation of the solidified model were examined.

We found that the conventional MPF model can reproduce experimentally observed dendritic structures by performing a phase-field simulation using the temperature distribution obtained by a CtFD simulation of HX. The MPF simulation revealed that the segregation behavior of solute elements largely depends on the regions of the melt pool, such as the cell boundary, the interior of the melt-pool boundary, and heat-affected regions. The sensitivities of the various interfaces to liquation and solidification cracks are compared based on the predicted concentration distributions. Moreover, the feasibility of using the conventional MPF model for PBF is discussed in terms of the absolute stability limit.

[1]*The University of Texas at Austin*
[2]*Caltech*

ABSTRACT

We consider the Bayesian inverse problem of inferring heterogenous material parameters from displacement measurements of an elastically-deforming system. The Bayesian inverse problem is challenging due to the infinite-dimensional nature of the parameter field. We present neural operator representations of parametric PDE solution operators (specifically, mappings of material property to deformation in elasticity) that also learn the Fréchet derivatives of these operators with respect to the parameter field. When trained, these derivative-informed neural operators (DINOs) enable scalable and efficient MCMC sampling methods, which employ gradients and Hessians of negative log posteriors to accelerate the sampling. The DINO can be used as a proposal mechanism in a delayed-acceptance MCMC method to obtain asymptotically exact posterior samples, or as a replacement for the PDE when its repeated solution is prohibitive. In either case, the resulting methods can obtain significantly larger effective sample sizes than existing methods, for a given compute budget. Numerical experiments involving non-destructive evaluation of materials as well as inversion of elastic parameters for the 2011 Tōhoku earthquake are presented.

The presentation is based in part on "Derivative-Informed Neural Operator: An Efficient Framework for High-Dimensional Parametric Derivative Learning" (Journal of Computational Physics, 2024), "Derivative-informed projected neural networks for high-dimensional parametric maps governed by PDEs", (Computer Methods in Applied Mechanics and Engineering, 2022), and the manuscript "Efficient Geometric Markov Chain Monte Carlo for Bayesian Inversion Enabled by Derivative-Informed Neural Operators" (2024).

TOPOLOGY OPTIMIZATION OF AN AIRFOIL UNDER MASS AND NATURAL FREQUENCY CONSTRAINTS USING GAUSSIAN FUNCTION PARAMETERIZATION

Daniel Oluwalana[*1] and Kai James*[1]

[1]*Georgia Institute of Technology*

ABSTRACT

Key Words: Topology Optimization, Gaussian Function Parameterization, Frequency Constrained Structures, Aerostructural Design

Topology optimization is a procedure focused on enhancing the structural efficiency of a design subject to physical constraints such as mass, stress, deflection, and frequency. This method strategically distributes material across a design domain to optimize performance. This study focuses on a modified two-dimensional NACA 0012 airfoil under prescribed flight conditions. Central to our methodology is integrating mass and minimum natural frequency constraints to enhance material distribution within this redesigned airfoil structure. Gaussian function parameterization [1] is also employed to optimally distribute the structural supports that hold the airfoil in place. We formulate the frequency constraint as a bounded eigenvalue problem involving a combination of scaled stiffness and mass matrices. To identify the lowest natural frequency, we employ the Kreisselmeier–Steinhauser (KS) aggregation function, which is applied to the set of all computed frequencies. This function is chosen for its smoothness and differentiability. Additionally, we compute frequency constraint sensitivities using an adjoint-based method for derivative evaluation applied to the KS function.

Our approach diverges from traditional methods by allowing flexibility in the placement of supports while keeping the aerodynamic load distribution fixed. In this way, we are able to optimize support locations concurrently with the internal airfoil structure, thereby improving the design's structural and aerodynamic performance. The study compares two different optimization strategies: the Method of Moving Asymptotes (MMA) [2] and the Generalized Optimality Criteria (GOC) Method [3]. We compare the performance of each optimization algorithm to gain knowledge about the ability of each method to handle this unique problem, which combines SIMP density parameters with explicit geometry parameters.

The study's outcomes illuminate the potential of this integrated approach in topology optimization, especially for structures where aerodynamic performance is as crucial as structural integrity.

COMPUTATIONAL MOLECULAR MAGNETIC RESONANCE IMAGING IN DIGITAL HEALTH AND PETRO-PHYSICS DESIGN

Awojoyogbe Omotayo[1] and Michael Dada*[1]

[1]*Federal University of Technology*

ABSTRACT

Understanding of processes such as carrier mobility, electron transfer reactions, chemical reactions in fluids, electron solvation in fluids and electron attachment and localization in clusters relies crucially on the understanding of electron dynamics in fluids at the molecular level.
In this talk we present mathematical and computational concepts (generally applicable to the analysis of biological and non-biological systems) at the molecular level with special application to digital health and petro-physics design.

i. Digital health and petro-physics design can be likened to complex systems and are often dominated by large numbers of processes. For example, when deviations occur in normal human system, human disease conditions are produced. Understanding these processes is important not just in unravelling the causes of diseases, but also the manner of disease propagation and the best plan for treatment. The inadequate understanding of molecular dynamics of diseases is one reason why many diseases remain incurable and become life-threatening. Computational molecular magnetic resonance imaging now provides new ways of visualizing molecular dynamics and management of human diseases.

Currently, the available imaging equipment no longer matches the increasing number of patients requiring healthcare. The few available imaging machines are costly to maintain while financial difficulties are making acquisition of new ones nigh impossible. Obviously, experimental methods alone are no longer enough for efficient diagnosis, therapy and prognosis. These challenges may now require development of appropriate mathematical tools and sophisticated computer simulations based on the Bloch NMR flow equations to complement laboratory and clinical observations. Such mathematical techniques [1] have the potential to provide insight into the imaging of molecular interactions through the analysis of relaxation processes as observed on computational molecular magnetic resonance.

ii The mathematical technique [1] is unique, flexible, adaptable and generally applicable for the analysis of matter (physical and biological). The technique is useful to design NMR signals of different petro-physical properties such as porosity, tortuosity and relaxation rate of rocks fluid so that reservoirs comprised of mixed lithology and mineralogy can be easily evaluated. The computational tools are useful for repetitive data processing which is otherwise difficult due to hardware limitations and logistic issues.

ABSTRACT

In this study, we have developed an unresolved coupling model based on a drag model for Computational Fluid Dynamics (CFD) and Finite Element Method (FEM) using beam element. The proposed method involves conducting structural analysis by considering the fluid forces obtained through the drag model as external forces. Simultaneously, fluid analysis is performed, taking into account apparent volume changes and alterations in the flow field around the beam element.

As a result, even in cases where the spatial resolution of the fluid is coarse concerning the dimensions of the beam element, coupled calculations based on the drag model become feasible as long as the velocity field is appropriately obtained. Consequently, this approach proves to be suitable for large scale tsunami-structure interaction problem, including the process of houses in a coastal area being washed away by a tsunami.

In the presentation, we elucidate the formulation and implementation of the proposed methodology, and present validation results regarding the fluid forces acting on beam elements subjected to unsteady free-surface flow. Furthermore, to demonstrate the utility of the proposed approach, simulation results are presented where a wooden house models is subjected to flows mimicking a tsunami, leading to their loss.

EQUATION DISCOVERY THROUGH GENETIC PROGRAMMING REFLECTING THE IMPORTANCE OF GENERATED TERMS

Kenji Ono[*1] and Kanae Shiragami*[1]

[1]*Kyushu University*

ABSTRACT

Efforts to estimate equations from data have garnered significant attention in a data-driven context, and recently, deterministic methods employing sparse estimation have been the focus of interest. In this paper, we propose an efficient method for estimating equations by adopting an exhaustive approach using genetic programming while evolving generations, all while retaining useful partial terms for expressing the equation. In our proposed method, genetic programming generates terms of partial differential equations, and the error between the equation constructed from these terms and the data is evaluated. Even if important terms are present in the generated equation, if the candidate equation itself receives a low score, it may lead to a long computation time to obtain an optimal solution or potentially fail to find one. To address this issue, we introduce Evolutionary Feature Synthesis (EFS), which combines multiple regression. We incorporate fitness, indicating how well candidate equations match the data, as well as importance measures for individual terms in the equation, making the search more effective. As a validation step, we conducted numerical experiments to estimate the governing equation from fluid simulation data and evaluated the validity of the proposed method. The data used in our numerical simulation were generated by solving one-dimensional linear advection, non-linear advection, and diffusion equations with various initial conditions.

The proposed approach demonstrated its ability to provide appropriate partial differential equations in both cases. As a result, it was shown that the proposed method can reproduce the original equations from simulated Computational Fluid Dynamics (CFD) data without prior knowledge of fluid dynamics. Additionally, to reduce the estimation time, an investigation was conducted to determine how much data is required to accurately estimate the equations. It was observed that a significant reduction in estimation time can be achieved by using a certain amount of temporal data, and the reduction of spatial data had a phenomenon-dependent impact on estimation accuracy.

ABSTRACT

A suction-bucket is being developed as a foundation structure for a fixed-type offshore wind turbine. The suction-bucket is a cylindrical structure with a closed top surface. In the construction of suction-bucket, the bucket is submerged until the bottom edge touches the seabed. Then, seawater inside the bucket is forcibly discharged to increase a difference in hydrostatic pressure, which is called suction pressure, between inside and outside of the bucket, causing the bucket to penetrate the seabed. The bucket installed to a predetermined depth by this method can be used as the foundation structure for the offshore wind turbine facility.

The suction pressure is an important indicator in design and installation of this foundation. An excessive suction pressure causes buckling of steel structure and ground failures, while an insufficient suction pressure causes an insufficient penetration during the installation. Especially in sandy soil, seepage flow will be generated in the ground due to the pressure gradient and it makes more difficult to evaluate suction pressure. Moreover, the seepage flow may change the soil properties and cause seepage failures.

In this study, to take into account changes in the soil properties during installation of the suction-bucket and to evaluate the suction pressure properly, a coupled model has been developed by coupling discrete element method (DEM) for describing behaviors of soil particles and computational fluid dynamics (CFD) for describing the seepage flow. In general, spherical particles larger than actual soil particles are used in large-scale DEM simulations to reduce computational load. However, it is difficult to simultaneously represent changes in hydraulic properties (pore structure) and mechanical properties of soil masses constituting the ground. For example, although large frictional or rotational resistance is necessary to reproduce the porosity of loose soils, high resistance makes it difficult to change into dense soils.

Therefore, we developed a model that can simultaneously satisfy both these hydraulic and mechanical properties as a single spherical DEM particle. This model can be used to perform large-scale coupled CFD-DEM simulation with a low computational load that properly account for changes in soils. The results of verifying the applicability of this model through model experiments are reported in this presentation.

AIR-TAXI TRAJECTORY AND DESIGN OPTIMIZATION USING SURROGATE MODELS

Nicholas Orndorff[*1] and John Hwang*[1]

[1]*University of California, San Diego*

ABSTRACT

Urban air mobility is an emerging vision with the potential to radically transform urban transportation. The air taxi concepts that are being proposed to enable this vision are capable of vertical takeoff followed by horizontal cruising flight. The transition from takeoff to cruise is dominated by nonlinear dynamics and complex, multidisciplinary interactions. As such, this transition significantly influences both the design and the performance of the aircraft. However, the complexity of the transition trajectory makes it difficult to include trajectory optimization and analysis in the preliminary design process. We address this by creating a co-design problem, wherein the physical parameters of the aircraft are simultaneously optimized along with the transition trajectory. The co-design problem is solved by forming a gradient-based multidisciplinary design optimization (MDO) framework which contains standard aerospace disciplines (e.g., aerodynamics and structures) as well as control. We optimize aircraft trajectories by transcribing the continuous-time optimal control problem as a discrete-time nonlinear programming (NLP) problem with collocation points where the state and the control are simultaneously defined. This method, known as shooting, integrates the equations of motion over time in order to determine the state trajectories for given control inputs. During optimization, the optimizer acts as an omniscient controller by iteratively selecting controls that minimize our objective and satisfy the constraints. Within the NLP problem we include five physics-based sub-discipline models. However, some of the physical phenomena we wish to model are complex. In that case we rely upon automatic differentiation to simplify the implementation. Some of these complex models are still too computationally expensive to include, or they contain numerical singularities for certain inputs. In this case we use radial-basis functions and tensor-product splines as surrogate models which not only reduce complexity, but also maintain fidelity and increase robustness. These surrogates are trained on data that is generated offline using the original physics-based models. This novel, surrogate-based trajectory-optimization approach is fast and robust, which means that it is well suited to co-design problems where the trajectory must be optimized many times within an inner loop of a larger aircraft design problem. Additionally, by using physics-based models we can compute actual physical objectives for the trajectories (e.g., minimum energy and minimum time) as well as for the air-taxi design (e.g., minimum mass) that are of interest to industry as well as academia.

TURBULENCE SUBGRID CLOSURE FOR THE LATTICE BOLTZMANN METHOD VIA ARTIFICIAL NEURAL NETWORKS

Giulio Ortali[*1], Nicola Demo[2], Alessandro Gabbana[1], Gianluigi Rozza[2] and Federico Toschi[1]*

[1]*Eindhoven University of Technology*
[2]*International School for Advanced Studies*

ABSTRACT

This work introduces a novel approach to learning Turbulence Subgrid Closure models within the context of Lattice Boltzmann Method using physics-constrained Artificial Neural Networks.
The Lattice Boltzmann Method (LBM) is a class of computational methods, stemming from the kinetic theory of gases, used to simulate the dynamics of fluid flows at the mesoscopic level. The fluid is represented via the dynamics of a set of discrete particle distribution functions (populations). These populations evolve according to the stream and collide algorithm, where at each time step populations hop from lattice-site to lattice-site and then incoming populations collide among one another. We work in the context of 3D Homogeneous Isotropic Turbulence on a cube with periodic boundary conditions, considering a fully resolved setting, generating ground truth Direct Numerical Simulation (DNS) data, and different coarse graining factors.
We learn a novel collisional term, expressed as a correction to the BGK collisional operator, using a physics-constrained Artificial Neural Network trained on DNS data. The model comprises a standard Multi-Layer Perceptron, followed by post-processing layers enforcing mass and momentum conservation, trained on multi-step prediction.
The proposed model shows promising results, closely capturing both energy spectra and higher-order statistics of filtered DNS data compared to traditional techniques such as the Smagorinsky turbulence model. Remarkably, our approach is fully local both in space and time, leading to reduced computational costs, enhanced generalization capabilities and interpretability. Additionally, this formulation can be in principle used to learn any new collisional operator, given the proper ground truth data, and to acquire a deeper understanding in the physics of turbulent flows.

DEVELOPMENT OF A DEFORMATION TECHNIQUE FOR VASCULAR ANALYSIS MODELS USING VESSEL CENTERLINES

Naoya Imai[1], Chen Wang[1], Masaharu Kobayashi[1] and Marie Oshima[1]*

[1]The University of Tokyo

ABSTRACT

In order to provide an appropriate diagnosis for unruptured cerebral aneurysms, a follow-up examination is often performed by medical images to observe growth in a size of aneurysm and changes in hemodynamic factors such as a magnitude of wall shear stress. However, since medical images taken at various times are considered different images even of the same patient, mesh generation is conducted for each geometry model to create individual analysis models. Because of different analysis models, it is difficult to compare changes quantitatively in simulations results between analysis models. Therefore, it is important to compare simulation results with the same number of mesh elements and nodes.

In this study, we develop a method to transform the analysis model into a target one using centerlines. The method consists of five steps. In the first step, the three-dimensional vascular models served as standard vascular model as well as target ones are segmented and constructed from medical images taken at different times. In the second step, the centerlines of both models are extracted[1]. In the third step, the analysis model of standard vascular model is created by using Gmsh[2], which is a three-dimensional finite element mesh generator. The fourth step provides the information on connection between centerline and surface triangular meshes. In the final step, the target analysis model is created by transforming the centerline of the standard analysis model into that of target analysis model by applying transformation matrix between standard and target ones. The surface of target analysis model can be also transformed using connection information of centerline and surface triangular meshes. The smoothing method is also developed to smooth distorted surface meshes[3].

The verification and validation of the present model was conducted using the simple geometry. The present method was also applied to patient-specific simulations of femoral artery, in which CT images were taken at three different bending angles. The geometry and the simulation results were compared between three cases.

FLOW SIMULATION BASED ON THE IMMERSED-INTERFACE APPROACH OF MULTIPHASE, COMBUSTION FLAME AND WALL BOUNDARY

Nobuyuki Oshima[*1], Nobuto Nakamichi[1] and Younghwa Cho[1]*

[1]*Hokkaido University*

ABSTRACT

A most typical target of flow simulation is to get a solution under the boundary shape of fluid, which may be given by the wall-boundary or interactively solved as the phase interface. It becomes difficult as the shape or dynamics of boundary becomes complex. In order to treat the complex interface problem, level-set approach is a useful mathematical tool, where a volume profile of scalar function defines the interface as similar as physical solution of fluid flow variables.

Oshima [1] has mathematically examined the conservation law equation governing the fluid interface assuming a combustion flame and a phase interface and related them to the viscosity solution of the level-set equation. It is shown that the phase field approximation of the non-equilibrium phase boundary and the flamelet approximation of the combustion field can be derived. These are formalized by differential equations associated with physical conservation laws derived from the principle equations for the macroscopic behavior of the fluid interface, with additional steps (e.g. reinitialization of the level-set solution) and special By constructing the discretization formula without using numerical approximation (for example, artificial viscosity by upwind difference), mathematical analysis of the accuracy and stability of the numerical method based on this has become easier.

Next question is “Can we assume a principle equation that satisfies a continuous physical solution of solid wall boundary with the modeling resolution?”. Furthermore, looking at the development of model-based design (MBD), which attempts to construct a unified methodology by digitizing everything from design concepts to performance prediction, manufacturing methods, and product evaluation, Discretization of solid boundaries also requires a systematic research method supported by universal mathematical foundations. Oshima [2] has proposed a kind of its answer as the following equation system, where a fluid occupancy function defines the solid wall boundary.
These immersed-interface approaches make us essentially free from a “grid-generation” which may insists a huge efforts of engineering simulation. This research introduces several examples in two/three-dimensional, steady/unsteady solutions applied to multiphase flow, combustion flame and wall boundary problems.

MODELING SHORT CRACK PROPAGATION IN 3D POLYCRYSTALLINE MICROSTRUCTURES UNDER CYCLIC LOADING USING ADAPTIVE CRACK INSERTION

Damin Xia[1] *and Caglar Oskay**[1]

[1]*Vanderbilt University*

ABSTRACT

In this study, we present a computational framework for simulating microstructurally short crack propagation in three-dimensional polycrystalline microstructures subjected to fatigue loading. Fatigue initiation process that broadly consists of nucleation of a short crack and growth of the short crack until the crack reaches sufficient length to grow based on Paris's criterion. Under certain loading conditions, fatigue initiation life could take a very substantial part of the overall fatigue life. Currently, fatigue initiation prediction models rely on the idea of tracking a fatigue indicator parameter, which does not explicitly account for short crack growth.

The proposed framework integrates a texture-dependent crack propagation criterion, crystal plasticity finite element modeling, and an adaptive crack insertion technique. We address two primary challenges that are present particularly in the context of modeling 3D short crack growth: firstly, the implementation of a distance-based smoothing technique to mitigate stress and strain oscillations at the crack tip, and secondly, the use of an adaptive local smoothing mechanism during each growth step to minimize error accumulation. The efficacy of each component of the proposed framework is detailed and tested. The proposed framework is constructed in a modular fashion such that different and material specific propagation criteria could be incorporated. Numerical investigations indicates that the proposed framework could efficiently simulate short crack growth until fracture in both full 3D and quasi-2D polycrystalline microstructures, capturing the phenomena of crack tilting and twisting, which are prominent in experimental observations of 3D crack growth. The proposed short crack propagation framework contributes to the understanding and prediction of short crack growth in polycrystalline materials.

MODELING OF SOFT MULTISTABLE STRUCTURES

Juan Osorio[1] and Andres Arrieta*[1]

[1]*Purdue University*

ABSTRACT

Reconfigurable structures, soft materials, and metamaterials have introduced new opportunities for mechanical computation, control complexity reduction, and shape programmability. Recently, architecture materials composed of patterned arrays of bistable units have gained interest due to their capabilities of exhibiting multiple energy minima, unit activation path dependency, and influence of local prestress in its global shape. As each unit cell can be reversibly inverted at a local scale, multiple stable shapes at a global scale are achieved. These shapes are highly dependent on the unit geometry, inversion sequence, number of units, and unit spatial distribution, which makes their behavior challenging to analyze and predict. Given this, simpler yet robust models need to be utilized to predict the final state of the structure, enabling faster analysis for inverse design.

This work presents a lumped-element model to determine the final shape of our metastructure in terms of the number of units, spatial distribution, and unit cell geometric parameters. We explore the effect of interrelations between units and their spatial arrangement in our metastructure's global stable shape, enabling us to target specific target positions. We further examine the interaction between units and their role in generating geometric frustration within the structure and allowing us to determine optimal strategies to leverage all these multiple states in applications such as soft robotics and mechanical computation. This opens a route for the fast design of multistable soft robots and shapes targeting of soft metastructures.

REDUCED-ORDER MODELING WITH AND WITHOUT LINEARIZED ADJOINTS

Samuel Otto[1], Nicolas Boulle[2], Diana Halikias[3] and Alex Townsend[3]*

[1]*University of Washington*
[2]*University of Cambridge*
[3]*Cornell University*

ABSTRACT

Reduced-order modeling entails identifying a low-dimensional collection of variables that can be used to reliably predict a system's response or output. Techniques such as Randomized Singular Value Decomposition (RSVD), active subspaces, Balanced Proper Orthogonal Decomposition (BPOD), and the recently introduced Covariance Balancing Reduction using Adjoint Snapshots (CoBRAS) rely on adjoints to extract these variables efficiently. Since the adjoint is often difficult or impossible to access in practice, we study the extent to which adjoints are required, and what types of prior information allow us to avoid accessing the adjoint in the simplified setting of linear operator learning. While our analysis shows that some information about the adjoint is required, this information can come from prior knowledge about the operator's properties rather than direct queries to an adjoint solver. For nonnormal elliptic PDEs, we show that regularity properties provide useful information that can be leveraged to construct low-rank approximations with guaranteed accuracy from queries to the forward solution operator only. The queries are constructed using eigenfunctions of a prior self-adjoint operator such as the Laplace-Beltrami operator (LBO). Intuitively speaking, the smoothing properties of the solution operator limits the system's sensitivity to high-wavenumber inputs. Specifically, if elliptic regularity guarantees that solutions of the adjoint equation would have k weak derivatives in L^2 and the spatial domain has dimension d, then our approximation of the solution operator based on queries using the leading n eigenfunctions of the LBO has asymptotic error $\mathcal{O}(n^{-k/d})$ with respect to the operator norm. We demonstrate this approach numerically by constructing low-rank approximations for solution operators of an advection-diffusion equation ($k=2$) with space dimension $d=1$ and for linear elasticity problems ($k=2$) with space dimensions $d=2$ and $d=3$.

PHASE-FIELD MODELING OF ELASTIC MICROPHASE SEPARATION

Hamza Oudich[*1], Pietro Carrara[1] and Laura De Lorenzis[1]*

[1]*ETH Zurich*

ABSTRACT

Spinodal decomposition is a process where an initial homogeneous but unstable mixture spontaneously separates
into two or more stable phases with a distinctive arrangement termed spinodal structure. This process can be modeled with the Cahn-Hilliard equation [1] which is based on the definition of a chemical energy density depending on an order variable, i.e. the phase field, representing the smooth transition between the unstable initial mixture and the stable phases. Spinodal structures are characterized by a length scale that, if no competing processes are accounted for, coarsens over time until complete segregation of the stable phases. Recent studies suggest that for certain mixtures involving a solid matrix, the elastic parameters of the matrix govern the coarsening stage and can even arrest it, a phenomenon that is denoted as elastic microphase separation [2].

In this work, we propose a phase-field model that captures the main features of elastic microphase separation observed in [2]. We extend the Cahn-Hilliard free-energy functional [1] to include the elastic strain energy density as well as an additional coupling term. The model is first investigated in 1D and the results show that the mechanical deformation controls both the composition of the stable phases and the initial characteristic length of the spinodal structure. Moreover, we numerically show that the proposed coupling is able to predict the arrest of the coarsening phase at a length scale controlled by the model parameters. The formulation is then extended to the multi-dimensional setting and compared to experimental results. The numerical results show excellent agreement with the experimental evidence, especially in terms of initial and arrested pattern morphology.

CONCERNING ADAPTIVE REFINEMENT FOR FEM APPROXIMATIONS OF MULTIPLE EIGENVECTORS OF SCHROEDINGER-TYPE OPERATORS

Jeffrey Ovall[*1] and Stefano Giani*[2]

[1]*Portland State University*
[2]*Durham University*

ABSTRACT

Techniques for a posteriori error estimation and adaptive algorithms for clusters of eigenvalues and their associated invariant subspaces have received significant attention over the 15 years. The general consensus is that, regardless of the particular error estimation technique and/or marking strategy, the goal of an adaptive step is not necessarily to reduce the approximation error associated with the current computed eigenbasis, but rather to reduce the error associated with its span. Independently, but over roughly the same period, significant advances have been made in the understanding of eigenvector localization, i.e. the strong concentration of the "mass" of some eigenvectors in relatively small portions of the domain, for Schroedinger-type operators. Spatial localization of such eigenvectors implies similar spatial localization of associated wave phenomena, and this has practical applications in the design of materials and structures. In this talk, we bring together these two threads of research, presenting a non-standard adaptive approach in this context that provides surprisingly(?) good performance.

SURROGATE-BASED PARTITION METHODS FOR INTERFACE PROBLEMS

Justin Owen[*1], Pavel Bochev[1] and Paul Kuberry[1]*

[1]*Sandia National Laboratories*

ABSTRACT

Partitioned methods for coupled problems rely on data transfers between subdomains to synchronize the sub- domain equations and enable their independent solution. By treating each subproblem as a separate entity, these methods enable code reuse, increase concurrency and provide a convenient framework for plug-and-play multiphysics simulations. However, accuracy and stability of partitioned methods depends critically on the type of information exchanged between the subproblems. The exchange mechanisms can vary from minimally intrusive remap across interfaces to more accurate but also more intrusive and expensive estimates of the necessary information based on monolithic formulations of the coupled system. These transfer mechanisms are separated by accuracy, performance and intrusiveness gaps that tend to limit the scope of the resulting partitioned methods to specific simulation scenarios. Data-driven system identification techniques provide an opportunity to close these gaps by enabling the construction of accurate, computationally efficient and minimally intrusive data transfer surrogates. This approach shifts the principal computational burden to an offline phase, leaving the application of the surrogate as the sole additional cost during the online simulation phase. In this paper we formulate and demonstrate such a surrogate-based partitioned method for a model advection-diffusion transmission problem by using Dynamic Mode Decomposition (DMD) to learn the dynamics of the interface flux from data. The accuracy of the resulting DMD flux surrogate is comparable to that of a dual Schur complement reconstruction, yet its application cost is significantly lower. Numerical results confirm the attractive properties of the new partitioned approach.

CONFIGURABLE ML-POWERED DEFEATURING FOR SIMULATION

Steven Owen[*1]*

[1]*Sandia National Laboratories*

ABSTRACT

In the rapidly evolving field of computational mechanics, the integration of machine learning (ML) has emerged as a transformative force. This abstract highlights our ongoing work at Sandia National Laboratories, where we leverage the power of ML to streamline and enhance the design-to-simulation process.

Design-to-simulation encompasses a multitude of intricate tasks, often characterized by their user-intensive, time-consuming, and error-prone nature. Our focus has been on identifying and targeting the most cumbersome aspects of this process, in collaboration with domain experts and analysts. Through close examination of their workflows, we endeavor to harness ML technologies to make their tasks more efficient, less prone to errors, and less tedious.

We have previously developed ML-based tools for defeaturing that employ a supervised learning procedure, utilizing decision tree methods. This approach, focused on enhancing design-to-simulation, has been a part of our ongoing efforts. This approach has proven to be both accurate and efficient. It not only predicts meshing outcomes but goes a step further by predicting the "best" CAD operations compatible with, Cubit(R), a CAD based tool used for geometry preparation and meshing.

The training of our ML models is grounded in a large dataset comprising thousands of CAD models and their corresponding meshes, along with the operations applied to them. This rich dataset forms the foundation upon which our ML algorithms make informed predictions, facilitating a smoother and more streamlined simulation process.

In this presentation, we will discuss our progress on a new configurable ML-based defeaturing environment. This environment incorporates the insights gained from our ML models, enhancing predictions for physics-specific simulation models. By combining the power of ML with the expertise of seasoned analysts, we aim to provide accurate predictions that not only optimize meshing but also select the most suitable CAD operations.

A MASS CONSERVATIVE FINITE ELEMENT METHOD FOR A NONISOTHERMAL NAVIER-STOKES/DARCY COUPLED SYSTEM

Jessika Camaño[1], Ricardo Oyarzúa[2], Miguel Serón[2] and Manuel Solano[3]*

[1]Universidad Católica de la Santísima Concepción
[2]Universidad del Bio-Bio
[3]Universidad de Concepción

ABSTRACT

We propose and analyze an H(div)-conforming and mass conservative finite element method for the coupling of nonisothermal fluid flow with nonisothermal porous media flow. The governing equations are the Navier-Stokes/heat system, commonly known as the Boussinesq system, in the free-fluid region, and the Darcy-heat coupled model in the membrane. These systems are coupled through buoyancy terms and a set of transmission conditions on the fluid-membrane interface, including mass conservation, balance of normal forces, the Beavers-Joseph-Saffman law, and continuity of heat flux and fluid temperature. We consider a velocity-pressure-temperature variational scheme for the Boussinesq system in the free-fluid region whereas in the membrane region we consider a dual-mixed formulation for the Darcy system coupled with a primal equation for the temperature model.
In this way, the unknowns of the resulting formulation are given by the velocity, pressure and temperature in both domains.
For the associated Galerkin scheme, we combine an H(div)-conforming scheme for the fluid variables and a conforming Galerkin discretization for the heat equation. Therefore, the resulting numerical scheme produces exactly divergence-free velocities and also allows preserve the law of conservation of mass at a discrete level. The analysis of the continuous and discrete problems is carried out by means of a fixed-point strategy under a sufficiently small data assumption. We derive optimal error estimates under an additional assumption over the data and present numerical results illustrating the performance of the method.

FIBREPLUG: A MULTISCALE TEXTILE COMPOSITES MODELING TOOL

Jide Oyebanji[1], Changze Sun[1], Mohamed Nasr Saleh[1], Kapil Krishnan[1] and Zhongwei Guan[1]*

[1]*Technology Innovation Institute*

ABSTRACT

This study introduces a novel multi-scale modeling tool, FibrePlug [1], which advances the understanding of mechanical behavior of textile composites; combining the characteristic computational efficiency of macro-scale modeling with the ability to observe mechanical behavior of bundled filaments, which micro-scale modeling offers. When observed across multiple scales, the behavior of fibre reinforced polymer (FRP) composites significantly deviates as a function of the geometric scale under which such behaviors were observed [2]. This study, therefore, is particularly important as such understanding of the behavior of FRP across multiple scales becomes critical to the design and manufacture of components made from them. Previous attempts made towards the generation of meso-scale fabric models were limited to studying the material behavior at yarn level [3], leaving unresolved, the challenge of investigating filament-level response to practical loading applications including impact and stitching.

FibrePlug, the tool introduced in this research, is an open-source plug-in for multiscale modeling of textile composites. Developed within the ABAQUS Really Simple GUI (RSG) and Fox GUI development environments, FibrePlug advances the understanding of the behavior of composite materials beyond the limits imposed by traditional homogeneous macro- and meso-scale modeling. The plug-in allows for cross-scale modeling of textile composites.

The woven textile composite models generated with FibrePlug were validated experimentally by observing the mechanical deformation of bundled filaments under loading conditions imposed as a result of through-thickness stitching. This behavior and effective properties were observed with varying pin sizes and materials. This research opens a new domain of possibilities into investigating the responses of woven textile composites under different industrial applications including automobile, aviation and defense.

A TWO-SCALE HIERARCHICAL PHFGMC FRAMEWORK FOR THERMO-MECHANICAL PROPERTIES OF C/C-SIC CMCS

Royi Padan[*1], Chen Dahan-Sharhabani[1], Omri Regev[2] and Rami Haj-Ali[1]*

[1]Tel-Aviv University
[2]Rafeal Systems

ABSTRACT

A state-of-the-art ceramic matrix composites (CMC) design for space or hypersonic applications requires a reliable and cost-effective method for predicting, estimating, and quantifying their mechanical properties. CMCs present complex anisotropic mechanical properties. Relating the properties to the specific CMC's composition and weaving architecture is expected. However, CMCs, especially C/C-SiC, are also highly affected by the microstructure of the local multi-phase material. Therefore, it is unsurprising that many recent studies employed different micromechanical models to evaluate CMCs' material properties.

Advanced micromechanical modeling of CMCs needs to balance computational demand and proper depiction of the local microstructure. The parametric high-fidelity generalized method of cells (PHFGMC) is an efficient numerical method to solve such detailed and relatively large-size computational problems [1]. Several works have already used the general method of cells to capture the elastic properties of a filament wound C/C-SiC [2] or even to evaluate the thermo-mechanical damage of a C/SiC CMC [3]. However, these studies have some limitations, such as using a linear displacement formulation (hence, ignoring the inter-phase tension shear coupling) and describing the complex structure using an idealized geometrical model.

The current study develops a two-scale hierarchical, PHFGMC-based framework to evaluate the thermo-mechanical properties of a C/C-SiC CMC. The repeated unit cells (RUC) are defined based on Computed tomography (CT). Both nano-CT (having a 1-micron resolution) and micro-CT (10-micron resolution) techniques were used to extract different geometrical models in a two-scale hierarchy. Finally, two PHFGMC micromechanical models are nested and integrated to represent the CMC micro and meso material levels. The proposed multiscale PHFGMC framework enables a realistic depiction of the material structure and allows for calculating the effective orthotropic properties of a single layer. Preliminary calculations show good agreement with test results. The proposed modeling can be used to design a broad class of CMC materials with different weave architectures and serve as a basis for damage evaluation prediction.

VOROTO: MULTISCALE TOPOLOGY OPTIMIZATION OF VORONOI STRUCTURES USING SURROGATE NEURAL NETWORKS

Rahul Kumar Padhy[*1], Krishnan Suresh[1] and Aaditya Chandrasekhar[2]*

[1]*University of Wisconsin, Madison*
[2]*Argonne National Laboratory*

ABSTRACT

Cellular structures found in nature exhibit remarkable properties such as high strength, high energy absorption, excellent thermal/acoustic insulation, fluid transfusion, etc. Many of these structures are Voronoi-like; therefore researchers have proposed Voronoi multi-scale designs for a wide variety of engineering applications. However, designing such structures can be computationally prohibitive due to the multi-scale nature of the underlying analysis and optimization.
In this work, we propose the use of a neural network (NN) to carry out efficient topology optimization (TO) on multi-scale Voronoi structures. The NN is first trained using Voronoi parameters (cell site locations and associated thicknesses) to predict the homogenized constitutive properties. This network is then integrated into a conventional TO framework to minimize structural compliance subject to a volume constraint. Special considerations are given for ensuring positive definiteness of the constitutive matrix and maintaining microstructural connectivity. Several numerical examples are provided to showcase the proposed method.

IMPLEMENTING INTEGRATED EARTHQUAKE SIMULATOR FOR SEISMIC PERFORMANCE ASSESSMENT OF INDIAN CITIES

Mahendra Kumar Pal[*1], Nishi Singh[2] and Maddegedara Lalith[3]*

[1]Indian Institute of Technology (BHU) Varanasi
[2]Delhi Development Authority
[3]Earthquake Research Institute, The University of Tokyo

ABSTRACT

As per the records of National Center of Seismology of Indian government, more than 100 earthquakes of magnitude 3.0 or higher occurred in Indian sub-continent or neighboring region, which is evidence of increased frequency of seismic activities in the region. Increased frequency of seismic events has raised the concern over resilience of built environment in India. Moreover, unplanned Indian cities which are mainly comprised of un-engineered structures built in highly vulnerable land, are anticipated to put around 200 million city dwellers to risk against earthquake or earthquake induced disaster by 2050 according to reports of world bank and United Nation. Therefore, it is necessary to strengthen our built environment and seismic assessment is the first step in that direction.

In contrast to conventional study of seismic response of individual structures, performance analysis of cluster of structures is essential to assess the damage at city level so that officials and residents can choose reasonable preparation to mitigate the losses of earthquakes. Moreover, modeling of entire earthquake event i.e., generation and propagation of an earthquake, responses of structures and damage, and actions by people and communities for earthquake damage is required. To do this, a digital model of city is pre-requisite. More importantly, a numerically efficient tool is also needed.
Integrated Earthquake Simulation (IES) provides different predictions of earthquake hazards and disasters depending on the earthquake scenario. With the help of Geographical Information System (GIS), IES automatically construct the computer model of any city. IES perform the soil amplification analysis, seismic response analysis and mass agent simulation to mimic the entire event of earthquake.

We have used IES to simulate the three different earthquake events scenarios in the selected region of New Delhi. We obtained the total displacement and storey drift in each building against 1995 Kobe Earthquake, 2001 Bhuj Earthquake, and 2015 Gorkha Earthquake. In modeling the 2015, Gorkha Earthquake, a synthetic ground motion has been used, which is generated by combining three major seismic waves of earthquake. The preliminary results suggest that buildings which are five storey or higher have higher value of storey drift.

Geometric mechanics formulations and structure-preserving discretizations for continuum mechanics and kinetic models

STRUCTURE PRESERVING DISCRETIZATION FOR THE LINEAR WAVE EQUATION

Artur Palha[*1]*

[1]*Delft University of Technology*

ABSTRACT

Structure-preserving discretisations, by construction, enable the conservation of many invariants of the dynamics of PDEs. For example, energy, momentum, helicity (or enstrophy in 2D), in the Navier-Stokes equations, also potential enstrophy in the shallow waters equations, magnetic and cross helicity in MHD, etc. Besides the formal relevance, there are also concrete practical benefits of employing numerical discretisations that preserve some of the structure of the original equations. Structure preserving discretisations fundamentally rely on a set of function spaces that constitute a discrete de Rham sequence.

Most structure preserving discretization approaches address time evolution in a standard space plus time manner. Spatial finite-dimensional function spaces that constitute a de Rham sequence are employed for the spatial discretization and then a choice is made among the many available time integration methods.

There is a growing interest in numerical techniques for direct spacetime discretization (where time is address as any other coordinate). The potential advantages of this approach are, for example: spacetime anisotropic adaptivity, unified algorithmic parallelism, arbitrary order in spacetime.

In this work we will focus on the linear wave equation as a prototypical example for investigating different structure preserving time integration approaches. We will investigate a standard leap-frogging approach, ADER time stepping time integrator, and compare it to a spacetime structure preserving approach. We will discuss the spacetime de Rham complex and the spacetime formulation of the linear wave equation in differential geometry.

IMPLICIT NEURAL REPRESENTATIONS MEETS INTERPRETABLE PARAMETERIZED REDUCED-ORDER MODELING

Weichao Li[1] *and Shaowu Pan**[1]

[1]*Rensselaer Polytechnic Institute*

ABSTRACT

Learning interpretable reduced-order models of nonlinear PDE dynamics have been a long-standing problem in data-driven modeling of dynamical systems. Early works can be traced back to Operator Inference, Sparse identification of nonlinear dynamics (SINDy) and Sindy-Autoencoder, etc. However, these approaches still suffers from scalability issues of scalable nonlinear dimensionality reductions. On the other hand, novel dimensionality reduction framework that leverage implicit neural representation such as Neural Implicit Flow shows great promises on scalable 3D PDE data even on dynamic mesh. Here we propose a novel framework combining the idea of implicit neural with learning interpretable nonlinear dynamics from data. We compared our framework against state-of-the-art operator learning techniques (e.g., FNO) and a recent related work called DINo that leverages a vanilla feedforward neural network to learn the nonlinear latent dynamics. Furthermore, we extended our interpretable reduced-order learning framework to a parametric setting. Our testing cases range from wave equations, forced 2D Naiver Stokes equations to incompressible flow over a 2D cylinder.

QUANTUM ANNEALING-BASED SOLUTION METHODS FOR TOPOLOGY OPTIMIZATION

Wenxiao Pan[1]*

[1]*University of Wisconsin, Madison*

ABSTRACT

This talk presents quantum annealing-based solution methods for topology optimization (TO). Both convex and non-convex TO problems are considered. According to the problem's properties and structure, appropriate sub-problems are formulated so that they can be solved on an annealing-based quantum computer. In particular, the methodology can effectively tackle TO problems formulated as mixed-integer nonlinear programs (MINLP). Acknowledging the present limitations of quantum hardware, each MINLP problem is partitioned into two parts, so that the resulting sub-problems are adequately compact and hence solvable on currently accessible quantum computers characterized by a scarcity of qubits and limited connectivity. The first part can be efficiently solved on classical computers, while the second part with a reduced number of variables is solved on a quantum computer. By such, practical TO problem of varying scales can be handled on near-term quantum annealers. Computational efficiency and solution quality are assessed through solving a selection of benchmark TO problems and conducting comparisons with classical methods commonly employed in the field. This research offers pragmatic avenues for integrating quantum computing into the realm of TO, presenting the potential for leveraging quantum advantages in the practical design of topologies for diverse applications.

MACHINE-LEARNING-BASED ASYMPTOTIC HOMOGENIZATION AND LOCALIZATION CONSIDERING BOUNDARY LAYER EFFECTS

Xiwei Pan[*1], Zhengcheng Zhou[1], Chuang Ma[1], Shaoshuai Li[1] and Yichao Zhu[1]*

[1]*Dalian University of Technology*

ABSTRACT

Asymptotic homogenization offers a way to efficiently analyze the mechanical behavior of multiscale configurations. But near a multiscale boundary, the homogenization strategy should be modified, as the underlying periodicity assumption breaks down there. In this article, we introduce a machine-learning-based asymptotic homogenization and localization scheme to formulate such boundary layer effects. To this end, we define a set of boundary layer cells, where external loading conditions are imposed on one side of the cell, and matching conditions with the interior periodic cells are imposed on the opposite side. The proposed theory identifies a mathematical expression for equivalent surface elasticity constants, surface balance equation and surface energy corresponding to periodic and spatially-varying microstructures due to the boundary layer presence. Implied from the asymptotic results, neural networks can be trained to memorize the interrelationship between key local quantities, such as the magnitude of the local maximum von Mises stress, and the local mechanical and geometric features, so as to avoid the repeated calling of cell problems when conducting failure estimation. Equipped with the trained neural networks, the online calculation for key (boundary-localized) quantities of interest under arbitrary loading conditions is expected to be accelerated substantially.

HALF-CLOSED DISCONTINUOUS GALERKIN DISCRETISATIONS

Yulong Pan[*1] and Per-Olof Persson[1]*

[1]*University of California, Berkeley*

ABSTRACT

We introduce the use of half-closed nodesets where nodes in each element are placed only on a subset of element boundaries in Discontinuous Galerkin (DG) methods. This is as opposed to more commonly seen closed nodesets in DG, whereby in each element nodes are placed on all element boundaries. This provides extra freedom in the choice of node placement which we show allows for more efficient assembly of DG operators compared to closed nodesets. We also consider the effect of this choice of nodeset on commonly used linear solver techniques such as static condensation and block-based methods such as block-Jacobi, and outline some advantages to using half-closed nodes for these solver methods. Finally we demonstrate its use on a range of test problems including in CFD, and benchmark its performance on these numerical examples.

ACCURATE ABSORBING BOUNDARY CONDITIONS FOR TWO-DIMENSIONAL PERIDYNAMICS

Gang Pang[*1] and Xavier Antoine*[2]

[1]*Beihang University*
[2]*Université de Lorraine*

ABSTRACT

The aim of this talk is to construct accurate absorbing boundary conditions (ABCs) for the two-dimensional peridynamics equation of motion which describes nonlocal phenomena arising in continuum mechanics based on integrodifferential equations. To this end, a full discretization of the system is used based on a Crank-Nicolson scheme in time and an asymptotically compatible scheme in space. Recursive relations for the Green's functions are then derived and numerically used to evaluate the nonlocal ABCs. In particular, these absorbing boundary conditions solve the corner reflection problem with high precision. The numerical analysis of the complete fully discretized scheme is implemented and numerical examples are finally reported to demonstrate the validity of the resulting ABCs.

ASSESSING THE IMPACT ON THE GLASS TRANSITION TEMPERATURE OF BITUMINOUS BINDER FROM ULTRA-THIN DIAMOND NANOTHREAD

Yingying Pang[*1] and Haifei Zhan*[12]

[1]*Zhejiang University*
[2]*Queensland University of Technology (QUT)*

ABSTRACT

The nature of the glass state has been recognized by Science as one of the 125 challenges urgently awaiting resolution in the 21st century [1]. Despite decades of theoretical studies, the nature of the glass transition remains ambiguous and debated, while none has definitively addressed the issue [2]. We herein attempt to assess this complex phenomenon to events occurring at the molecular scale.

This work focuses on bitumen as the research subject, primarily comprising two parts. One aspect involves utilizing a data-driven model to accurately identify the glass transition region in molecular dynamics. By taking the derivative of the volume, we clearly captured the glass and rubber states. The other aspect involves introducing diamond nanothread (DNT) as a means to explore, from the perspective of molecular movement and microstructural arrangement, how the structure can regulate the glass transition temperature (Tg). DNT fillers induce inhomogeneity, which would promote the motion of small molecules while hindering the motion of large molecules□resulting in a higher Tg.

Glass transition region in this study is captured by simultaneously considering macroscopic volume and microscopic structure, which could move one step closer to unveil the mystery of the glass state, contributing to the broader comprehension of this intricate scientific challenge.

ABSTRACT

The expanding field of machine learning has led to many branching approaches to data driven learning of mechanistic models. One of these branches is physics informed neural networks (PINN), which incorporates the use of a physics-based model to guide how the network learns [1]. Grounding the learning with a physical underpinning extends the standard neural network beyond a simple 'black box' model and provides a mechanism to perform parameter estimation of the imposed mechanistic model. Parameter estimation within a typical PINN involves frequentist statistics. In this talk, we compare its suitability as a method for parameter estimation to standard approaches in inverse modelling using Bayesian inference [2].

We present a series of numerical investigations considering various PINN architectures, assessing their capacity to estimate system parameters and compare their outcomes to benchmark results obtained using Bayesian inference under similar conditions. The first architecture type considered is the more common representation of a PINN, which embeds physics into the loss function [1]. The second architecture type tested embeds the assumed physics into the units of the neural network itself [3]. We compare and contrast these methodologies for two dynamical systems governed by ordinary differential equations. Specifically, from engineering mechanics, we consider the vibrations of a mass-spring system, and from infectious disease modelling, we consider population-level disease transmission using compartmental models.

This talk aims to assess the strengths and weaknesses of PINNs against established methods for Bayesian inference for the task of parameter estimation and subsequently for forecasting. The objective is to better understand of these two different paradigms, and additionally to compare the performance of different PINN implementations.

A CONSISTENTLY LINEARIZED STOCHASTIC FINITE ELEMENT FORMULATION FOR GEOMETRIC NONLINEAR COMPOSITE SHALLOW SHELLS

Lukas Panther[*1], Werner Wagner[1] and Steffen Freitag[1]*

[1]*Karlsruhe Institute of Technology*

ABSTRACT

Material properties such as young's modulus are subject to uncertainties. This natural variability is called aleatory uncertainty and cannot be reduced. The influence of uncer tain structural parameters on the behavior of mechanical structures is considered in the context of stochastic structural analysis. Due to the stochastic modeling of material properties, the quantities of interest, e.g. displacements and stresses, are random variables. The Monte Carlo Simulation (MCS) is a widely used method to estimate statistics such as mean value, variance and higher moments of these variables. Although the MCS is very flexible, it is impractical with respect to computational time. The polynomial chaos expansion (PCE) is a particularly efficient way to replace the necessary computationally expensive MCS [1]. Within the spectral stochastic FEM (SSFEM), the PCE is directly integrated into the FE formulation of structural elements [2]. The application of the SSFEM to geometric nonlinear mechanical structures remains comparatively unexplored. In this contribution, the SSFEM is applied to geometric nonlinear shell structures of composite material under the influence of uncertain structural parameters such as material and geometrical properties. A comparison of results of the SSFEM and the MCS shows the efficiency of the method. Special focus is set on the consistent linearization, which is necessary to achieve quadratic convergence in the context of a Newton iteration scheme. Furthermore, the polynomial degree is investigated, which has a strong influence on the quality of the results. Challenging tasks such as limit points in stability analysis are examined, which includes studies on the convergence behavior of the extended FE formulation. In addition, the sensitivity of the uncertain input parameters to the quantity of interest are part of the investigations.

MODELLING OF SOLUTE TRAPPING AND NON-EQUILIBRIUM MICROSTRUCTURE DURING RAPID SOLIDIFICATION OF ADDITIVE MANUFACTURING

Chinnapat Panwisawas[*1]*

[1]*Queen Mary University of London*

ABSTRACT

Understanding the underlying mechanisms of metal additive manufacturing (AM) through computational materials engineering necessitates to materials design and process optimisation. The stochastic nature of emerging AM microstructure induced by thermal-chemical-fluid dynamics is the key to maximise the AM performance. It is likely induced by metal powder size/shape distribution, energy input by process parameters, processing-induced defects (e.g. porosity, crack), and second phase precipitation, which all result in heterogeneous non-equilibrium microstructural variations and site-specific behaviour. Solute element transport during rapid and repeated thermal cycle in metal AM which is able to induce non-equilibrium, non-uniform microstructure remains unprecedented. We have developed a computational materials engineering approach to reveal the solute transport induced by melt convection which dilutes the partitioned solute at the solidification front and promotes solute trapping and elucidates the mechanisms of the subsequent microstructural transitions to ultra-fine cells and then to coarse cells. These suggest solute trapping effect could be made used of for reducing crack susceptibility by accelerating the solidification process. The detailed solidification pathway exhibits promising potential for additively manufactured ‘hard-to-print’ superalloys and aids the future materials design for better 3D printability.

A COMPACT QUANTUM MACHINE LEARNING FRAMEWORK PREDICTING PROPERTIES OF COMPLEX MATERIALS

Hsu-Kai Cheng[1], Po-Yu Yang[1] and Chun-Wei Pao[1]*

[1]Academia Sinica

ABSTRACT

Machine learning (ML) is increasingly being leveraged to predict complex material properties, such as potential energies. Traditional ML models are parameter-dense, often containing thousands to hundreds of thousands of parameters, and typically estimate global properties based on localized atomic contributions —neglecting long-range interactions. We introduce a quantum machine learning (QML) framework designed to overcome these limitations by accurately predicting energies of complex material systems. This framework employs a renormalization technique that condenses atomic descriptors into a feature map, facilitating the encoding of systems with any atom count into a quantum ML circuit utilizing fewer than ten qubits. Utilizing two novel QML circuit architectures, the quantum convolutional neural network (QCNN) and the quantum deep neural network (QDNN), our models, with fewer than one hundred parameters, achieve significant predictive accuracy for both Co0.25Ni0.25(HfTiZr)0.5 complex alloy and lead-based metal-organic frameworks (MOFs). This ultra-compact QML approach, with parameter counts drastically lower than those in classical models, offers a scalable solution for predicting the energetics of complex materials of varying sizes.

ALASKA WALL SYSTEM: EXPERIMENTAL AND NUMERICAL COMPARISONS OF A COST-EFFECTIVE MITIGATION SCHEME

*Photios Papados**[1]

[1]*Engineer Research and Development Center, U.S. Army Corps of Engineers*

ABSTRACT

Under the auspice of the international cooperation SHIELD, a specific test wall arrangement was tested at Ft. Polk, Louisiana, USA, in 2021.

The idea behind this exercise was to emulate a “planter-type” structure which can be used as a mitigation scheme both in urban environments and the military theater. This specific arrangement consisted of two (2) rows of three (3) Alaska wall units that were buried 1.45 m below the surface, thus exposing 2.25 m of clear wall aboveground. The two sets of walls were separated by 2.0 m (clear distance). The in-between void was filled with indigenous material (a combination of sand and silty clay type of soil). The overall arrangement was subjected to a close-in detonation at a scaled distance of 0.4 m/kg(1/3), in TNT equivalent terms.

This presentation discusses the establishing of the loading environment (CFD analyses), the generation of a series of Lagrangian FE models (CSM analyses) in predicting the structural response, and comparison of experimental and numerical results. Shortcomings and difficulties encountered during this project will also be discussed.

QUANTITATIVE BENCHMARK FOR LASER POWDER BED FUSION MELT POOL SCALE MODELS

Hélène Papillon-Laroche[1], Amishga Alphonius[1], Magdalena Schreter-Fleischhacker[2], Yohann Vautrin[3], Florin Ilinca[4], Jean-Philippe Harvey[1] and Bruno Blais[1]*

[1]*Polytechnique Montréal*
[2]*Technical University of Munich*

[4]*National Research Council of Canada*

ABSTRACT

Laser Powder Bed Fusion (LPBF) is a 3D printing process using metal powder as the raw material. A laser selectively melts the powder bed, and the raw material is consolidated using a layer-by-layer building strategy. At the melt pool scale, solid-liquid phase change, surface tension and evaporation effects are involved, and their highly dynamic interaction drives the melt pool (MP) morphology, thermal history, and the occurrence of defects in the final part. To predict the latter, high fidelity thermo-fluid models are currently used. However, precise knowledge and quantification of the model errors and their sources is absent as verification and validation are either disregarded or incomplete. This hinders meaningful insight from the current LPBF MP predictions.

This work proposes a reproducible quantitative benchmark to evaluate the accuracy and adequacy of LPBF MP scale models. It is twofold: verification via a code-to-code comparison and validation with experimental data. It focuses on the static irradiation of a bare plate of Ti-6Al-4V, experimentally studied by Cunningham et al. [1]

The code-to-code comparison of results is performed using selected high-fidelity thermo-fluid models. Space and time refinement studies are proposed to analyze the sensitivity of the solution to the chosen discretization. Targeted verification metrics are the MP and vapor depression (VD) dimensions, and temperature gradients. Monitoring of the error norms assesses if the different thermo-fluid models converge to the same reference solution, defined as the solution obtained with the finest discretization. The second part of the benchmark assesses the models' adequacy using Cunningham et al. [1] experimental results. This validation step focuses on the temporal evolution of the MP and VD dimensions, and we are interested in the predictive capacity of the models for the different melting modes encountered in the experimental setup.

The presentation focuses on the benchmarking of two diffuse finite-element based thermo-fluid frameworks, developed by independent groups: Lethe from Polytechnique Montréal, and MeltPoolDG from the Technical University of Munich. It also aims to advertise this new benchmark to other research groups and encourage them to verify and validate their thermo-fluid models using the proposed studies. Hence, it provides the required numerical results to compare their own solutions. Special care is taken to thoroughly describe the benchmark case, material properties, and solver parameters ensuring reproducibility.

GOAL-ORIENTED CALIBRATION OF MODELS AND ASSOCIATED MODELING ERRORS

Antonin Paquette-Rufiange[*1], Serge Prudhomme[1] and Marc Laforest[1]*

[1]*Polytechnique Montréal*

ABSTRACT

Models of increasing complexity are now commonly used to predict quantities of interest for physical systems at various scenarios. However complex these models are, they are but abstractions of the system of interest. They involve simplifying hypotheses, which induce some modeling errors; in other words, they only provide approximate responses of the system of interest. Such hypotheses usually introduce unknown parameters, the so-called model parameters, that need to be calibrated. The formulation of the calibration process will directly affect the values of the calibrated parameters, the modeling error in the model, and hence the predictive capability of the model.

We propose a novel approach for calibration that identifies both the model parameters and the modeling errors. Our calibration process relies on the fact that each value of the model parameters generates its own model with associated modeling errors. For a given value of the model parameters, we calibrate the modeling error by representing it as a Gaussian process, as proposed by Kennedy and O'Hagan [1]. More precisely, we calibrate the (hyper)parameters of the modeling errors via maximum likelihood [2]. The novelty of our calibration approach resides on how the values of the model parameters are inferred, that is, we define an objective functional with respect to the intended use of the model and seek the model parameters that minimize a functional of the modeling errors. For example, one goal may be to minimize the modeling error at a specific scenario or for a set of scenarios of interest. The proposed approach is therefore referred to as a goal-oriented method for calibration of the model parameters.

The pertinence of this approach will be illustrated on a simple problem to highlight the influence of the modeling errors on the calibration of the model parameters. This example will also illustrate that our methodology alleviates the identifiability problem between the modeling errors and the model parameters. The calibration process will further be applied to the thermal problem presented at the Sandia Challenge 2008. Different objective functionals will be studied, demonstrating the versatility of our approach and the way it can improve the predictive capability of a model.

GOAL-ORIENTED CALIBRATION OF MODELS AND ASSOCIATED MODELING ERRORS

Antonin Paquette-Rufiange[*1], Serge Prudhomme[1] and Marc LeForest[2]*

[1]Polytechnique Montréal
[2]Polytechnique Montréal)

ABSTRACT

Models of increasing complexity are now commonly used to predict quantities of interest for physical systems at various scenarios. However complex these models are, they are but abstractions of the system of interest. They involve simplifying hypotheses, which induce some modeling errors; in other words, they only provide approximate responses of the system of interest. Such hypotheses usually introduce unknown parameters, the so-called model parameters, that need to be calibrated. The formulation of the calibration process will directly affect the values of the calibrated parameters, the modeling error in the model, and hence the predictive capability of the model.

We propose a novel approach for calibration that identifies both the model parameters and the modeling errors. Our calibration process relies on the fact that each value of the model parameters generates its own model with associated modeling errors. For a given value of the model parameters, we calibrate the modeling error by representing it as a Gaussian process, as proposed by Kennedy and O'Hagan [1]. More precisely, we calibrate the (hyper)parameters of the modeling errors via maximum likelihood [2]. The novelty of our calibration approach resides on how the values of the model parameters are inferred, that is, we define an objective functional with respect to the intended use of the model and seek the model parameters that minimize a functional of the modeling errors. For example, one goal may be to minimize the modeling error at a specific scenario or for a set of scenarios of interest. The proposed approach is therefore referred to as a goal-oriented method for calibration of the model parameters.

The pertinence of this approach will be illustrated on a simple problem to highlight the influence of the modeling errors on the calibration of the model parameters. This example will also illustrate that our methodology alleviates the identifiability problem between the modeling errors and the model parameters. The calibration process will further be applied to the thermal problem presented at the Sandia Challenge 2008. Different objective functionals will be studied, demonstrating the versatility of our approach and the way it can improve the predictive capability of a model.

NUMERICAL ANALYSIS OF POST-TENSIONED WALLS' MECHANICAL BEHAVIOR FOR HOUSING VIA A SIMPLIFIED MODEL OF ITS CONSTITUTIVE TENSOR

Jairo A Paredes[1], César Dávalos[2], Jefer Castro[1] and Daniel Bedoya-Ruiz[1]*

[1]*Universidad Nacional de Colombia*
[2]*Universidad Autónoma de Ciudad Juárez*

ABSTRACT

Housing construction requires industrialized and efficient construction procedures that allow the massive construction of housing, providing the required quality of life. The post-tensioned concrete system has been adapted to develop post-tensioned walls that allow the prefabrication of homes and their assembly in the field. The experimental tests applied to this type of wall, built at full scale, establish the structural parameters and their performance capacity under static load.
Previously, constitutive models have been proposed based on an isotropic damage model for concrete modeling, the classical elasto-plasticity theory for bar modeling, and the elasticity theory for post-tensioning cables. Combining the three models through mixing theory reflects their mechanical behavior for implementation in numerical simulation. The complexity of the interaction of the models lends itself to using code developed expressly for this type of simulation.
This document establishes a methodology for the simulation of post-tensioned concrete walls through commercial programs using a simplified model for their characterization and analysis, whose input will be the constitutive tensor of the composite material assigned to each finite element. The constitutive matrix of the composite material will be computed considering the percentages of volumetric participation of the simple materials that compose it, the working orientation of the fiber-type materials through the theory of series/parallel mixtures, and the inclusion of the axial deformation of the cable as an effect of post-tensioning.

A GRAPH NEURAL NETWORK BASED REDUCED-ORDER MODEL FOR FLAPPING DYNAMICS

Aarshana Parekh[1] and Rajeev Jaiman*[1]

[1]*University of British Columbia*

ABSTRACT

An elastic foil, cantilevered at the trailing edge, also known as the inverted foil, exhibits an intriguing self-induced flapping motion when exposed to fluid flow. This fluid-structure interaction phenomenon holds significant interest for its applications in renewable energy harvesting. In this study, we numerically investigate how inverted foil's response changes when positioned in tandem with a stationary circular cylinder. The problem is modeled using a higher-order variational solver, incorporating fully coupled three-dimensional Navier-Stokes and nonlinear structural equations. This methodology is based on the combined field explicit interface formulation proposed by [1]. Our observations reveal that for a specific range of parameters, the flapping motion is wake-induced, driven by synchronization between the foil's motion and the shedding of vortices from the cylinder. Consequently, the foil demonstrates sustained and controlled oscillations, rendering it ideal for efficient energy harvesting. To further enhance energy efficiency and fortify the design of resilient energy harvesting systems, parameter optimization becomes crucial.

Effective optimization using traditional computational simulations involves performing analysis over a wide parameter spectrum which is both time-consuming and computationally expensive. Addressing this challenge, we propose a graph neural-based reduced-order model (GNN-ROM) tailored specifically for the inverted foil problem. This model adeptly handles mesh-structured data involved in full-order simulations without necessitating modifications, allowing it to effectively simulate fluid-structure interactions efficiently and faster. Our model uses the rotation equivariant, quasi-monolithic GNN proposed by [2]. This framework is based on the arbitrary Lagrangian-Eulerian formulation, wherein time series prediction of the system states is made with two sub-networks. Essential coefficients describing mesh motion are extracted by proper orthogonal decomposition, which are predicted over time using a single multilayer perceptron. Simultaneously, the GNN-ROM evolves the flow field based on the system state. The structural state is implicitly modeled by the mesh movement on the solid-fluid interface. This proposed model is currently undergoing training and validation using our full-order simulation data. Once established, it stands poised to serve as a robust surrogate model for the inverted foil, facilitating the fast parametric optimization and control of inverted foil-based energy harvesting devices.

SYNTHETIC INFLOW TURBULENCE GENERATION BASED ON CONDITIONAL NEURAL FIELD ENCODED LATENT DIFFUSION MODEL

Meet Hemant Parikh[*1], Xin-Yang Liu[1], Pan Du[1], Xiantao Fan[1] and Jianxun Wang[1]*

[1]*University of Notre Dame*

ABSTRACT

Eddy-resolving turbulence simulation techniques, such as Direct Numerical Simulations (DNS) and Large Eddy Simulations (LES), often necessitate the generation of stochastic inflow boundary conditions. Conventionally, people employ recycling-based approaches, which involve conducting a separate, fully turbulent flow simulation under periodic boundary conditions. The turbulence field obtained from this precursor simulation, upon reaching a statistically steady state, is then utilized as the inlet condition for the primary simulation. Although this approach effectively captures the statistical and dynamical properties of turbulence, it is computationally demanding and time-intensive. Alternatively, various synthetic inflow turbulence generators have been developed, including methods like the synthetic random Fourier method, synthetic digital filtering method, and synthetic coherent eddy method, among others. These synthetic techniques are designed to efficiently synthesize inflow turbulence on-the-fly without the need for extensive precursor simulations or data storage requirements. However, they often struggle to accurately replicate the complex dynamical properties and coherent structures of true turbulence. This shortfall frequently results in considerable computational overhead, due to the need for a larger computational domain to dissipate nonphysical features and allow for the re-development of turbulence within the primary simulations.

Recent developments in deep learning have offered new solutions for turbulent inlet generation. Existing explorations have utilized sequence models like Long Short-Term Memory (LSTM) and transformers to learn the dynamics from simulation data. However, these models often encounter error accumulation during long-term rollout predictions, especially for chaotic and turbulent regimes. Additionally, their ability to handle the stochastic nature of turbulence is limited. Although generative models, such as Generative Adversarial Networks (GAN), show promise, they are challenging to train and often lack generalizability across different flow conditions or meshes. To address these issues, we propose a method leveraging both conditional neural fields (CNF) and latent diffusion models (LDM). This technique uses CNF to encode spatiotemporal features into a hidden space, where LDMs generate new samples based on varying Reynolds numbers. By harnessing the strengths of both CNF and LDM, we are able to build an effective, mesh-independent inlet turbulence generator for various flow conditions.

ABSTRACT

Massive storage of energy has been a challenge for society and an cheap, secure and reliable solution has not been achieved. Hydrogen seems to play a crucial role in the future energetic mix but among many other considerations it requires very large storage volumes to face the energetic demand nowadays. Underground salt caverns are being considered as an efficient and cheap alternative for hydrogen storage at industrial scale. This research is devoted to analyze by numerical simulation the conditions, viability and efficiency of using salt caverns. The developed models involve non linear structural analysis, creep, fatigue, thermal effects, dynamic simulations and many other relevant aspects [1].

Stability and viability conditions must be determined both in dome formations and in bedded saline ones since they equally appear in nature. The models developed consider the effects of geothermal gradient with the depth and its effect on nonlinear structural phenomena and non linear halite formations. Furthermore, operating conditions and different operation cycle configurations by means of maximum and cushion gas pressures, and injection and withdrawal cycles among others are also analyzed to verify the most adequate strategy and the useful life of the facility under different operation scenarios. Maximum deformations allowed on the top of the cavern have demonstrated to be critical aspects for the viability of this type of geological storage systems and an expected useful life of 30 years is the goal. Taking into account these considerations our findings show that under adequate conditions, geometries and operating conditions salt caverns are an adequate option to store massive amounts of hydrogen and, consequently, of energy.

Finally, some application examples of applications under real conditions have been analyzed.

MULTISCALE COMPUTATIONAL HOMOGENIZATION FOR FLOW THROUGH POROUS MEDIA

Thomas Paris[1], Vincent Bruyere*[2], Patrick Namy[2], Sylvain Chupin[1] and Denis Rochais[1]*

[1]CEA
[2]SIMTEC

ABSTRACT

Macroscopic modeling of flow through porous media requires knowledge of equivalent properties (permeability, conductivity, diffusivity) for calculations. Depending on microstructure topology and fluid flow regimes at the microscopic scale, great disparities in equivalent properties can be found in the literature.

Multiscale computational homogenization (EF^2) is shown to be an interesting tool and could be used as a guideline to choose with greater confidence the most suited formulation for specific porous media. A numerical twin strategy is used to surpass experimental limitations in order to describe flow through specific and complex porous microstructures. Analytical formulations for permeability at the macroscale are discussed and compared to lower scale calculations.

Finally, numerical twin strategy seems not only able to recover consistent permeability values but also to capture different mechanisms both sides of the spectrum such as inertia effect for high Reynolds number and wall effect for high Knudsen number and rarefied gas regime.

A REDUCED-BASIS METHOD FOR UNCERTAINTY QUANTIFICATION IN RANS SIMULATIONS OF HYPERSONIC TURBULENT FLOWS

Eric Parish[*1], Elizabeth Krath[1] and Patrick Blonigan[1]*

[1]*Sandia National Laboratories*

ABSTRACT

The Reynolds-averaged Navier—Stokes (RANS) equations are the workhorse analysis tool for simulating hypersonic turbulent flows in complex environments. Unfortunately, RANS models have uncertainties which can bias their predictions. This work presents a reduced-basis method (RBM) for quantifying parametric uncertainties in the RANS equations. Our approach leverages entropy variable transforms, a globalized Newton solver, and a quasi-multigrid solution strategy to construct a robust, stable, and accurate Galerkin RBM. We further equip this RBM with QoI-based error indicators to aid in greedy training and a posteriori error estimation. We present results on a suite of hypersonic flow problems, including the HIFiRE-1 ground test, and demonstrate the efficacy of our approach for UQ analyses.

POLYGONAL STAGGERED DISCONTINUOUS GALERKIN METHODS FOR PROBLEMS IN POROUS MEDIA

Eun-Jae Park[*1]*

[1]*Yonsei University*

ABSTRACT

In this talk, we first present the staggered DG method on general meshes for the Poisson equation. Then, some applications to interface problems are considered such as coupling of Darcy-Forchheimer and Stokes equations, and a single-phase flow in porous media with a fracture. In the case of s fractured porous media, the bulk variables are solved using staggered DG method and an interface variable is solved using the continuous Galerkin method. We derive optimal convergence for both pressure and velocity fields. Numerical experiments suggest that our method is more accurate when polygonal meshes are used among various mesh configurations; moreover, our method is robust to mesh distortion. These observations allow us to consider unfitted methods without any special treatment. With background meshes generated independent of fracture, numerical solutions converge in optimal order.

ABSTRACT

Hydrogen embrittlement fracture is essential in various industrial applications, particularly in ensuring the structural integrity, especially when a material is exposed to hydrogen-rich environments. Hydrogen embrittlement involves the diffusion of atomic hydrogen into the material lattice, interacting with various microstructural features. For instance, hydrogen enhanced localized plasticity (HELP) appears as hydrogen-enhanced plastic deformation localized around stress concentrators leading to microcrack initiation, while hydrogen enhanced decohesion (HEDE) mechanism involves the accumulation of hydrogen atoms at material interfaces inducing decohesion between grains or phases. In this study, a computational framework is presented, which integrates a ductile fracture modeling and a hydrogen diffusion modeling, to investigate the role of hydrogen in triggering localized plasticity and its subsequent impact on fracture initiation. For a ductile fracture modeling, the Gurson-Cohesive model (GCM) is employed. In GCM, the Gurson model represents continuum damage evolution while a finite element-based cohesive zone model describes crack surface discontinuity in conjunction with the traction-separation relation. The transition from continuum damage to discontinuous crack is defined using a crack initiation criterion, which accounts for porosity and triaxiality. The investigation extends to understanding the influence of hydrogen on the softening behavior of the traction-separation relationship on the discontinuous crack surface. Parametric studies explore the sensitivity of material properties and environmental conditions. This exploration describes the factors influencing fracture behavior from HELP and HEDE mechanisms, contributing to the identification of critical parameters for material susceptibility to hydrogen-induced fracture. By combining numerical models of hydrogen diffusion considering the HELP and HEDE mechanisms and the ductile fracture model, this study provides an understanding of hydrogen-induced fracture, contributing significantly to the ongoing efforts in designing materials resilient to hydrogen embrittlement in practical engineering applications.

THERMODYNAMICS-INFORMED LATENT SPACE DYNAMICS IDENTIFICATION (TLASDI) FOR REDUCED-ORDER MODELING OF DYNAMICAL SYSTEMS

Jun Sur Park[*1], Siu Wun Cheung[2], Youngsoo Choi[2] and Yeonjong Shin[3]*

[1]*Korea Institute For Advanced Study (KIAS)*
[2]*Lawrence Livermore National Laboratory*
[3]*North Carolina State University*

ABSTRACT

In this work, we present a thermodynamics-informed latent space dynamics identification (tLaSDI) method for learning an intrinsic invariant manifold which comply with the first and second principles of thermodynamics from data. Our approach utilizes an autoencoder to provide a nonlinear latent representation and the reconstruction of the high-dimensional data, and the corresponding latent space dynamics are captured using GENERIC formalism informed neural networks (GFINNs). The GFINNs are designed to exactly satisfy the degeneracy condition of the GENERIC formalism, ensuring that the latent space dynamics adhere to fundamental thermodynamics principles, such as energy conservation and entropy inequality restrictions. To enhance the accuracy and efficiency of data-driven reduced-order modeling, we perform simultaneous training of the autoencoder and GFINNs. Additionally, we introduce the loss components based on rigorous error estimates to further improve the accuracy of the prediction. The numerical results demonstrate that the tLaSDI method shows great potential for enhancing the computational efficiency of high-dimensional dynamical systems while maintaining accurate predictions.

NEW MULTI-FIDELITY METHOD FOR HIGH-DIMENSIONAL PROBLEMS WITH DIFFERENT SETS OF INPUT VARIABLES

Youngseo Park[1] and Ikjin Lee*[1]

[1]*KAIST*

ABSTRACT

Many researches regarding multi-fidelity (MF) modelling have been studied in decades, due to its ability to construct accurate model despite of the limited number of high-fidelity (HF) data by utilizing a number of low-fidelity (LF) data. However, conventional MF methods construct a single model for the entire input space, which make them require numerous samples for high-dimensional problems having more than ten input variables. To alleviate this problem, MF methods combined with the high-dimensional modelling techniques, such as high dimensional model representation [1] and mapping [2], are proposed. Nevertheless, these methods assume that the input sets of MF data are consistent, which would not be true especially for high-dimensional problems. To solve this issue, new MF method is proposed for high-dimensional problem with different sets of input variables.

The proposed method categorizes input variables into three groups; common variables that are present in both LF and HF, variables that exist only in LF model, and those that exist only in HF model. First of all, LF model is built by using high-dimensional modelling technique. Subsequently, HF data are utilized to train the MF model by reflecting correlation of LF and HF responses. In the training process, the relationships of input variables only in HF and those only in LF are also trained, which make it possible to predict response of different input sets. Numerical examples show the proposed method construct accurate MF model in the high-dimensional problems having different input sets.

ON TRIANGULAR SELF-STABILIZED VIRTUAL ELEMENTS FOR KIRCHHOFF-LOVE SHELLS

Tiago Park Wu[*1], Paulo de Mattos Pimenta*[1] *and Peter Wriggers*[2]

[1]*University of São Paulo*
[2]*Leibniz Universität Hannover*

ABSTRACT

We present low-order triangular virtual elements for linear Kirchhoff-Love shells. The domain decomposition by flat triangles directly approximates the shell geometry without resorting to a curvilinear coordinate system or an initial mapping approach. In light of the available low-order virtual element procedures for each plane elasticity and plate bending problem, the membrane and plate are conveniently superposed in space. The serendipity VEM is applied for the membrane and we explore the stabilization-free VEM for the plate as an attempt to provide a starting point for its future evolution. A nonconforming plate scheme is withal considered. Numerical examples of static problems are presented to show the potential of our formulation to further Kirchhoff-Love shell virtual element developments.

ON DEFINING A FEATURE AND LABEL SPACE FOR ML GUIDED DEFEATURING

Sam Parry[1] and Steven Owen*[1]

[1]*Sandia National Laboratories*

ABSTRACT

In Computer-Aided Design (CAD), defeaturing is the process of optimizing 3D models for finite element simulation by simplifying or removing non-essential geometric features. Unnecessary complexity in the CAD part leads to overly complex meshes that require more resources to simulate. Despite the significance of defeaturing, the process remains a tedious, time-consuming task that relies on the expertise and in-situ decision making of a skilled analyst. Our research seeks to bridge the gap to automation by leveraging machine learning techniques to expedite defeaturing operations, reducing the manual workload on analysts and enhancing the efficiency of CAD model optimization. We propose a Machine Learning (ML) driven approach to defeaturing by which an analyst is shown a ranked list of operations ordered by their predicted improvement to mesh quality. We also propose a definition of a comprehensive feature and label space that can be used to train ML models for predicting the likely success and resulting mesh quality improvement of each possible defeaturing operation.

DISCONTINUOUS FINITE CELL METHOD FOR PROBLEMS IN SOLID MECHANICS

Jamshid Parvizian[*1], Stefan Kollmannsberger[1], Ernst Rank[1], J. Egerer[1], E.J. Quiroz[1] and J.A. Vargas[1]*

[1]*Technical University of Munich*

ABSTRACT

The finite cell method (FCM) starts with a regular mesh on a simple domain which embeds the domain of a PDE, and benefits from an arbitrary extension of the high-order approximation of the unknowns into the enveloping domain by assuming a very soft material in the extended region [1]. The method has been successfully investigated in a variety of problems in solid mechanics and beyond. The discontinuous finite cell method (DFCM) is not an extra step in FCM, but rather a natural step back to the phase before cell matrices are being assembled; thus solving the element equations of each cell almost independently, with the additional boundary conditions that arise from neighbouring cells. The main drawback, at first glance, is in increasing the number of degrees of freedom; however, this provides many opportunities to benefit from the advantages of both FCM and the discontinuous Galerkin FEM. While the FCM provides fast and simple solutions in dealing with inclusions as well with cells cut by the boundary, the discontinuous feature offers a good remedy for cells that are completely divided by material discontinuities, and makes it easy to add or remove cells, and thus to move boundaries.
In this paper, we present the formulation of the DFCM, and demonstrate its merits compared to similar methods using several examples.

ABSTRACT

Uncertainty quantification is an essential component of a digital twin and plays a central role in establishing trust in the model's predictions and enabling robust decision making. This is particularly salient when digital twins are employed as enablers for personalized medicine [1,2]. While digital twins can play a key role in tailoring therapeutic interventions, the underlying mathematical and computational models must be calibrated with noisy data that are infrequently collected and may only be indirectly informative. In particular, mechanistic modeling of high grade gliomas proves challenging due to significant heterogeneity, both in physiology and response to treatment. This heterogeneity has also proved challenging in the clinic, resulting in low median survival rates despite an aggressive standard-of-care. We present a methodology that utilizes non-invasive quantitative magnetic resonance imaging (MRI) collected longitudinally. The first (post-operative) MRI sequence in the time course is used to generate a patient-specific computational geometry and assign initial conditions. Tumor extent and cellular density are estimated from the acquired MRI data and projected onto the computational domain. These data are then used to inform spatially varying model parameters in a reaction-diffusion partial differential equation (PDE) describing tumor invasion and proliferation through the solution of a Bayesian inverse problem. Specifically, we seek to compute the Laplace approximation to the posterior by first solving a PDE-constrained optimization problem to compute the maximum a posteriori (MAP) point. The inverse of the Hessian at the MAP point which is taken to be the covariance operator of a Gaussian centered at the MAP point. We comment on the ill-posed nature of the problem and the role that regularization plays in obtaining faithful reconstructions, highlighting how total-variation based regularization can capture sharp variations in the sought-after diffusion and proliferation rates that are associated with the underlying material interfaces of the anatomy (e.g. gray/white matter).

MODELLING SYMMETRY BREAKING AND GEOMETRIC FRUSTRATION IN BISTABLE KIRIGAMI FOR ON-TARGET ANISOTROPIC MORPHING

Damiano Pasini[*1], Chuan Qiao[1], Filippo Agnelli[1], Deepak Pokkalla[1] and Nicholas D'Ambrosio[1]*

[1]McGill University

ABSTRACT

Programming the bistable morphing of kirigami metamaterials for flat-to-3D deployment is a challenging task due to the complexity of the slit pattern and the underlying physical relations between slit symmetry and geometric frustration. In this work I will present a material modelling strategy to generate anisotropic shape morphing in bistable kirigami that leverages symmetry breaking to induce geometric frustration in their deployed state. While current bistable kirigami deploys with preserving shapes that are frustration-free, here the entire morphing space is mapped to access anisotropic deployment yielding non-uniformly scaled shapes that are geometrically frustrated in their second state of equilibrium. I will explain the physical mechanism underpinning anisotropic deployment and elucidate the interplay between anisotropy, bistability, and scaling transformation. Finally, I will show examples of inversely designed kirigami where anisotropic deformation is leveraged to achieve target three dimensional shapes and functionalities so far unattainable with existing isotropically scalable kirigami.

[2]Sandia National Laboratories

ABSTRACT

Circuit simulations, often referred to as Spice simulations, are foundational to modern circuit design, assessment and qualification. Traditional Spice simulations use circuit descriptions built from compact device-level models by applying Kirchoff's current and voltage laws. This leads to systems of differential algebraic equations (DAEs) that must be solved numerically. Unfortunately, this approach does not scale well across system hierarchy levels because the size of the underlying DAE is proportional to the number of discrete devices in the circuit. At the same time, many commonly used circuits (e.g., operational amplifiers, comparators, voltage regulators, etc.) have relatively simple scripted behaviors that can be captured by simpler models reproducing the relevant input-output relationships. Such behavioral circuit models are an alternative to detailed transistor-level simulations that can potentially address the simulations' scalability challenge at higher levels of system integration.

This talk is the first in a series of two talks where we present recent work to establish a data-driven framework for the rapid development and deployment of scalable behavioral models for functional circuit blocks. To that end we consider circuit models having canonical system identification architectures, such as Hammerstein, Wiener, and Hammerstein-Wiener architectures. To motivate our approach we first show that some already established compact circuit models can be expressed in terms of these architectures. Then, we demonstrate that nonlinear circuits with simple, scripted behaviors can be approximated well by these canonical system identification architectures without introducing unnecessary additional computational complexity. In particular, we show that parsimonious Hammerstein-Wiener models are effective surrogates for nonlinear CMOS amplifier and comparator circuits. To train these models we use a combination of DC and transient transistor-level Spice (Xyce) simulation data. We present strategies for identification of the static nonlinearity in the models and discuss identification of the linear time invariant (LTI) portion of the models from time domain data. We conclude with several simulation results showing that our data-driven compact models can accurately reproduce circuits' behavior over a wide range of input conditions and frequencies.

LEARNING THE OPTIMAL PARAMETERS GOVERNING CONFLUENT TISSUES TO SHAPE THEIR EMERGENT PROPERTIES

Alessandro Pasqui[*1] and Hervé Turlier*[1]

[1]*Collège de France, Université PSL, CNRS*

ABSTRACT

Confluent tissues are complex biological tissues whose macroscopic properties and behaviors are essential to understand for the advancement of knowledge in areas such as developmental biology, tissue engineering, and regenerative medicine. These tissues are commonly described as energy-based physical systems characterized by an internal energy optimization process, in which the energy function minimized by the system depends on microscopic parameters associated with each cell. It has been shown how appropriate choices of these microscopic parameters give rise to a wide and diverse expression of macroscopic behaviors, such as a rigidity transition between a liquid phase and a solid phase [1], or the formation of patterns in the tissue. To solve the inverse problem of obtaining specific material properties, these systems can be associated with an external loss function dependent on the microscopic parameters explicitly and implicitly through the minimum energy state. Here we present an innovative framework, a fully differentiable vertex model written in Google Jax to quickly and easily address the inverse problem of learning these microscopic cellular parameters to achieve a given target behavior for confluent tissues [2]. Our framework allows us to leverage bilevel optimization techniques to learn optimal parameters for these systems in order to achieve target macroscopic behavior, such as specific patterns within the tissue, like the formation of rosette structures, or specific system properties, such as liquid or solid phases, or even infer the optimal cellular parameters to match some real microscopic data. Implementing this framework in Jax allows the model to be fully differentiable, which gives us the freedom to automatically differentiate any energy or loss function with respect to any parameter of the system. Thus, our framework allows us to address inverse problems using techniques from machine learning, such as automatic implicit differentiation and equilibrium propagation, and even use GPUs and TPUs to accelerate optimization processing time. In summary, this framework opens new avenues of research leveraging these machine learning techniques for material parameter identification in developmental biology for confluent tissues.

A NOVEL ENSEMBLE APPROACH TO UNCERTAINTY QUANTIFICATION IN OPERATOR LEARNING

Ravi Patel[*1]*

[1]*Sandia National Laboratories*

ABSTRACT

Operator learning is a recently developed generalization of regression to mappings between functions. It promises to drastically reduce expensive numerical integration of PDEs to fast evaluations of mappings between functional states of a system, i.e., surrogate and reduced-order modeling. Operator learning has already found applications in several areas such as modeling sea ice, combustion, and atmospheric physics. However, even in the ideal case where operator learning recovers the training data, there will be uncertainty in interpolatory and extrapolatory regimes. A useful model is one that is transparent about its shortcomings. Single point estimates, hide the broad range of models that reasonably fit training data but present vastly differing predictions. Operator learned models with uncertainty quantification (UQ) would expose users of the models to the full range of surrogate predictions. In this talk, we introduce a novel ensemble approach to UQ in operator learning and compare it to a more standard variational Bayes approach in synthetic benchmarks and a climate application.

TIME DELAY EMBEDDINGS TO DISENTANGLE UNSTABLE PERIODIC ORBITS IN CHAOTIC ATTRACTORS

Prerna Patil[*1], Eurika Kaiser[1], Nathan Kutz[1] and Steven Brunton[1]*

[1]*University of Washington*

ABSTRACT

The data-driven modeling of dynamical systems is rapidly developing, especially for fluid systems. However, many leading algorithms require high-dimensional, full-state training data, while for many real-world systems only very limited or partial measurements are available.

To address this challenge, our work employs time delay embeddings, offering a systematic approach to reconstruct an attractor from such constrained time series measurements. Specifically, we investigate the effectiveness of long-time delay embeddings in capturing
progressively intricate unstable periodic orbits (UPOs) within a chaotic system. In fluid dynamics, these orbits correspond to exact coherent structures (ECSs). The behavior of a chaotic attractor can be understood as the combination of all its periodic orbits. This is particularly relevant when studying the turbulent behavior of fluid flows, which can be represented by an infinite number of these orbits. While an infinite number of orbits are needed to fully describe the system, the dominant dynamics can be captured by the shortest, or ‘fundamental’, orbits. By finding enough of these orbits, we can make predictions about the statistical behavior of turbulent flow.

Our results show that, for long time delay embeddings, UPOs disentangle and converge to a discrete Fourier decomposition. We present an analysis for the disentanglement of these UPOs of the Lorenz attractor and Rössler attractor. The time delay embeddings obtained for these UPOs can be further used to model the dynamical system and forecast its behavior.

LEARNING AND ADAPTING - SECRETS TO SUCCESSFUL, MODELING, COMPUTING AND PREDICTING

Abani Patra[1]*

[1]*Tufts University*

ABSTRACT

We will survey in this talk a consistent approach pioneered by Prof Oden among others of iteratively learning and adapting models that underlies many successful developments in modeling and predictive simulations. The simple questions ``how good is the model" and ``how to improve it" are answered repeatedly and consistently until a simulation fit to purpose is accomplished. We see this approach in the classical a posteriori error estimates for finite element models followed by adaptive updates to mesh and models. While, these questions are simple the answers are not! Error analysis of models is rarely a simple comparison of a few samples of ground truth to model prediction since the purpose of a model is to predict on unseen cases and often at ranges and scales beyond those observable. Similarly, strategies for model improvement presume both clear identification of model inadequacies and robust strategies to improve them.
Machine learning (ML) and predictions based on such methodologies that are transforming our approaches to challenging problems in computational simulation based predictions are but the latest of the methods that are amenable to this paradigm. I will present in this talk, development of a consistent over several decades of strategies that make this a consistent paradigm for complex physics based simulationst.

FAST MODELING OF POSTFIRE DEBRIS FLOWS FOR HAZARD RISK ANALYSIS

Abani Patra[*1] and Palak Patel*[1]

[1]*Tufts University*

ABSTRACT

Computational models that can efficiently simulate geophysical flows like debris flows and landslides are crucial for creating hazard maps that can be used to identify high-risk zones, which helps implement preventive measures (Vallis,2016). However, simulating large flows over natural terrain uses large computing and data resources. Additionally, the uncertainty in the data sources and model parameters requires large ensembles for uncertainty quantification and hazard analysis to study the behavior of such flow. To address this challenge, we present an interesting approach that first creates a deep learning surrogate model to emulate geophysical flow using a modified U-Net architecture that is effective for simulating geophysical flow for its ability to extract spatial patterns in the flow fields (Lino et al 2020). This model can be trained on large ensembles of fast-to-compute feature-rich small flow computed using our first principles code TITAN2D, a geophysical flow modeling software (Patra et al 2005). Once trained, this model can then be extended to a larger unseen terrain using only a limited number of expensive simulations building on the ideas of transfer learning. This model can be further employed to perform fast approximations of the Titan2D simulations and to explore parameters uncertainty and hazard analysis using the Monte-Carlo approach. Here we illustrate this scheme on a case study from post-fire debris flows in Southern California.

THE "OSTEOSTAT": AN OSTEOCYTE-BASED THEORY OF BONE MECHANOBIOLOGY

Yves Pauchard[*1] and Pascal Buenzli*[2]

[1]*University of Calgary*
[2]*Queensland University of Technology*

ABSTRACT

The osteocyte network in bone is believed to play an important role for how bone tissues sense and respond to mechanical stimulation. Yet, bone adaptation to mechanical loads is often conceptualised as a simple bone optimisation response to mechanical stimuli, such as Wolff's laws, in which overloaded regions of bone are consolidated and underloaded regions of bone are removed. Such laws are based on mechanical variables only; they lead to a one-to-one correspondence between bone structure and mechanical loading, and they presume the existence of a reference mechanical state, the mechanical setpoint.

In this contribution, we extend a theory of bone tissue sensing and adaptation based on osteocytes [1] to provide new understanding of the role played by osteocyte signals in bone tissue regulation. This theory embodies the mechanical setpoint as osteocyte properties involved in mechanotransduction. It includes setpoint adaptation due to the replacement of osteocytes during remodelling, making the setpoint space and time dependent. As a result, bone structure depends on the loading history rather than the current loading state, consistently with experimental observations. Our work extends [1] by accounting for varying osteocyte populations within bone tissue, allowing us to determine osteocyte lifespan due to bone removal and cell death, and to explore bone adaptation under osteocyte disruptions, which is particularly relevant to age-related bone loss. We present numerical investigations of this new theory of bone adapation to explore how mechanobiological response curves (effective Wolff's laws) are modulated by setpoint adaptation during remodelling and by disruptions to osteocyte signals due to loss of osteocytes with age. We find that biological disruptions of remodelling balance cannot always be compensated by mechanical feedback. Our model suggests that setpoint adaptation during remodelling may have significant observable consequences, such as an increase in average osteocyte density during unloading, and hysteresis in bone response signatures that resemble lazy zones.

DEVELOPMENT AND VALIDATION OF AN OPEN-SOURCE QCT-BASED FINITE ELEMENT ANALYSIS AND PHASE FIELD MODELING FOR FRACTURE PREDICTION IN GOAT TIBIA

Debangshu Paul[1], Zachariah Arwood[1], Pierre-Yves Mulon[1], Dayakar Penumadu[1] and Timothy Truster[1]*

[1]*University of Tennessee*

ABSTRACT

Predicting mechanical responses under various load conditions is of significant interest in the field of orthopedic research. Despite an abundance of research on finite element (FE) modeling for human bones, studies specifically focusing on the tibia remain notably limited. Given that mechanical properties and structural form of goat tibias closely mimic those of human tibias, they can serve as excellent models for comparative orthopedic research. While existing literature on ovine bone research offers rich in vivo models, it lacks a validated FE model of the tibia subjected to thorough spatial error assessment.

This article presents a novel open-source-based FE model of a goat tibia incorporating phase field fracture representation. The model was validated using Digital Image Correlation (DIC)-measured strain under compression, offering a valuable tool for bone biomechanics research. A model of bone geometry was constructed from a 3D quantitative computed tomography (QCT) scan of the goat tibia. Density was calculated from Hounsfield values and spatially distributed within the FE mesh. To validate this FE model, we conducted a uniaxial compression test by applying the load along the shaft axis. A DIC system provided high-resolution strain measurements across the surface of the tibia, with results found to align well with FE simulation outcomes - thus validating our elastic model.

To quantitatively predict three-dimensional fractures, we used a high-performance computer (HPC) environment to couple our elastic model with a phase field model – resulting in fracture initiation and evolution predictions that closely mirror experimental observations. This high-fidelity QCT-based approach offers a framework for personalized modeling of human tibias enabling patient-specific analysis relating to fracture risk, implant effectiveness, and optimal treatment strategies.

ABSTRACT

The grain structure orientation, size, and distribution play a significant role in dictating the mechanical properties, and residual stress distribution in an Additively Manufactured (AM) metal component. In temperature-based metal AM processes such as Laser Powder Bed Fusion (L-PBF), or Directed Energy Deposition (DED) techniques, the accurate calculation of the melt-pool geometry, is crucial for the evolution of grain structures, and the development of in-process stresses during and post-deposition. Accurate calculation of the melt-pool geometry is important because it improves the prediction accuracy of the temperature gradient on the solidification front. For alloys with Face or Body body-centered cubic (FCC/BCC) crystal structures, the local orientation of the temperature gradient dictates the primary dendrite growth along a specific preferable easy growth direction of the material. This phenomenon has been observed to be more dominant in the Wire-Arc DED (WA-DED) processed Inconel alloys, wherein the fabricated components have consistently shown epitaxial growth of columnar grains oriented along the build (vertical) direction. In the Finite Element (FE) based sequentially coupled thermomechanical simulations of the WA-DED process, the usual practice is to model the deposit geometry as a rectangular block. A direct advantage of this assumption is the geometrical consistency with brick elements employed during the FE analysis. However, this assumption is inconsistent with the freeform shape of the deposited track during the WA-DED process. This work explores the importance of accurate modeling of the deposit freeform shape in the thermomechanical FE simulations for the prediction of the solidification front, local temperature gradients, the evolving in-process deformations, and the post-solidification residual stress. Additionally, the importance of freeform deposit shape on the grain structure formation, the grain orientations, and grain shapes and sizes are also estimated using the recently developed Discrete Dendrite Dynamics (DDD) model [1, 2]. Note the simulations are supported by experimental measurements and tests (such as Thermocouple, XRD, and EBSD) at various stages for calibration and validation.

PARALLEL NEWTON-KRYLOV AND QUASI-NEWTON SOLVERS FOR NONLINEAR CARDIAC MODELS

Luca F. Pavarino[*1], Nicolás Barnafi[2], Ngoc Mai Monica Huynh[1] and Simone Scacchi[3]*

[1]*University of Pavia*
[2]*Pontificia Universidad Católica de Chile*
[3]*University of Milan*

ABSTRACT

This talk focuses on preconditioned Newton-Krylov and quasi-Newton solvers for nonlinear cardiac models arising in electrophysiology and cardiac mechanics. The preconditioners considered belong to the classes of both Algebraic Multigrid Methods (AMG) and Dual-Primal Domain Decomposition, such as Balancing Domain Decomposition by Constraints (BDDC) and Dual-Primal Finite Element Tearing and Interconnecting (FETI-DP). We first study the performance of AMG and BDDC preconditioners in a Newton-Krylov solver for cardiac mechanics, varying the choice of BDDC local and coarse solvers, primal degrees of freedom, finite element degree and investigating the strong scalability of the solvers [1]. We also study alternative nonlinear solvers for cardiac mechanics where the classical Newton-Krylov method is replaced by inexact Newton-Krylov and quasi-Newton methods, varying the problem size, data magnitude and number of processors, showing in some cases a significant speed-up over the standard Newton-Krylov method [2]. BDDC and FETI-DP preconditioners with deluxe scaling can also be applied to Newton-Krylov solvers for the Bidomain model in cardiac electrophysiology where a polylogarithmic convergence rate bound can be proven and validated by parallel numerical tests, showing that the proposed parallel solvers are scalable and quasi-optimal [3].

ABSTRACT

We propose a novel PDE-constrained shape registration algorithm to capture the elastic deformation and growth of biological tissues from imaging data. Shape registration is the process of evaluating optimum alignment between pairs of geometries through a spatial transformation function. The presented framework evaluates the optimum spatial transformation function through minimization of an energy functional which consists of a distance measure reflecting the mismatch between the shapes and hyperelastic strain energy. We carry out the registration such that the spatial mapping satisfies partial differential equations that describe linear momentum balance of growing soft tissues.

We use 3D tensor product B-spline basis functions to interpolate 3D space. Here, the movement of the B-spline control points, composed with an implicit function describing the shape of the tissue, yields the total deformation gradient field. The deformation gradient is then split into growth and elastic contributions. The growth tensor captures addition of mass, i.e. growth, and evolves according to a constitutive equation which is usually a function of the elastic deformation. Stress is generated in the material due to the elastic component of the deformation alone. Our approach follows existing finite element implementations of growing tissue, but within the isogeometric analysis framework [1]. We apply the proposed shape registration framework to study tissue expansion during skin reconstruction surgery. Here, we characterize skin growth on a porcine animal model. The registration framework is able to achieve analysis of skin growth in the complex geometries that are available from 3D photography instead of the simplified models. We also apply the registration framework to study the mechanics of tricuspid valve deformation in patients with hypoplastic left heart syndrome (HLHS) [2]. The resulting geometry will be used in a fluid-structure interaction simulation framework to help understand the key functional metrics that indicate the onset of TR in HLHS newborns. We anticipate that our PDE-constrained shape registration method will improve our understanding of biological and medical problems in which tissues undergo extreme deformations over time.

PREDICTION OF PROGRESSIVE FRACTURE IN THIN MONOLITHIC AND LAMINATED GLASS PLATES WITH AN EFFICIENT RANDOMIZED PHASE FIELD MODEL

Sidharth PC[1] and B. N. Rao*[1]

[1]*Indian Institute of Technology Madras*

ABSTRACT

This study utilizes a phase-field approach to analyze brittle fracture in four-point bending of monolithic and laminated glass plates. Objectives include a thorough comparison of phase-field fracture formulations for thin glass plates, evaluating dimensional reduction and mesh parameters, and validating temperature-dependent material properties for polymer foils. Acknowledging limitations in the Bourdin–Francfort–Marigo model, two additional phase-field fracture models are explored. Challenges in resolving the phase-field length-scale parameter are addressed, proposing methodologies for determining fracture energy. Despite discrepancies in crack localization, phase-field models show agreement with measured stresses and resistance in laminated glass. The study also explores the enhanced post-critical response of laminated glass, attributing it to the composite effect of stiff glass layers and compliant polymer films. This ductility makes laminated glass suitable for safety-critical applications without sacrificing aesthetics. Traditional deterministic failure models struggle to reproduce this response, leading to the introduction of a randomized model using Weibull variables for layer-wise tensile strength. Employing a dimensionally-reduced phase-field formulation, numerical simulations demonstrate the randomized model's potential, although the predicted response falls short in ductility compared to experiments. This emphasizes the importance of considering strength variability along the beam length and incorporating it into phase-field formulations for an accurate representation of laminated glass behavior

FRACTURE PROPAGATION ALONG CONTACT INTERFACES

Chris Pearce[1], Lukasz Kaczmarczyk[1], Andrei Shvarts[1] and Ignatios Athanasiadis[1]*

[1]*University of Glasgow*

ABSTRACT

This work focuses on an implicit computational framework for simulating crack propagation along contact interfaces and surfaces under load in three-dimensional bodies. We restrict ourselves to brittle fracture and frictionless contact and focus on numerical challenges associated with the coupling of unilateral constraints emerging from both the contact conditions and fracture criterion.
The formulation is based on the configurational mechanics framework and is solved using the finite element method. The approach utilises a monolithic Arbitrary Lagrangian-Eulerian formulation permitting simultaneous resolution of crack propagation and unilateral contact constraints. Contact is embedded in the model using the well-known mortar contact formulation.

Evolving cracks are explicitly modelled as displacement discontinuities within the mesh. Heterogeneous approximation of arbitrary order is used to discretise spatial displacements, enabling hp-adaptive refinement around the crack front and the contact interfaces traversed by the crack. The result is a holistic approach which handles issues associated with thermodynamic consistency, numerical accuracy and robustness of the computational scheme.

Several numerical examples are presented to verify the model formulation and implementation. The examples also highlight how contact pressure on surfaces traversed by cracks influence their propagation.

The approach is validated by comparison of our simulations with both academic and industrial problems, involving cracks of complex morphologies propagating along contact interfaces between multiple deformable bodies.

USE OF THE STRESS TENSOR FOR PLOTTING LOAD PATHS IN ORTHOTROPIC LAMINATES

Garth Pearce[*1] and Donald Kelly*[1]

[1]*University of New South Wales*

ABSTRACT

The use of pointing vectors defined by columns of the Cauchy stress tensor to plot load paths for transfer of loads in structural mechanics has been recognised for some time [1,2] and more recently verified in two-dimensional elasticity by the work of Tamijani et al [3].

The stress tensor is given by the results of a finite element analysis. It has been shown, for example in [2], that the three columns of the stress tensor are vectors that are parallel to the force flow in each of the coordinate directions. Contours parallel to these vectors define walls across which the corresponding force does not flow. Defining neighbouring contours, initiating where load is introduced to the domain, defines paths along which load is transferred. When there are no distributed forces the load transferred along the path is constant. When body forces are present, such as gravity or inertia loads in transient dynamics, the force being transferred between the walls will vary. The imagery is therefore enhanced by color coding the contours according to the magnitude of the path vector. This color coding indicates the load per unit area being transferred locally along the path.

The stresses can come from a static linear elastic analysis, or from a transient or material nonlinear solution in structures with beam, plate or solid components. Applications in [2] included force transfer through a bolted joint and transient stress propagation in a helicopter frame following impact.

This paper will focus on the three-dimensional load transfer within laminated orthotropic materials including load transfer between plies in the presence of geometric discontinuities and ply drops. The role load paths can play in optimal fiber placement will also be discussed.

MACROSCALE MODELING OF WOOD FRACTURE UTILIZING THE PHASE FIELD APPROACH

Sebastian Pech[*1], Markus Lukacevic[1] and Josef Füssl[1]*

[1]TU Wien

ABSTRACT

Wood, as a naturally grown material, exhibits an inhomogeneous material structure as well as a quite complex material behavior. For these reasons, the mechanical modeling of fracture processes in wood is a challenging task and requires a careful selection of numerical methods. Promising approaches like limit analysis or the extended finite element method (XFEM) in combination with microstructure materials models deliver good but not yet satisfying results. Particularly the latter approach, including XFEM, has severe difficulties with crack paths in regions with complex morphology, mainly around knots. Therefore, in this work, the focus is laid on the recently emerging and very popular phase field method [1]. Especially geometric compatibility issues that limit the use of XFEM can be avoided, as the crack is not discretely modeled but smeared over multiple elements. This allows the formation of complex crack patterns, defined by the underlying differential equations and boundary conditions but not restricted by the mesh geometry. The present implementation [2,3] contains a stress-based split which allows proper decomposition of the strain energy density for orthotropic materials. Furthermore, the geometric influence of the wood microstructure on crack propagation is taken into account by a structural tensor scaling the length scale parameter of the phase field [3]. For solving the system of differential equations, a staggered approach with an additional Newton-Raphson loop is used. The developed algorithm was tested on various problems. Compared to XFEM more computation time was needed as the phase field method requires a finer discretization. However, crack patterns, including branching and merging, could be modeled very stable and accurately, even in the vicinity of knots where the material structure of wood is particularly complex and interface zones exist.

EFFICIENT SOLVERS FOR BIOT'S EQUATIONS

Álvaro Pé de la Riva[1], Carmen Rodrigo Cardiel[1] and Francisco J. Gaspar Lorenz[1]*

[1]*University of Zaragoza*

ABSTRACT

In this work, our goal is to design efficient numerical methods for the poroelastic Biot's equations that model the soil consolidation process. Discretization of these equations yields large-sparse linear systems whose efficient solution is a key point. For the solution of Biot's equations there are two main approaches: iterative coupling methods and monolithic or fully coupled methods. Both strategies will be considered by means of several numerical methods such as the so-called fixed-stress split method and monolithic multigrid methods. Moreover, the authors will propose improved versions of these methods and show their good performance for some numerical experiments.

[1]*Eindhoven University of Technology*

ABSTRACT

A Discrete Slip Plane model has been developed to account for the heterogeneity of plastic deformation at the subgrain scale, as well as for nonstandard, highly orientation-dependent plastic mechanisms facilitated by the substructure of some of the phases of interest. The model is founded on the concept that individual, atomic slip planes have a different likelihood of becoming active due to the presence of dislocation sources and obstacles on them. It hence considers the discrete slip on each of them and assumes it to depend on the ratio of the resolved shear stress and a slip resistance which is sampled from a statistical distribution which takes into account the presence of sources and obstacles [1].

In the numerical implementation of the model, a large number of (atomic) discrete slip planes are collected into bands, whose response is governed by the weakest of the discrete slip planes contained in them. The thickness of the bands is considered a numerical parameter. For sufficiently small values, the result is found to be insensitive to the band thickness. The resulting governing equations resemble those of conventional crystal plasticity, albeit with slip system specific and spatially varying properties. They are solved using the finite element method and fully consistent Newton-Raphson iterations.

The model has been validated against micro-tensile tests on advanced high strength steel samples which have locally been thinned to a few micron, so that their microstructure is practically uniform through the thickness. This allows us to construct finite element models which capture the full, three-dimensional microstructure of the region of interest in great detail and without the usual uncertainty on the subsurface microstructure [2]. A very good agreement between the experimental and numerical slip patterns is observed.

Simulations of three-dimensional representative volume elements of the material allow us to understand particular features of its macroscopic response, such as e.g. the very steep initial hardening observed for martensite.

ABSTRACT

Abstract
There has been considerable research devoted to modeling fractures driven to propagate in a porous elastic medium by the injection of a viscous fluid. Once fluid injection ceases, the fracture may, depending on the dominant process among the multiple competing physical processes, continue to propagate till arrest or arrest immediately, deflate without changing its footprint, and then finally recede due to the loss of fluid to the porous medium. Recent analytic work [1] has established the tip asymptotics for receding hydraulic fractures that close due to leak-off to the permeable medium as well as the multiscale asymptotes that govern the arrest-recession transition. These multiscale asymptotic results have enabled the development of rigorous numerical schemes to explore the recession dynamics of plane strain and radially symmetric hydraulic fractures [2]. These detailed studies have made possible the identification [3] of the so-called Sunset Solution, which is a similarity solution that emerges close to the ultimate collapse of the fracture. The asymptotic analysis performed in [3] establishes that the existence of the Sunset Solution is due to a fundamental decoupling of the kinematics from the dynamics in the governing equations, which leads to a robust way to measure the Carter leak-off coefficient from the rate of change in the fracture aperture at the wellbore.

In this talk we will outline the derivation of the receding asymptote and provide numerical evidence for the similarity solution that emerges close to the ultimate closure of the fracture. We will derive a particularly simple analytic expression for this Sunset Solution and demonstrate how it can be used to estimate the so-called Carter leak-off coefficient from aperture closure measurements, which characterizes the porous medium.

ABSTRACT

Quantifying the biomechanical behavior of cardiovascular tissues holds immense potential to enhance our understanding of (i) smooth and cardiac muscle cell responses to mechanical cues and (ii) how structural and compositional alterations within these tissues impact their overall functional behavior. Such insights are crucial to unravel disease mechanisms (e.g. atherosclerosis, aneurysm, myocardial infarction), to optimize and personalize current treatment strategies (e.g. annuloplasty ring or stent sizing), and to develop novel medical devices (e.g. artificial heart valves or vascular grafts). Such studies depend critically on the accuracy of the underlying constitutive models, which govern the thermodynamically consistent relationship between the tissue's deformation and internal stress state. Given cardiovascular tissue's highly non-linear, transverse isotropic or even orthotropic mechanical behavior and a vast ever-increasing library of potential constitutive models, identifying the most accurate material model can be a challenging procedure prone to significant user bias. To resolve this subjectivity and democratize computational engineering analysis for all, we leverage constitutive artificial neural networks and machine learning to automate and democratize constitutive model discovery for these intricate materials. Based on arterial and myocardial biaxial tensile and triaxial shear testing data, our framework autonomously identifies the optimal material models and parameters from a library of over 232 = 4,294,967,296 possible material models. By seamlessly integrating the discovered material models into a universal material subroutine for (in)compressible (an)isotropic tissues, our work advances the implementation of these models into cardiovascular finite element simulations. This not only enhances user-friendliness and robustness but also mitigates the vulnerability to human error. The automated approach signifies a significant stride towards a more inclusive, user-friendly, and accurate framework for cardiovascular biomechanics simulations, ultimately contributing to improved medical treatments for cardiovascular diseases.

ABSTRACT

Impact of a sphere on a plate has been recognized as a fundamental problem in contact dynamics, which couples the nonlinear contact between the sphere and the plate and the energy dissipation by the flexural wave on plate. For an elastic contact, the dynamics can be formulated using a highly nonlinear ordinary differential equation (Zener's equation), which cannot be solved exactly but only be approximated. However, elastic contact suggests low-speed impact, which is rather rare in engineering application. For a high-speed impact, both the flexural wave and the contact plasticity account for the loss of kinetic energy. Therefore, we must take the contact plasticity into account, which introduces to the problem not only more complexities, but also loading-unloading asymmetry. In this work, we modeled the elastoplastic dynamics between the sphere and plate by bringing the MYC plastic contact model into Zener's equation. With dimension analysis, this model can be controlled by only two nondimensional parameters. Solving the present equation via analytical and empirical methods, this model can accommodate the elastic impact, the fully plastic impact, as well as the transition in-between.

TRANSPORT AND DISPERSION OF ACTIVE COLLOIDS IN PERIODIC DOMAINS

Zhiwei Peng[*1]

[1]*University of Alberta*

ABSTRACT

Transport and mixing within suspensions of swimming microorganisms are important for the understanding of many biological and industrial processes, such as infection by motile bacteria or the formation of biofilms. Different from passive particles, the ability of active swimmers or particles to self-propel gives rise to interesting dynamics including accumulation at confining boundaries and upstream swimming in the presence of a pressure-driven flow. Such unusual phenomena are a consequence of the non-equilibrium nature of active matter.

Transport and dispersion of self-propelled or active Brownian colloids often takes place in applied flows and confining boundaries. In this talk, I will present a theoretical and computational framework—the generalized Taylor dispersion (GTD) theory—that allows us to characterize the long-time drift and dispersion of active colloids in the presence of flows through periodic domains such as corrugated channels and periodic porous media. GTD allows us to reduce the Smoluchowski equation that governs the spatial-temporal evolution of the particle dynamics in its full position orientation phase space into a couple of macrotransport equations that apply at long times. The long-time transport coefficients are obtained by taking appropriate statistical moments. In pressure-driven flow through flat channels, we show that active particles can swim upstream and exhibit non-monotonic dispersion behavior in contrast to the monotonic flow-enhanced dispersion of passive matter. These predictions are consistent with those observed in experiments and Brownian dynamics (BD) simulations. Upstream swimming of bacteria poses a clinical threat in introducing catheter-associated urinary tract infection. Leveraging this theoretical and computational framework, we designed a catheter tube with internal periodic protrusions that are shown to reduce upstream swimming, and thus reduce infections by 1-2 orders of magnitude. With a prescribed pressure gradient, we calculate the flow field and the particle dynamics in the flow using a mixed continuum-BD approach. Computational results are validated against experimental measurements using 3D-printed catheter models.

ARTIFICIAL NEURAL NETWORK EVALUATION OF GEOMETRIC CONSTANTS IN POLYTOPAL ELEMENT METHODS

Silvia Bertoluzza[1], *Beatrice Crippa*[2] *and Micol Pennacchio**[1]

[1]*Consiglio Nazionale delle Ricerche*
[2]*Politecnico di Milano*

ABSTRACT

We presents an application of Artificial Neural Networks (ANNs) for the evaluation of geometric constants associated with polytopal element methods designed for solving partial differential equations. The constants under consideration play a key role for the numerical methods considered, impacting areas such as, among other things, a posteriori error estimates and method-specific stabilization parameters.
Leveraging ANNs, our methodology focuses on learning the dependencies between these constants and the geometric metrics of polytopal elements.
The algorithm's primary costs are confined to data processing and learning phases, that can be performed offline once and for all, resulting in an efficient method for computing the constants.

SIMULTANEOUS ENERGY HARVESTING AND SENSING USING PIEZOELECTRIC ENERGY HARVESTER BASED ON METAMATERIAL-INSPIRED STRUCTURES

Patricio Peralta-Braz[*1], Mehrisadat Makki Alamdari[1], Elena Atroshchenko[1] and Mahbub Hassan[1]*

[1]University of New South Wales

ABSTRACT

Piezoelectric Energy Harvesters (PEHs) are devices that enable taking advantage of the mechanical energy available in various sources of vibrations, transforming it into electrical power to supply low-power devices autonomously. Efficiency plays a critical role in these technologies, which depends strongly on achieving close synchronisation between the resonance frequency of the harvester and the source. On the other hand, there has been a growing interest in utilising these devices as sensors to acquire information about the source of vibration. Integrating these functions simplifies system design and optimises energy usage by efficiently directing generated energy to power other system components, such as a transceiver for cloud-based data transmission. This study introduces a novel design for Piezoelectric devices based on a Metamaterial-Inspired Structure for Simultaneous Energy Harvesting and Sensing (SEHS) system, aiming to enhance efficiency and power generation at low frequencies. The dynamic behaviour of the devices is modelled based on the Kirchhoff-Love plate theory and Hamilton's principle. Isogeometric Analysis (IGA) is used to solve the problem due to its capability to represent exactly complex geometries. Metamaterial-inspired structures often require multiple patches for representation, and to address this, Nitsche's method is incorporated. This method effectively manages C0-continuity and imposes conditions on the continuity of Dirichlet and Neumann's boundary conditions across interfaces. A machine learning framework is presented to infer relevant information from a highway bridge. It comprehensively describes the framework, including its key components and methodology. This study provides a valuable tool for designing and optimising SEH systems based on metamaterial-inspired structures, opening new avenues for practical applications. Numerical studies are conducted to assess the performance of metamaterial-inspired devices compared to traditional configurations.

HYBRID FINITE-ELEMENT / NEURAL-OPERATOR MODELING OF ICE-SHEET DYNAMICS

Mauro Perego[*1], QiZhi He[2] and John Jakeman[1]*

[1]*Sandia National Laboratories*
[2]*University Of Minnesota*

ABSTRACT

Modeling the dynamics of Greenland and Antarctic ice sheets is critical to provide probabilistic projections of sea-level rise. In order to accurately quantify the uncertainty of the sea-level projections due to uncertainty in the model parameters, we need to run the ice-sheet models for a large number of parameter samples, which is often infeasible due to the cost of ice-sheet computational models. To address this issue, we propose a hybrid approach to approximate existing finite-element ice-sheet models at a fraction of their cost. In this approach, the finite-element model for the ice momentum equations, which is the most expensive part of an ice-sheet model, is replaced by a Neural Operator, while the classic finite-element discretization for the evolution of the ice thickness is retained. We demonstrate the approach modeling the Humboldt glacier in Greenland. We show that the hybrid model is accurate and an order of magnitude faster than the traditional finite-element model. The hybrid model can provide statistics of the glacier mass loss that are in agreement with those computed using the reference finite-element model. For increased accuracy, the hybrid model can be effectively used in a multi-fidelity strategy where a relatively small number of evaluations of the finite-element model (considered the high-fidelity model) are used together with evaluations of the hybrid model to improve the projection of the glacier mass loss.

PHASE-FIELD MODELING OF BRITTLE FRACTURE UNDER CYCLIC LOADING: A NEW GRADIENT-BASED ENERGY SPLIT CRITERION

Umberto Perego[*1], Ayrton R. Ferreira[2] and Alessandro Marengo[3]*

[1]*Politecnico di Milano*
[2]*University of São Paulo*
[3]*Tetra Pak*

ABSTRACT

In this work we propose a computationally effective new criterion to avoid crack propagation under prevailing compression states due to load reversal in phase-field modeling of brittle fracture. In classical approaches the elastic energy is split into ‘active’ and ‘passive’ components. The ‘active’ ones enter into the phase-field driving force, whereas the ‘passive’ ones do not. The most popular approaches are probably the volumetric-deviatoric split, and the spectral split. For a summary of existing approaches along with a new proposal, see the recent work [1] and the references therein.
Making use of a simple example, similar to the one proposed in [1], we show the limitations of the volumetric-deviatoric and of the spectral energy splits. To overcome the problem, we simply propose to eliminate the contribution of the elastic energy from the phase-field driving force in those regions where the stress state is promoting crack closure. This is obtained by identifying the crack direction based on the current phase-field distribution and by computing the sign of the normal stress component in this direction. This in line with what has been proposed by other authors (see, e.g. [2]).

The formulation is based on two assumptions. The first one is the identification of the normal-to-crack direction with the damage gradient direction [2]. The second assumption consists of considering the sign of the projection of the stress tensor on the normal-to-crack direction at a point as an indicator of whether at this point the crack is opening or closing. In the first case, the whole elastic energy is ‘active’ and contributes to the crack driving force. In the second case, it is ‘passive’ and it does not contribute.

The accuracy of the present model under cyclic loading is assessed by means of the analysis of several benchmark problems. The obtained results confirm that the proposed energy split matches classic crack propagation predictions under tensile loading for Mode I and II, confining crack propagation to points subjected to prevailing tensile states while recovering the intact stiffness upon load reversal.

SOLUTION-ACCELERATION VIA HYBRIDIZATION OF FLUX RECONSTRUCTION METHODS

Carlos Pereira[*1] and Brian Vermeire*[1]

[1]*Concordia University*

ABSTRACT

Resolving complexities that characterize flows of practical engineering applications often poses significant challenges to numerical simulations. These challenges arise from a large number of degrees of freedom required to resolve the underlying physics accurately. High-order methods offer increased accuracy with reduced computational cost per degree of freedom. Among these methods, the Flux Reconstruction (FR) [1] approach is able to recover existing formulations, such as Discontinuous Galerkin (DG), via correction functions.

FR methods have proven effective in handling industrial flows governed by the Euler and Navier-Stokes equations on complex geometries. These type of problems typically involve grids with localized regions of stiffness introduced by the element size, which limit the maximum allowable time-step size in explicit time stepping. On the other hand, the computational cost of implicit time discretizations, associated with solving nonlinear systems that require linearization and preconditioning, scale with (p + 1)^d for a given spatial order p+1 and problem dimension d.

Hybridization of high-order methods, as pioneered by Cockburn et al. [2] DG methods and further extended to FR by Pereira and Vermeire [3], can be used to reduce computational cost of implicit discretizations. By introducing a trace variable and a global conservation statement, hybridization effectively reduces the scaling of the implicit system down to that of a lower-dimensional problem, typically allowing for smaller problems that require reduced computational cost.

Purely implicit methods remain computationally expensive for practical problems with increased numerical stiffness even after hybridization. In this sense, Implicit-Explicit (IMEX) integration can reduce geometry-induced stiffness by partitioning using an implicit method in regions of high geometry-induced stiffness and larger elements with an explicit method. Pairing hybridized and standard FR methods for the implicit and explicit portions, respectively, enables a significant reduction of computational cost over purely explicit methods. We demonstrate how hybridization can be used as a solution-acceleration technique to enable faster results without sacrificing accuracy. Results are illustrated via a series of numerical examples, including turbulent flow over a multi-element airfoil, showcasing speedup factors up to 50 times.

COMPARATIVE ANALYSIS OF PGFRP COOLING TOWER STRUCTURAL CONFIGURATIONS

João Paulo Pereira[*1], Eliane Maria Carvalho[1] and Janine Vieira[1]*

[1]*Universidade Federal Fluminense*

ABSTRACT

Pultruded glass fiber reinforced polymer (pGFRP) profiles are light, strong and corrosion resistant, and for decades have been used in large frame structures such as cooling towers. In this type of structure, it is common to use channel beams eccentrically connected to square hollow section (SHS) columns by a single bolt, which allows for easy assembly and savings in terms of connecting hardware. However, little is found in scientific literature about their structural performance. The current study assesses the structural behavior of this type of structure and compares it to a cooling tower designed as a traditional steel structure with I-beams and wide flange columns. The design of the structures is based on the Brazilian pre-standard for pultruded composite structures and finite element (FE) models were developed in the software SAP2000. The comparison is based on the total weigth, natural frequencies and quantity of materials, with the aim of stating the most optimized configuration for cooling towers made of pultruded composite material.

A STUDY ON THE EFFECTS OF SOLIDITY RATIO ON VIRTUAL GRATING MODELING OF WAVE-SLAT INTERACTION

Lucas Soares Pereira[*1], Liang-Yee Cheng[1], Vytor dos Reis Yamauti[1], Rubens Augusto Amaro Jr[1] and Fabricio Simeoni de Sousa[1]*

[1]*University of São Paulo*

ABSTRACT

The wave impact on coastal and offshore structures can lead to damages or stability issues. Aiming to mitigate the wave-induced loads, wave breakers that allow partial water circulation are effective. An example is the grating with a set of thin inclined slats, in which flow deflection may occur, depending on the angle of attack. Considering that the hydrodynamics can be affected by tiny spacing between the slats, the analysis of the effectiveness of such grating structures usually involves different spatial scales. As most particle methods, which are very effective to simulate highly nonlinear fluid structure interactions with free surface piercing structures, employ a single uniform resolution across the entire computational domain, the simulations of multi-scale Wave-Structure Interactions (WSI) problems requires a considerable number of particles to model both the fluid and solid domains. A computationally cost-saving alternative to model the effects of flow deflection due to the inclined slats is the adoption of the Virtual Grating (VG) technique. In the VG, the grating structure is modeled as a control volume and the particles' velocity normal to the slats inside the region are set to zero, reproducing the effects of the inclined slats. In the present work, the effects of the grating solidity ratio on the accuracy of the VG technique are investigated through simulations of wet dam break. For this purpose, the VG was implemented in an in-house projection-based Moving Particle Semi-implicit (MPS) framework, herein called MPS-VG. To verify the results obtained by the MPS-VG, simulations using the conventional particle-based MPS modeling are also performed. As a result, the correction factor for the deflection angle as a function of the solidity ratio is obtained.

MULTISCALE MESH-BASED GRAPH NEURAL NETWORKS WITH ADAPTIVE MESH REFINEMENT FOR PHASE FIELD FRACTURE PROBLEMS

Roberto Perera[*1] and Vinamra Agrawal*[1]

[1]*Auburn University*

ABSTRACT

Phase field (PF) methods, coupled with adaptive mesh refinement (AMR), have been widely used to study crack propagation in materials due to their robust formulation and ease of implementation. Despite their advantages and recent advancements in scalable implementations, PF fracture simulations can be slow and expensive, limiting their adoption in high-throughput applications. Mesh-based graph neural networks (GNNs) have shown promise in engineering problems involving complex physics on a mesh. However, mesh-based GNNs suffer from over-smoothing in problems involving very fine meshes due to a large number of required message-passing steps.

In this work, we develop a dynamic multiscale mesh-based GNN formulation for multiphysics problems with AMR. We use this approach to study PF-fracture problems using block-structured AMR (BSAMR) in brittle materials under tension and shear loads. We construct graphs using meshes of different resolutions where mesh points act as graph nodes and mesh edges act as graph edges. The proposed mesh-based GNN approach mimics a conventional iterative multigrid solver and applies a series of downsampling (coarsening) and upsampling (refining) steps on encoded feature vectors. We use skip-connections to connect similar levels at downsampling steps and upsampling steps to transfer information. The proposed approach mitigates problems of over-smoothing by linking points in fine-resolution regions over longer distances. Next, we propagate the solution in time and identify areas for mesh refinement. We perform BSAMR by inserting nodes (or mesh points) and edges (or mesh edges) and updating the graphs at corresponding levels.

We used this approach to simulate Mode-I and Mode-II fractures in brittle materials. First, we generated the training dataset for Mode-I crack using physics-based PF fracture simulations on a square domain with a crack (of different lengths and angles) on the left edge. We trained the dynamic multiscale mesh-based GNN on these simulations, performed validation studies, and tested the GNN framework for accuracy and performance. Next, we optimized the framework's architecture for optimal speed and accuracy. Finally, we used transfer learning (TL) to extend the framework to Mode-II loading and new crack locations within the domain. The framework demonstrated excellent accuracy and speedups compared to physics-based PF fracture simulations.

[2]*Cornell University*
[3]*Upstate Medical University*

ABSTRACT

Mechanical ventilation is a double-edged therapy in which objectives such as relieving the work of breathing, improving gas exchange, and avoiding alveolar overdistension must be balanced to sustain life. Determining the appropriate ventilator configuration is challenging as inter-subject variability is large and comorbidities are frequent. The development of personalized therapies may help optimize the clinical outcome. Computational lung models can be tailored to the patient's physiology, offering insight into their pulmonary mechanics across different scales.

While applications of lung models continue to emerge, validation against clinical data remains scarce, often presented only as proof of concepts. In this work, a novel computational model is formulated and validated using experimental data during mechanical ventilation. We develop a non-linear poromechanical model of the lung parenchyma coupled with a 0D model of flow across the patient's airway tree, using patient-specific geometries extracted from CT images and based on the work of Avilés-Rojas and Hurtado (2022) and the coupling approach of Berger et al. (2016). This approach simulates the lung's response to mechanical ventilation stimuli and assesses its predictive capabilities. Our approach is validated using previous studies' porcine data of volume-control ventilation experiments. Two validation approaches are employed: (i) the global model response is compared against experimental respiratory mechanics signals during volume-control ventilation. (ii) the end-inspiratory model prediction for the porosity distribution is compared against end-inspiratory CT data using regional aeration histograms.

By assessing the gap between the numerical predictions and actual lung behavior, we aim to guide future research endeavors. Our ultimate goal is to provide a clinically robust model to contribute to developing personalized mechanical ventilation therapies.

IMPLICIT SHOCK TRACKING FOR HIGH-SPEED FLOWS WITH ATTACHED SHOCKS

Matthew Zahr[1] *and Alexander Perez**[1]

[1]*University of Notre Dame*

ABSTRACT

Shock tracking aims to generate a mesh such that element faces align with shock surfaces and other non-smooth features to perfectly represent them with the inter-element jumps in the solution basis, e.g., in the context of a finite volume or discontinuous Galerkin (DG) discretization. These methods lead to high-order approximations of high-speed flows and do not require nonlinear stabilization or extensive refinement in non-smooth regions because, once the non-smooth features are tracked by the mesh, the high-order solution basis approximates the remaining smooth features. Implicit shock tracking methods recast the geometrically complex problem of generating a mesh that conforms to all discontinuity surfaces as a PDE-constrained optimization problem. The optimization problem seeks to determine the flow solution and nodal coordinates of the mesh that simultaneously minimize an error-based indicator function and satisfy the discrete flow equations.

For problems with shocks attached to surfaces, implicit shock tracking requires nodes to slide along surfaces of the object, which can be challenging for complex geometries. In this work, we develop a parametric description of surfaces of the domain from a high-order surface mesh and directly optimize the parametric coordinates of each surface node in the shock tracking setting. This ensures all surface nodes will conform to their original boundaries throughout the optimization procedure, and successfully produces shock-aligned meshes for flows with attached shocks.

DATA-DRIVEN SCALE-BRIDGING APPROACHES FOR COMPLEX ALLOYS

Danny Perez[*1]

[1]*Los Alamos National Laboratory*

ABSTRACT

The extremely large compositional space of complex alloys such as High Entropy Alloys (HEA) promises the development of highly tailored materials solutions with unique combinations of properties. However, the correspondingly astronomically large configurational space of local atomic environments makes the predictions of mesoscale materials properties, such as radiation resistance or elasto-plastic response, from atomistic simulations extremely challenging.

We present a comprehensive computational framework to accelerate the development of atomistic-to-mesoscale scale-bridging models through i) physics-informed machine learning to learn how the properties of local atomic environments affect the response of the material, and ii) uncertainty-quantification (UQ) to guide the generation of additional atomistic data to optimally inform the mesoscale models. We present two examples, the prediction of defect transport coefficients and the development of flow rules for crystal plasticity, that were autonomously developed using a large-scale computational framework guided by UQ. This approach offers a promising avenue to exploit massive scale computing to assist the exploration of the chemical space of HEA for specific applications.

POLYGONAL MESH GENERATION WITH OPTIMAL CONNECTIVITY USING DEEP REINFORCEMENT LEARNING

Arjun Narayanan[1], Yulong Pan[1] and Per-Olof Persson[1]*

[1]University of California, Berkeley

ABSTRACT

We consider the task of generating polygonal meshes for straight-sided geometries using a machine learning approach. We only allow for a set of basic mesh edit operations, namely edge insertion/deletion and vertex insertion/deletion. The objective function is a combination of the desired degree of the vertices as well as the faces (that is, the number of sides of the polygonal element). This allows us to generate for example fully triangular or quadrilateral meshes, by simply specifying the desired face degrees 3 or 4. At the boundary nodes we employ a heuristic which is aimed at producing high-quality final meshes. A deep neural network is applied to the half-edge data structure of the mesh, and it is trained on randomly generated geometries using reinforcement learning. We demonstrate the performance of the framework, and show the generation of nearly optimal meshes with triangular, quadrilateral, or higher polygonal elements. We also consider the benefits of introducing the element qualities into the objective function.

A HALF-CLOSED DG-SEM METHOD FOR WAVE PROPAGATION AND FLUID DYNAMICS

Per-Olof Persson[*1] and Yulong Pan*[1]

[1]*University of California, Berkeley*

ABSTRACT

We present a Discontinuous Galerkin Spectral Element Method (DG-SEM) with half-closed nodes and demonstrate its benefits for problems such as time-domain wave propagation and the compressible Navier-Stokes equations. For quadrilateral elements, we use one-sided Gauss-Radau points to obtain one additional degree of quadrature precision over the commonly used Gauss-Lobatto nodes. This results in an exact and diagonal mass matrix, and less aliasing error for convection dominated problems. Compared to Gauss-Legendre nodes, our scheme produces fewer connectivities and in particular generates a sparsity pattern similar to continuous Galerkin methods. For triangular elements, we develop half-closed nodesets that have optimal quadrature degrees as well as sparse interpolation operators for any additional quadrature nodes. We use this to develop efficient implicit solvers based on static condensation and iterative preconditioners operating on smaller blocks than traditional DG.

MULTISCALE CHEMO-THERMO-HYGRO-MECHANICAL BEHAVIOUR OF BLENDED CONCRETES AT ELEVATED TEMPERATURES

Simon Peters[1] and Günther Meschke*[1]

[1]*Ruhr University Bochum*

ABSTRACT

Cement is one of the largest global CO2 emission sources worldwide. Replacing ordinary Portland cement clinker with silica fume, fly ash or other supplements can reduce the enviromental impact up to 50%. However, this contemporary cements show higher explosive spalling risks under fire loading in experiments. Although, the origin of this behaviour is still unclear, the drying front of concrete under fire loading was identified as important influence on the spalling behaviour. Due to the variety of blended concrete compositions, experimental investigations of the drying front are very costly. Computational models offer a possible remedy to capture the drying front for a variety of blended concretes and can lead to important insights into the problem's specifics with its multiphysical nature.

Based on chemo-thermo-hygro-mechanical analyses, the drying front of blended concretes under fire loading is investigated at macro scale, considering four primary state variables, i.e., gas pressure, capillary pressure, temperature, displacement and two internal variables, i.e., dehydration degree, chemo-mechanical damage.

A stochastic model employing Arrhenius equations for each cement constituent is utilised to quantify the dehydration degree for different blended concretes. The initial volume fractions of the studied cement composition are determined through a hydration model. Subsequently, the water release, porosity increase, and Young’s modulus of the hardened blended cement paste under elevated temperatures are coupled with the dehydration degree through established stoichiometric chemical dehydration formulas and Eshelby-type homogenisation.

Utilising a micro-poro-mechanical framework, the localisation of chemo-thermo-mechanical damage and stress states is achieved through Eshelby-type homogenisation techniques across various observation scales - concrete, mortar, and cement paste. Macroscopic stresses and the thermal incompatibility between aggregates and hardened cement paste induce stresses at different levels. At the cement paste scale, localised stresses drive thermo-mechanical damage, characterised by the expansion of randomly distributed and oriented penny-shaped inclusions. The chemo-mechanical damage is captured by dehydration induced porosity in both cement paste and aggregates.

Blended concretes, namely CEM II/A-LL, CEM III/B, CEM II/B-V, CEM II/B-Q, are analysed in the context of a numerical sensitivity study comparing the calculated drying fronts. It turns out that the grinding fineness and the hydration degree, both of which mainly determine the initial permeability, have a major influence on the drying front. Moreover, the monosulfoaluminate, ettringite and C-S-H volume fraction mainly determine the water release of cement paste due to dehydration, which also affects the drying front.

ABSTRACT

Sea ice plays an important role in the global climate by reflecting solar radiation and influencing ocean circulation making it essential to accurately simulate sea ice dynamics in the coupled Earth system. In this talk we describe a new Material-Point-Method (MPM)-based discretization for sea ice being implemented within the Model for Prediction Across Scales (MPAS)-Seaice framework in the Energy Exascale Earth System Model (E3SM) [1,2]. The MPAS-SI-MPM model couples Lagrangian particles with an efficient mesh-based solution of the equations of motion. Lagrangian particle methods have certain advantages over Eulerian grid-based methods for sea ice modeling due to their ability to naturally handle advection, maintain a sharp ice edge, and capture large deformations, but require additional algorithms for locating the particles on the mesh and mapping values between the mesh and particles. The salient feature of MPAS is the use of unstructured Voronoi meshes. The unstructured Voronoi meshes are Spherical Centroidal Voronoi Tesselations (SCVTs) which allow for both quasi-uniform discretization of the sphere and local refinement. The MPM implementation within MPAS requires an adaptation to this spherical Voronoi mesh. We will describe our implementation, which couples a reference element formulation of Wachspress shape functions with an element local mapping to the sphere [3], show that components of the algorithm converge as expected, and demonstrate performance on standard test cases.

SOLUTION OF RIEMANN PROBLEMS WITH REAL CHEMISTRY FOR COMPRESSIBLE FLOWS USING NEURAL OPERATORS

*Ahmad Peyvan**[1]

[1]*Brown University*

ABSTRACT

Deep operator networks (DeepONet) constitute a class of neural network models designed to acquire the mapping between input and output spaces. For this study, we used DeepONet to solve the Riemann problems for compressible flows. In particular, DeepONet is trained to map the initial pressure ratio in a Sod problem to final time profiles of density, velocity, and pressure for low to very high-pressure ratios. Additionally, we examine Riemann's problems incorporating real chemistry, in which the output encompasses the density of chemical species in addition to pressure and velocity. The DeepONet inferred solution also satisfies physical constraints such as mass and momentum conservation as well as entropy conservation. The primary advantage of DeepONet is, after training, swiftly acquire the solution from previously unseen input data within a fraction of a second.

REAL-TIME AERODYNAMIC LOAD ESTIMATION FOR HYPERSONICS VIA STRAIN-BASED INVERSE MAPS

Julie Pham[*1], Omar Ghattas[1] and Karen Willcox[1]*

[1]*The University of Texas at Austin*

ABSTRACT

We present an efficient inverse formulation for estimating aerodynamic pressure loads on a hypersonic vehicle using a strain-based sensing strategy. Real-time characterization of aerodynamic loads is critical for guidance, navigation, and control applications. In hypersonic flight environments, direct measurement of these quantities of interest is often intractable due to the harsh aerothermal conditions. Our work targets the hypersonic environment by employing strain-based sensing to infer the aerodynamic surface loads from sparse measurements of structural strain, first introduced in [1]. The strain response induced by the aerodynamic loads is governed by the partial differential equations (PDE) of linear elasticity, leading to a PDE-constrained inference problem. In our work [2], we pose the inference task as a least-squares problem with a high-dimensional linear constraint arising from a finite element discretization of the governing PDE. Due to the linearity of the constraint, a closed-form solution is available via the normal equations, which provides an inverse map from strain measurements to the aerodynamic pressure quantities of interest. Pre-computation of the inverse map, which comprises the high-dimensional system matrices, enables real-time evaluation of the least-squares solution (estimator) for a given strain measurement. The estimator is formulated for both (1) a parameterization of the surface pressure field via the proper orthogonal decomposition, and (2) a high-dimensional discretization of the surface pressure field. We employ a data-driven prior for regularization, constructed using computational fluid dynamics solutions of the surface pressure field. Additionally, the analytical covariance of the estimator provides explicit uncertainty quantification in the presence of sensor noise. The uncertainty statistics are used to formulate an optimal experimental design problem to identify the sensor configuration from a set of candidate sensors that minimizes the desired information criteria of the estimator covariance matrix. Numerical studies are conducted using the Initial Concept 3.X (IC3X) conceptual hypersonic vehicle. The results demonstrate the estimator performance for surface pressure reconstruction, as well as the corresponding force and moment coefficients, for a given noise level. We provide a discussion of accuracy, uncertainty, regularization, and optimal sensor placement for the IC3X testbed problem.

AN OPEN-SOURCE BENCHMARK FOR TRUSTWORTHY HIGH-DIMENSIONAL SYMBOLIC REGRESSION FOR ENERGETIC MATERIALS

Nhon Phan[1], Steve WaiChing Sun[1] and John Clayton[2]*

[1]Columbia University
[2]DEVCOM Army Research Laboratory

ABSTRACT

Symbolic regression requires heuristic searches of the expression trees to obtain mathematical expressions that optimize performance. These searches often suffer from the curse of high dimensionality and make the generation of mathematical expressions with more than one dimension difficult. This talk introduces and benchmarks strategies that leverage both the expressivity of deep neural networks and the interpretability of symbolic equations to discover underlying equations of state for energetic materials. In particular, we introduce an open-source framework in which a variety of mathematical models are inferred from a dataset obtained from molecular dynamics. We then compare the divide-and-conquer technique enabled by neural additive models and neural kernels to reduce the dimensionality of the symbolic regression problems with classical symbolic regression benchmarks based on genetic programming. Special emphasis is placed on (1) the approach to enforce physical compatibility (e.g., material frame indifference, material symmetry, thermodynamics) and (2) the predictive and descriptive accuracies of the models. Finally, the implications of the lack of universally accepted metrics, as well as the lack of open-source third-party validation to measure the interpretability and accuracies of the learned models, will be addressed.

DYNAMIC BEHAVIOR OF RIBBED VISCOELASTIC CNT-PDMS THIN-FILMS FOR MULTIFUNCTIONAL APPLICATIONS

Matthew Phillips[*1], Jong Ryu[1] and Mohammed Zikry[1]*

[1]*North Carolina State University*

ABSTRACT

Tailored ribbing structures were obtained by large-scale rolling in polymer thin-films by adding CNT inclusions, which significantly improved the mechanical behavior of systems subjected to dynamic compressive strain rates. A nonlinear explicit dynamic three-dimensional finite-element (FE) scheme was used to understand and predict the thermomechanical response of the manufactured ribbed thin-film structures subjected to dynamic in-plane compressive loading. Representative volume element (RVE) FE models of the ribbed thin-films were subjected to strain rates as high as 10000/s in both the transverse and parallel ribbing directions. Latin Hypercube Sampling of the microstructural parameters, as informed from experimental observations, provided the microstructurally based RVEs. An interior-point optimization routine was also employed on a regression model trained from the FE predictions that can be used to design ribbed materials for multifunctional applications. The model verifies that damage can be mitigated in CNT-PDMS systems subjected to dynamic compressive loading conditions by controlling the ribbing microstructural characteristics, such as the film thickness and the ribbing amplitude and wavelength. This approach provides a framework for designing materials that can be utilized for applications that require high strain rate damage tolerance, drag reduction, antifouling, and superhydrophobicity.

AN ALTERNATIVE ANISOTROPIC PLASTICITY MODELING APPROACH USING A SURROGATE ISOTROPIC MODEL AND STRONGLY TYPED-GENETIC PROGRAMMING-BASED SYMBOLIC REGRESSION

Brian Phung[1], David Randall[1], Karl Garbrecht[1] and Jacob Hochhalter[1]*

[1]*The University of Utah*

ABSTRACT

Interpretable machine learning has been used to train continuum plasticity models in a range of applications. While interpretable, these models must still be implemented for material- or structure-scale simulations (e.g., within a finite element solver), which can require considerable domain knowledge. To automate this process, an alternative approach is presented where an arbitrary anisotropic yield surface is mapped to a surrogate isotropic model. In this way, only a surrogate isotropic model needs to be implemented within a finite element solver, and the mapping is learned via interpretable machine learning. Such a method could potentially lower the technical barrier for modeling anisotropic yield behavior or automatically generate models from large sets of experimental data in high-throughput scenarios.

In this presented approach, a mapping between an anisotropic yield surface and the surrogate isotropic surface is provided as input to the implemented constitutive model. The approach is based on the work of Oller et al. [1], who used the transformed-tensor method to map an anisotropic yield criterion to a “fictitious” isotropic yield criterion. That method was recently extended by Randall [2] to determine the requisite transformation tensors as a function of evolving state variables (e.g., plastic strain) using strongly typed-genetic programming-based symbolic regression (ST-GPSR).
In this work, a proof-of-concept for the presented approach is demonstrated and evaluated. Using recent modifications to the GPSR code BINGO [2,3], transformation tensors mapping anisotropic yield surfaces to a surrogate isotropic surface are obtained for examples with varying complexity. These mappings are provided to a surrogate isotropic yield model implemented within a finite element solver. Finite-element simulations are performed, where the results from the presented mapping approach are compared and benchmarked against finite-element results for which the anisotropic yield behavior is explicitly implemented. The results from this study are expected to determine the efficacy and potential downfalls of the presented approach.

CORRELATION BETWEEN SURFACE-TO-VOLUME RATIO OF THE PARTICLE SHAPE AND ELASTIC PROPERTIES OF THE PARTICULATE COMPOSITES

Romana Piat[1] and Pascal Alexander Happ*[1]

[1]*University of Applied Sciences Darmstadt*

ABSTRACT

Presented studies are motivated by real-world particle shapes, observed using a scanning electron microscopy.
The focus of the presented studies was to understand the effects of the particle shapes on the effective elastic properties of the two-phase composites. For this, particles with polyhedral, undulated and other shapes were numerically modeled using analytical functions. Creation of some shapes, like polyhedral, are known from the literature [1] but Laplace's spherical harmonics [2], as well as the Goursat's surface and some others, were used for the first time to create novel particle shapes. Elastic properties of the composites with different particle shapes were calculated using the finite element analysis. The obtained results show good agreement with mean-field homogenization methods such like Mori-Tanaka and Lielens as well as other numerical results available in the literature [3]. Further, the dependence of the effective Young's moduli of the composite on the shape and the corresponding surface-to-volume ratio of the particles was studied.

For polyhedral, rotation symmetric and some other particles, the elastic properties of the composite were calculated and it was shown that for a particular volume fraction of the particles, an increase in the surface-to-volume ratio ψ results in an increase in the effective Young's modulus of the composite.

Comparing elastic properties, especially for the particles that are morphologically close to each other, e.g. particles obtained by Laplace harmonics, shows that the composites with these particles show dissimilar values of Young's moduli in spite of having the same surface-to-volume ratio. It can be concluded, that not only the surface-to-volume ratio but also other parameters like local surface curvature, concavity/convexity and sharpness of edges describing the local particle's geometry have substantial influence on the effective elastic properties of the composite. From this point of view, the studies of the correlation of these parameters with elastic properties of the particulate composites will be also interesting for the future studies.

GENERATIVE AI DESIGN OF MULTI-MATERIAL ROTORS FOR HIGH-PERFORMANCE PROPULSION APPLICATIONS

Zachary Cordero[1] *and Cyril Picard**[2]

[1]*MIT*

[2]*Massachusetts Institute of Technology*

ABSTRACT

The turbine of oxidizer-rich turbopumps in reusable oxidizer-rich and full-flow staged combustion rocket engines. These systems subject blisks to rapid thermal transients (10^4 °C/s) on startup and shutdown which drive low cycle thermal fatigue; extreme centrifugal loads and high operating temperatures (>700 °C) which drive creep; and high-pressure, high-temperature oxygen rich environments which drive catastrophic metal fires (e.g., if the rotor rubs against a stationary component). Conventional blisks in oxidizer-rich turbines are solid components made from single materials; common material choices include cupronickel alloys, Haynes 214, and Incoloy 909 because of their burn resistance, strength, and thermal shock resistance, respectively. However, because of low cycle fatigue, creep, and inelastic yielding, the service life of conventional monolithic blisks is limited to ~10 flight cycles, far less than the 100s of flight cycles envisioned for next-generation reusable launch vehicles. Another issue complicating blisk design is that the high-strength Ni-superalloys most resistant to mechanical failure have high concentrations of reactive elements which make them susceptible to catastrophic metal fires, highlighting a design tradeoff between reusability and reliability. Multi-material blisks offer a potential solution to these problems. For example, a multi-material blisk could combine thermally stable alloys, high strength alloys, and a burn-resistant alloy case, leveraging the best features of each material to mitigate thermal fatigue, creep, and metal fires, thus unlocking previously inaccessible combinations of turbine inlet temperature, oxygen pressure, and shaft speed. Motivated by this concept, we have been developing an apparatus for rapid experimental assessment of key material properties and a complementary generative AI design tool which together can be used to discover optimal multi-material designs for thermostructural applications. This framework replaces the generation of traditional curated material property curves with active learning, employing AI/surrogacy tools over conventional process-structure-property relationships. I will describe how we are using this framework to design a continuum multi-material blisk system for an oxygen-rich turbopump operating at turbine inlet temperatures substantially higher with service lives an order of magnitude longer than current state-of-the-art monolithic blisks.

OPTIMIZING ROTATING MACHINERY: A STUDY ON NATURAL FREQUENCY CONSTRAINTS APPLIED TO TOPOLOGY OPTIMIZATION OF FLUID-STRUCTURE INTERACTION PROBLEMS

Lucas Oliveira Siqueira[1], Anderson Soares da Costa Azevêdo[1], Emilio Carlos Nelli Silva[1] and Renato Picelli[1]*

[1]University of Sao Paulo

ABSTRACT

In some rotating machinery, the operation assembly presents tight tolerances, leading to wear problems caused by excessive vibrations. In this context, it is crucial to enhance the design of these components to reduce vibration levels and avoid resonant conditions. Based on that, this study focuses on topology optimization of fluid-structure problems considering turbulent swirl flow loading and natural frequency constraints on the 2D axisymmetric solids. The optimization problem proposed is compliance minimization subjected to volume and frequency constraints considering the three lowest natural frequencies. To ensure that the frequencies of interest are correctly constrained, the modal assurance criterion-based (MAC-based) mode-tracking method is employed to identify mode crossing during the optimization process. The governing equations are solved using separate domains, being the incompressible Reynolds-averaged Navier-Stokes equations with the k-ω turbulence model for the fluid, and linear elasticity with axisymmetry for the solid. The optimization method used is the Topology Optimization of Binary Structures with Geometry Trimming (TOBS-GT), which employs discrete (binary) design variables and different finite element analysis (FEA) and optimization meshes. Compliance sensitivities are computed through automatic differentiation using the adjoint method, while natural frequency sensitivities are derived through automatic differentiation using the forward method. Both FEA and sensitivities calculations are carried out in COMSOL Multiphysics. The integer optimization problem is solved via the branch-and-bound implementation in the CPLEX library. Three numerical examples are explored to study the design of the rotating solids through topology optimization. These examples include the rotating wall, the rotating and stationary wall system, and the stator structure. Results show that the method can increase the natural frequencies of the structures subjected to the interaction with a turbulent swirl flow in the context of rotating machinery.

CERTIFYING BIFURCATIONS IN ROMS VIA DEFLATED-GREEDY ALGORITHMS

Federico Pichi[1] and Maria Strazzullo*[2]

[1]*SISSA*
[2]*Politecnico di Torino*

ABSTRACT

This presentation focuses on the development of tailored reduced-order models (ROMs) designed for bifurcating nonlinear parametric partial differential equations (PDEs). In this framework, multiple solutions can coexist for given physical/geometrical parametric values. Traditional certified reduced basis techniques struggle to accurately represent non-uniqueness phenomena, as error estimators become unreliable when bifurcations occur. Consequently, ROMs for bifurcating PDEs have always relied on compression strategies, such as proper orthogonal decomposition (POD), or machine learning data-driven approaches [1].

The main goal of the talk is to propose a novel greedy algorithm for bifurcating systems based on the deflation strategy, a technique capable of finding the coexisting solution branches simultaneously [2]. These algorithms can (i) certify multiple behaviors of the system with an efficient exploration of the parameter space and (ii) identify the parameter responsible for the non-uniqueness of the solution through an adaptive strategy.

The deflated-greedy method leverages several techniques, including deflation and continuation, to enrich the reduced space with bifurcating solutions. On the other hand, the adaptive-greedy approach exploits the non-differentiability of the solution as a function of the bifurcating parameter.
The effectiveness of these strategies is tested on a classical benchmark defined by the Navier-Stokes equations in a sudden-expansion channel, featuring a symmetry-breaking phenomenon with three coexisting solution branches. The results are compared in terms of accuracy and error certification against state-of-the-art methodologies, e.g. standard greedy and POD.

MULTISCALE, MULTIMODAL COMPUTATIONAL MODELING OF MECHANOTRANSDUCTION IN THE DISTAL COLON AND RECTUM

Amirhossein Shokrani[1], *Bin Feng*[1] *and David Pierce**[1]

[1]*University of Connecticut*

ABSTRACT

Abdominal pain stemming from the large bowel is a primary manifestation of irritable bowel syndrome (IBS), significantly impacting quality of life. A major contributor to this pain is the mechanical distension of the distal colon and rectum. Mechanotransduction, the process converting mechanical stimuli in the colorectum into neural action potentials through sensory afferents, is pivotal in IBS-related bowel pain. Managing visceral pain in IBS remains a formidable clinical challenge due to the current limitations in research. While numerous medications effectively alleviate other types of pain, their efficacy in mitigating visceral pain is often limited, with potential adverse effects on the gastrointestinal system (GI). This study addresses this challenge by integrating experimental findings in afferent neural encoding and colorectal biomechanics into a comprehensive computational simulation framework. A three-layered, fiber-reinforced finite element model, accurately reproducing the nonlinear, heterogeneous, and anisotropic properties of the mouse colorectum using FEBio software, serves as the foundation. This model allows estimates of local mechanical stresses and strains around micron-scale afferent endings. The incorporation of a unique mechanosensitive neural membrane simulation replicates how local membrane tension encodes stress/strain into action potentials. Calibrated against experimental data, our neural membrane model considers NaV1.6 ion channels and mechanosensitive ion channels in spike initiation using NEURON. This multiscale model investigates three hypotheses on the mechanical gating of action-potential generation based on recent molecular-level insights into axon structure. Additionally, we explore the impact of afferent ending orientation on neural encoding properties. Beyond facilitating virtual analyses of colorectal mechanotransduction in prolonged visceral hypersensitivity, this work guides the design of new experimental studies to uncover the biomechanical and neurological mechanisms underpinning IBS-related bowel pain. Furthermore, it sheds light on potential mechanical and non-pharmacological interventions for colorectal diseases, contributing to the broader understanding and management of visceral pain associated with IBS.

FUZZY STATISTICS-AIDED INFERENCE IN EXPERIMENTAL DESIGN

ABSTRACT

Classical approaches to the design of experiments (DOE) aim to minimize the number of experimental tests by strategically distributing test points in the controlled factor space related to the studied process. This is often coupled with imposing a specific form of predictive model, typically a low-degree polynomial. Uncertainty propagation analysis, accounting for measurement uncertainties and disturbances from uncontrolled factors, is traditionally conducted using classical statistics, assuming a normal distribution in most cases. The drawbacks of such an approach include significant inaccuracies in predictive models under more extensive ranges of controlled factor variability, disparities between actual and predicted distributions, and interpretational challenges due to excessive precision in statistics and risk assessments, which are essentially computational artifacts unrelated to physical reality.

Proposed solutions to overcome these challenges involve the application of fuzzy evaluations. Grzegorzewski [1] generalized the decomposition of the decision problem into three components in a decision-making context: the data set, the statistical hypothesis, and the requirements. Each of these elements can be considered separately as either fuzzy or non-fuzzy. Buckley [2] developed an extensive mathematical framework for fuzzy statistical hypotheses. Traneva, Atanassova, and Tranev [3] actively extended the applications of intuitionistic fuzzy sets to decision-making processes.

This paper compares classical DOE analysis and its extension, which uses fuzzy statistics and inference procedures. The studied process involves laser treatment of special coatings applied through electro-spark deposition (ESD), modifying the geometry of the surface layer to achieve desired tribological properties. The application of fuzzy modifications to the analytical and inference processes facilitated the interpretation of the obtained results. It also led to developing a data-driven predictive model, enabling effective forecasting of multimodal trends, which was not feasible with traditional quadratic models.

INTERLAMINAR STRESS FORMULATION WITH EQUILIBRIUM BASED APPROACH APPLIED TO A SIMPLE MULTI-LAYER KIRCHHOFF-LOVE SHELL ELEMENT

Paulo Pimenta[*1] and Gustavo Gomes*[1]

[1]*University of São Paulo*

ABSTRACT

ABSTRACT

The present work focuses on equilibrium equations based on interlaminar stress formulation, applied to a new triangular multi-layer nonlinear shell finite element fully capable of simulating large displacements and rotations. The new shell element is an adaptation to a multilayer situation of the T6-3iKL element developed in [1], a Kirchhoff-Love shell kinematical model, considering the shell director across the layers as constant and the Rotation-continuity between adjacent elements and allowing multiple branches connections in the mesh. As a mean to guarantee the necessary degree of interpolation to represent the stress distribution throughout the thickness, the element considers strains along the edge of the element, as an extrapolation of the work developed in [2] and [3], and an additional bubble node. As for the interlaminar stress, an extremely simple approach is considered, a crank-nicolson equilibrium-based scheme, it is capable of representing complex stress distributions and establishing the foundations for future work on delamination analyses. The element is developed allowing for implementation of different material constitutive equations (Saint-Vennant, Neo-Hookean, and anisotropic materials). The model developed in this article is numerically implemented and results are compared to different references in multiple examples, showing the consistency and robustness of the formulation. It is believed that the multilayer extension with the desirable properties of no necessity of artificial penalty calibration, a simple kinematic, geometric exact, relatively small number of DOFs, the possibility to use 3D material constitutive models, easily connected with multiple branched shells and beams, and including possibly the simplest consideration of multilayers and interlaminar stress calculation, create a simple yet extremely capable shell element for interlaminar stress analysis.

A MULTI-PHYSICS FRAMEWORK TO INVESTIGATE THE COMPLEX FIRE-STRUCTURE INTERACTION IN MASS-TIMBER COMPARTMENTS

Guillermo Roa Muñoz[1], Marcelo Henríquez Suáres[1], Sergio Yanez[1], Carlos Felipe Guzmán[1], Erick I. Saavedra Flores[1] and Juan Carlos Pina[1]*

[1]University of Santiago of Chile

ABSTRACT

The use of structural wood products, such as cross-laminated timber (CLT), has undergone a substantial increase in the construction of both mid-rise and high-rise buildings. This can be attributed to the appealing visual attributes it offers, as well as its fundamental focus on sustainability. Among, the different mass timber elements, CLT panels are massive wooden boards, manufactured by gluing timber planks with alternating grain directions (90°). The resulting panels possess structural, thermal, and acoustic properties, that make them fit for use in mid-rise and high-rise buildings. Despite these benefits, the mechanical properties of timber are affected when exposed to elevated temperatures such as those present in fire scenarios. In CLT slabs the fire exposed layer generally becomes charred and experiences a loss in strength, while the top side layer, heated during the process, sees a reduction in its load-bearing capacity. These combined effects could potentially lead to structural collapse. Therefore, to promote its widespread adoption, it is imperative to thoroughly comprehend, the structural, thermal and fire behaviour of timber structural elements. This study focuses on the structural performance of CLT slabs in closed compartments exposed to fire conditions.

To investigate the structural fire performance of CLT structures, a one way coupled Computational Fluid Dynamics (CFD) - Finite Element Method (FEM) numerical approach is used to model the complex fire-structure interaction. For the CFD fire analyses the software Fire Dynamic Simulator (FDS) is used, whereas the ANSYS is used for the transient thermo-mechanical simulations. For the coupling between the CFD and FEM models the Adiabatic Surface Temperature (AST) approach was adopted. In the CDF domain, the modelling of the entire compartment is carried out, including the geometry, thermal properties of the different materials and the input heat release rate representing the fire load. Then, the transient thermal and subsequent thermo-mechanical analyses of the CLT slab is carried out, yielding the temperature at different depths and the structural response. The influence of the charring wood on the exposed surface of the CLT slab is incorporated in two ways. First, the contribution of the charred wood to the ongoing fired is accounted for in the fire simulation model. Then, in the transient thermo-mechanical model the evolution of the damage charred layer is also incorporated. Finally, the model is employed to assess the thermo-mechanical and fire performance of CLT slabs exposed to fire in mass timber compartments.

ABSTRACT

In Wall-Modelled Large-Eddy Simulations (WMLES) the flow away from a solid surface is resolved while the wall-layer is modelled. Typically, the interface between inner and outer layers does not coincide with the first grid point, and a buffer region is used to allow eddies to be created and develop into physically realistic structures. The present research aims to use Resolvent Analysis to synthesize near-wall eddies that are neglected in WMLES, thereby resulting in a more accurate representation of the momentum exchange between the bypassed near-wall layer and the outer flow. As a first step we calculate the force due to selected resolvent modes, and add it to the Navier-Stokes equations. The resolvent modes are characterized by their wavelengths in streamwise and spanwise directions, by their frequency and, very importantly, by the extent of their support in the wall-normal direction. Preliminary tests, carried out using a Wall-Resolved LES (WRLES), showed that (1) by changing the wavelengths of the resolvent modes we can affect independently various Reynolds stresses; (2) the resolved stresses adjust to the forcing, both in terms of their magnitude, and spectral distribution of the eddies responsible for the generation of shear stress $-\overline{u'v'}$; (3) that resolvent modes that span the inner/outer layer interface are more effective than those that lie entirely below this interface. Further tests consist of a series of WMLES in which the forcing due to various combinations of resolvent modes is added to the governing equations. Two Reynolds numbers are considered, Re=1,000 and 5,200. Since the resolvent modes were extracted from Re=1,000 calculations, the high-Re case provides a measure of how the approach can be extended to flow for which resolved LES or DNS data is not available. The use of the resolvent-mode-based forcing is found to affect the turbulent Kinetic Energy (TKE), which agrees better with the WRLES results. By selecting appropriate combinations of modes, the TKE and Reynolds-stress spectra are also improved, as the near-wall generation of eddies is enhanced by the forcing, in particular below the interface between outer and inner layer.

A KINEMATICALLY-EXACT REDUCED-ORDER ROD MODEL FOR ELASTOPLASTIC FAILURE IN THIN-WALLED MEMBERS

Marcos Pires Kassab[*1], Eduardo de Morais Barreto Campello*[1] and Adnan Ibrahimbegovic*[2]

[1]*University of Sao Paulo*

[2]*Universite de Technologie Compiegne – Alliance Sorbonne Universite*

ABSTRACT

This work profits from the embedded discontinuity FEM (ED-FEM) framework and a multiscale approach to derive a 7-DOF kinematically-exact reduced-order rod model for thin-walled members (starting from [1]) with a plastic hardening/softening constitutive equation (based on [2]-[3]) that emulates the coupling between local buckling effects and plasticity. The model is being implemented in an in-house finite element program for flexible thin structures, and shall be validated against reference solutions. The novelty as compared to [2]-[3] is the extension to the fully 3D context, including torsion-warping degrees-of-freedom and arbitrary (plastic) failure mode capabilities, allowing for the modelling of complex structural problems involving thin-walled members. Although kinematically-exact rod models are able to detect critical loads and represent post-critical configurations in most common scenarios, issues are bound to emerge when local effects (such as buckling of web and/or flanges) are relevant, especially when they are coupled with plastic deformations. For rod models, the combination of those factors can be satisfactorily represented in a phenomenological way by embedding them on a stress-resultant/cross-sectional strains hardening-softening plastic model, instead of enriching the model´s kinematics and related material law. One can employ multiscale modelling to generate constitutive relationships among the different strain and stress measures already containing information about plasticity, loss of geometrical stiffness, local buckling and even fracture conditions, with no or little increase on the number of degrees-of-freedom. The initial yielding behaviour can be handled through a plastic with hardening constitutive equation, whilst later buckling-plastic effects that lead to overall loss of bearing capacity of the structural element can be handled through a plastic with softening constitutive equation, in which discontinuities such as plastic hinges are present. For problems that involve strong discontinuities, the ED-FEM approach (see [2]-[3]) is an ideal match, allowing a local treatment of said discontinuities in a rather straightforward way. This approach introduces incompatible modes that have effects only inside the containing element, enriching its kinematics locally. Each incremental step of the numerical solution is solved by means of a split operator, whereby a Newton method´s step is performed with the usual rod´s DOFs (the local variables related to the discontinuities are statically condensed inside the elements), and then the local variables are solved in an element-wise fashion. This procedure adds little extra computational cost and proves to be quite robust, despite spoiling the quadratic convergence of the overall solution procedure.

AN INTEGRATED EXPERIMENTAL APPROACH FOR EROSION DYNAMICS: TRANSIENT TO STEADY-STATE

Patrick Pizette[*1], Johannes Christoffel Joubert*[2] and Daniel Nicolas Wilke*[2]

[1]*IMT Nord Europe*
[2]*University of Pretoria*

ABSTRACT

Transient erosion dynamics are characterised by rapid and often unpredictable changes in landscape, as dune erosion, due to short-term, intense events such as heavy rainfall, wind, flash floods, or human activities [1]. To capture these dynamics, our methodology integrates controlled laboratory experimental studies [2]. In the laboratory, experimental setups aim to replicate the effect of various erosion-inducing conditions, such as intense precipitation or concentrated flow. These controlled experiments enable precision control of erosion and deposition rates.

Steady-state erosion dynamics refer to the long-term, gradual processes of landscape alteration that occur under relatively stable environmental conditions. To study these dynamics, our approach integrates controlled laboratory experiments that simulate soil loss and permanent transects to accelerate laboratory data generation of representative erosion dynamics over extended periods in the field. These studies provide insights into the cumulative effects of erosion, factors influencing soil stability, and the effectiveness of erosion control measures.

An integrated approach for generating transient and steady-state erosion data provides a more holistic understanding of erosion processes. This experimental methodology not only helps in deciphering the immediate impacts of erosive events but also in understanding the long-term evolution of landscapes under continuous erosive forces. Such comprehensive data is essential for developing effective modelling strategies that can be used to predict soil conservation strategies, inform land-use planning, and mitigate erosion-related environmental impacts. By identifying appropriate model forms and calibrating erosion prediction models using the experimental data from transient and steady-state studies, we enhance the validity and applicability of the erosion prediction model. This integrated experimental approach application bas been faced up for a first application to coupled MLMs-DEM GPU (Meshless Lagrangian methods and Discrete Element Methods) models. Water-saturated system composed of particle bed that is immersed in a fluid has been simulated to obtain transient erosion with several particle size via MLMs-DEM simulations [3].

In summary, generating experimental validation data for erosion dynamics, encompassing both transient and steady-state aspects, is crucial for developing and refining erosion prediction models. This integrated approach is key to understanding and managing erosion processes in diverse environmental settings.

ABSTRACT

Sierra Structural Dynamics (SD) is a massively parallel, finite element-based structural dynamics simulation tool developed at Sandia National Laboratories to conduct important simulations supporting broad national security missions. SD has historically seen use in a variety of mechanical engineering applications, including modal analysis, random vibrations, shock response, and transient combined environments analysis, such as coupled structural-acoustics, thermal-structural, and especially fluid-thermal-structural interaction.

The ever-evolving combined environments specifications from engineers necessitate advances in the software's physics capabilities, and the high-fidelity models needed to capture uncertain structural loads and other challenging physical phenomena also require new software developments to fully utilize our modern, heterogeneous high-performance computing platforms.

This talk will focus on recent efforts in SD, including physics enhancements to characterize complex and uncertain structural damping, as well as assessments of performance and scalability for combined environments simulations.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology \& Engineering Solutions of Sandia LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

QUASI-BRITTLE FRACTURE MODEL FOR BERYLLIUM

JeeYeon Plohr[1], Abigail Hunter[1], Thomas Canfield[1] and Michael Prime[1]*

[1]Los Alamos National Laboratory

ABSTRACT

Beryllium is a challenging and interesting material to model; it retains ductility even when it fractures and exhibits twinning as well. Its dynamic response is highly rate-dependent. In an attempt to capture its complex behavior, a model called QBrT has been proposed. It is a mechanism-based, continuum-level model that incorporates viscoelasticity, twinning, and brittle damage in both compressive and tensile state. It accounts for the material behavior in a wide range of strain, strain rate, and temperature. We have parameterized this model for Beryllium and validated it using the plate impact experiments. We will present the simulation results of the Richtmyer-Meshkov instability (RMI), and compare them with the experimental results and the simulation of RMI using a plasticity model PTW. In conclusion, QBrT-Beryllium outperforms the PTW. Using this example, we will discuss the necessity of the Uncertainty Quantification (UQ) in the materials modeling.

Multiscale computational homogenization for bridging scales in the mechanics and physics of complex materials

PRE-TRAINED TRANSFORMER MODEL AS A SURROGATE IN MULTISCALE COMPUTATIONAL HOMOGENIZATION FRAMEWORK FOR ELASTOPLASTIC COMPOSITES

Zhongbo Yuan[1] and Leong Hien Poh[*1]*

[1]National University of Singapore

ABSTRACT

A composite material typically exhibits complex behavior at the engineer scale, arising from the interactions between its underlying constituent phases, as well as the competitions between micro-processes. It is generally a daunting task to develop an engineering model to adequately capture the essential micro mechanisms that propagate onto the macro scale. To this end, the multiscale computational homogenization method enables a consistent coupling across length scales, to give results that compare well with direct numerical simulations (DNS) having the full micro-structural details, without the need for any constitutive assumptions nor calibrations at the macro scale. Despite its predictive capabilities, the typical computational homogenization method is still computationally too expensive for most practical problems, as the coupling between micro and macro scales are solved simultaneously during its numerical implementation. In this presentation, focusing on the elastoplastic behavior of fiber-reinforced composite, we address this bottleneck with an offline development of a microscopic surrogate model for a given micro-structure, to be incorporated into a standard nonlinear FE framework, for rapid online implementations at the macro scale. For the offline training phase, we adopt the transformer-based architecture within a pre-training and fine-tuning framework. The proposed pre-trained transformer model is capable of parallelizing computations to effectively capture global dependencies within the strain-stress data sequences. To reduce the data generation cost, a constructed source representative volume element (RVE) having a single central heterogeneity with an identical volume fraction with the target RVE is utilized, to rapidly generate a huge source dataset for a pre-training process. The surrogate model is incorporated into a macro FE framework, and its predictive capabilities illustrated via the generic loading of two specimens with different microstructures, each having a different loading-unloading path.

PREDICTING AND CONTROLLING SINTERING-RELATED DEFORMATION AND DISTORTION WITH SURROGATE MODEL AND DIGITAL TWIN

Peter Polak[*1], Ran He[1], Mingxuan Xia[1], Baber Saleem[1], Xiaoxia Yu[1] and Jingzhe Pan[1]*

[1]University of Leicester

ABSTRACT

In ceramic manufacturing, controlling sintering-related deformations, including distortion, is of paramount importance. Finite Element Analysis with a well-suited constitutive law, can effectively predict sintering deformations and distortions. However, obtaining the necessary parameters for the constitutive law can be challenging. To address this issue, we employed an Artificial Neural Network (ANN) to establish a correlation between the parameters of the constitutive law and the corresponding predictions made by Finite Element Analysis, creating what we refer to as a Surrogate Model. This Surrogate Model is then used in a reverse manner within a Digital Twin framework to deduce the constitutive law's parameters based on observed sintering distortions during the manufacturing process.

PHYSICS-INFORMED MACHINE-LEARNING SOLUTION OF NONLINEAR PARTIAL DIFFERENTIAL EQUATIONS USING THE KOLMOGOROV-ARNOLD REPRESENTATION

Mikhail Poluektov[1]*

[1]*University of Dundee*

ABSTRACT

In 1950s, Andrei Kolmogorov and Vladimir Arnold showed that any continuous multivariate function can be represented by a specific composition of functions of a single variable [1]. Since then, it has been noticed that the Kolmogorov-Arnold (KA) representation can be a convenient machine-learning regression model – a predictive model that maps some vector input of a black-box system into a scalar output. However, the original Kolmogorov's proof was not constructive and did not provide insights into building the underlying functions of the representation based on the input-output data. There is a series of works that gives constructive proofs of the Kolmogorov's theorem and proposes convergent algorithms for determining the functions, see e.g. [2]. Recently, a lightweight iterative algorithm for construction of the underlying functions has been proposed [3] and subsequently improved (see arXiv preprint by the same authors), which simplifies the use of the KA representation as a machine-learning tool.
It has been shown that the KA representation in application to data modelling tasks performs equivalently to neural networks in terms of accuracy, but can require less computational time and resources for model identification, while having a capability to be implemented in a simpler code [3].
Physics-informed machine learning is an emerging field focusing on embedding physical constraints (e.g. conservation laws) into machine-learning models. One of the tasks considered within this field is solution of nonlinear partial differential equations (PDEs) using neural networks, which transpired to be a useful alternative to the established numerical discretisation schemes, especially in the case of scarcity of boundary data.
In the present talk, it is shown that the KA representation can also be used as a backbone of an efficient data-driven nonlinear PDE solver. The approach consists in replacing the unknown function of the PDE by the KA representation and identifying the parameters of the representation using the internal data generated by the PDE and the boundary data provided by the user. Several computational examples are given, including from the field of computational mechanics.

MESOSCALE MODELLING OF NEUTRON-IRRADIATED CONCRETE

Beatrice Pomaro[1], Jiangkun Zhang[1], Gianluca Mazzucco[1], Beaudin Freinrich Dongmo[1], Valentina Salomoni[1] and Carmelo Majorana[1]*

[1]*University of Padova*

ABSTRACT

In the context of ongoing license renewal and extended operation of in-service commercial nuclear power plants, there is an increasing focus on evaluating the long-term durability of concrete biological shields. To address this, a numerical approach is proposed within the framework of continuous computational methods. Specifically, a 3D thermo-mechanical and neutron diffusion (TMN) model for irradiated cementitious materials is developed, aligning with the Finite Element Method (FEM) at the mesoscale [1]. At this scale, the model accounts for radiation-induced volumetric expansion of aggregates as the primary interaction due to radiation. It incorporates a two-group neutron diffusion theory combined with heat conduction in the presence of thermal neutron capture.
Regarding the mechanical field, the model includes visco-elasto-plasticity and damage mechanisms [2], incorporating the most relevant interactions with radiation-induced material nonlinearities. A realistic geometry of a mesoscale concrete sample is numerically reproduced by treating it as a two-phase composite material consisting of aggregates and mortar. To validate the proposed model, an experimental study from the literature [3] is simulated. The numerical results in terms of damage propagation in neutron-irradiated concrete obtained with the model are juxtaposed to experimental results. This demonstrates the predictive capability of the proposed model for radiation damage triggering and evolution in concrete materials.

COMPUTATIONAL MECHANICS AND SCIENTIFIC MACHINE LEARNING FOR DIGITAL TWINS IN CRITICAL INFRASTRUCTURE PROTECTION

Alexander Popp[12], Tarik Sahin[1], Jacopo Bonari[2] and Max von Danwitz[2]*

[1]*University of the Bundeswehr Munich*
[2]*German Aerospace Center (DLR)*

ABSTRACT

The research field of computational mechanics, when interfaced with the advancements in scientific machine learning, opens new horizons in the development of digital twins, especially in the realm of critical infrastructure protection (CIP). This paper presents an integrated approach that combines traditional computational methods with novel machine learning techniques, thus aligning with the session theme "Enabling Technologies for Digital Twins: Model Reduction and Scientific Machine Learning".

Our initial focus delves into two foundational applications from our academic research at the University of the Bundeswehr Munich. The first encompasses the modeling and simulation of rough surface contact using traditional Boundary Element Methods (BEM). This established method is contrasted with our explorations in data-driven surrogate modeling techniques, showcasing how scientific machine learning can augment traditional computational mechanics. The second application transitions to the modeling and simulation of 2D and 3D contact mechanics. Here, conventional Finite Element Methods (FEM) are placed side by side with our recent work on Physics-Informed Neural Networks (PINNs).

The presentation then shifts its focus to address the emerging problem class of protecting critical infrastructures. At the DLR Institute for the Protection of Terrestrial Infrastructures, our group is spearheading the development of digital twins for this purpose. The primary goal is to forge accurate, reliable, and meaningful digital representations of critical infrastructure components for structural health monitoring, system surveillance, and the prediction of failure scenarios.

Among our ongoing projects, we spotlight a few key examples. The first involves the development of virtual sensing techniques for reinforced steel components in bridges, an initiative that merges model order reduction with computational mechanics. Another example details our efforts in simulating hazardous gas dispersion, utilizing model order reduction to enhance computational efficiency while maintaining accuracy. Lastly, we discuss our approach to damage assessment in critical infrastructures like wind turbine blades and bridges, employing physics-informed machine learning techniques to detect and predict structural weaknesses.

While the first part of this contribution presents mature and quantitative results from our academic research, the second part transitions to our current, more qualitative work-in-progress. This progression reflects the evolution from foundational research to applied, real-world challenges in critical infrastructure protection. Our work exemplifies the synergistic potential of computational mechanics and scientific machine learning, not just as discrete disciplines, but as integral components in the creation and implementation of digital twins for critical infrastructure protection.

DESIGN AND MECHANICS OF 3D WOVEN ARCHITECTED MATERIALS

Carlos Portela[*1], James Surjadi[1], Molly Carton[1] and Bastien Aymon[1]*

[1]MIT

ABSTRACT

Three-dimensional (3D) architected materials provide a pathway to defy the limitations of monolithic materials through their engineered internal microstructures, allowing them to exhibit unique and extreme properties. Thus far, research on the design of these architected materials has been primarily dominated by the quest to achieve extreme stiffness and strength, which limits their applicability in various fields. Unlike conventional truss-based architectures which induce stress concentrations and fail at strains lower than their constituent material, compliant woven architectures have recently been demonstrated to be able to sustain large tensile strains (several times larger than its constituent). However, the complex mechanics of woven architectures remain to be fully understood, and substantial bottlenecks exist in their design.

Here, we provide a computational design framework for woven architected materials that allows for spatial variation of fiber- and lattice-level parameters, allowing rapid generation of functionally graded architectures that can be fabricated at the micron scale and beyond. Variation of parameters at the sub-unit-cell level (on individual truss elements) greatly extends the design space and facilitates new modeling methods for these materials. Through reducing the lattice to a graph representation in order to create the weave topology, we facilitate the creation of woven architected materials with tailorable mechanical properties. Using this design framework, we present two modeling routes (high-fidelity and reducer-order) to quantify the architecture-dependent nonlinear properties, attributing contributions to nonlinear material properties and frictional contact. We discuss a specific hybrid design that attains improved stiffness and energy dissipation properties before failure. Through in situ micro-tension experiments to validate our models, we demonstrate that hybrid woven architectures can not only exhibit higher stiffness (more than an order of magnitude) than pure woven architectures, but also attain higher dissipated energy densities than the sum of their counterparts. This work aims to provide a pathway for the design of architected materials with tunable stiffness and enhanced toughness by harnessing deformation mechanisms in 3D woven architected materials. This fundamental mechanical understanding is useful for a wide range of applications, such as the development of 3D bio-scaffolds with engineered mechanobiological environments or soft pressure sensors with programmable electromechanical response.

EMBEDDED REDUCED MODELS IN THREE-DIMENSIONAL BODIES

David Portillo[*1], Guanfeng Zhang[2], Wenjie Xie[3] and Ignacio Romero[1]*

[1]Universidad Politécnica de Madrid
[2]Ansys Inc.
[3]Ansys Inc

ABSTRACT

Problems in which the so called reduced dimensional models, such as beams, shells or membranes, are embedded into a solid domain arise in many engineering applications or physical modelling: reinforcement bars in concrete structures, fibers in composite materials or padle rackets are some examples. We present a complete theory for modelling reduced dimensional models embedded in deformable solids. Although there are several reduced dimensional theories, each one with its own different model, in this work we deal with a general type of these reduced dimensional models which encompasses the most typical ones for beams, shells, membranes… This common description allows us to generalise the strategy for the most common structure embedded in solid problems.

The presented theory works in both small and finite strain regime. Moreover, we complete it with a numerical discretisation strategy that yields convergent approximations. The ideas, based on the Arlequin method [1, 2], can be used to prove rigorously that the method is unconditionally stable for linear problems. Extending the same principles to the finite strain range we expect the resulting methods to perform well. Although no proof can be given in this case, the numerical results obtained confirm the robustness of the formulation.

TRUSTWORTHY AND SCALABLE DATA-DRIVEN CLOSURE MODELS

Teresa Portone[*1], Mohammad Khalil[1] and Kyle Neal[1]*

[1]*Sandia National Laboratories*

ABSTRACT

Computational simulations of dynamical systems often require constitutive or closure models to represent unresolved phenomena, enhance computational efficiency, or correct model form error in the simulation. Data-driven closure models (DDCMs) employ machine learning (ML) to learn the closure term as a function of dynamic system states and have the potential to increase the predictive capability of computational simulations; however, trustworthiness and scalability of DDCMs are needed for adoption. In this work, we propose a methodology that addresses these needs by decoupling the estimation of the closure term from training the DDCM.

The time evolution of the closure term is estimated from experimental data using ensemble Kalman filters (EnKF) or other nonlinear filtering techniques. The DDCM is then trained independent from the dynamical system model, using the time evolution of the closure term as training data. Uncertainties that arise from sparse or noisy experimental data are mapped to the estimated closure term using the EnKF, then probabilistic ML algorithms propagate uncertainties to the DDCM. The approach is demonstrated on exemplar problems such as the Duffing oscillator, ecological models, and epidemiological models.

SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

[3]*University of Stuttgart*

ABSTRACT

Multiphase metal matrix composites are used in modern industries like energy, aerospace, and automotive. The materials are used in severe loading conditions like impact loads or thermal shocks. The presentation concerns a data-driven model of an interpenetrated composite. The geometry of the material phases is obtained using CT scanning. Further details, namely, the distribution of voids and inclusions are found with the scanning as well. Based on CT scans the 3D finite element and peridynamics models are derived from. Former analyses [1, 2] showed the importance of the existence of an interface zone in multiphase composites. In the current presentation, the diffusion-based mechanism of forming the interphase zone is shown. A constitutive law evaluated in [3] is considered. The constitutive law for the cohesive zone was obtained using molecular dynamics simulations. The effects of the MD-based law on mesoscale samples are presented.

A NEURAL NETWORK APPROACH TO NUMERICAL APPROXIMATION OF INFINITY AND P-LAPLACE PROBLEMS

Hannah Potgieter[*1], Ivan Au Yeung[2], Charles Cheung[2] and Steve Ruuth[1]*

[1]Simon Fraser University
[2]NVIDIA

ABSTRACT

Approximating solutions to infinity and p-Laplace problems poses numerical challenges, particularly for nonsmooth data. Infinity and p-Laplace equations appear in a variety of applications including image processing, optimal transport, and distance approximation. Numerical approximation via a finite element method is often effective but has some limitations such as large computation time on refined grids. We seek to examine the capabilities and accuracy of neural network solvers for infinity and p-Laplace problems. In this talk, we will present experiments using both physics informed neural networks (PINNS) and deep operator networks (DeepONets).

A CARTESIAN-MESH STOCHASTIC FINITE ELEMENT SOLVER TO PREDICT BONE STRENGTH VARIATION

Saleh Pouresmaeeli[1,2] and Pinaki Bhattacharya*[1,2]

[1]*The University of Sheffield*
[2]*INSIGNEO Institute for in silico Medicine*

ABSTRACT

Introduction
To bring a new drug to the market for bone disease, the effectiveness of the drug, i.e. improvement of bone strength, should be quantified by considering natural variability between individuals. A common practice to deal with bone variability is to apply a non-intrusive uncertainty quantification method such as Monte Carlo on finite element (FE) models of bones but with the drawback of requiring a large number of simulations. Here, a stochastic FE (sFE) solver was developed that uses an intrusive method to predict the variation in bone mechanics given the variability in bone tissue elastic properties.

Methods
The deterministic Cartesian-mesh (voxel-based) FE solver ParOSol [1] was used as the starting point. ParOSol solves the system of equations without storing the stiffness matrix, which leads to a very small memory footprint. The new sFE solver was developed by implementing the Polynomial chaos expansions (PCE) method [2]. The element-wise Young's moduli and nodal displacements were considered as uncertain inputs and outputs, respectively. The problem was solved using a conjugate gradients solver with Chebyshev's smoother preconditioning. PCE coefficients of nodal displacements were statistically analysed to quantify the variability in bone strength. The implementation was used to analyse an annular cylinder, a simplified diaphysis section (height, 0.03 m; inner/outer radii, 0.01/0.015 m), and meshed using hexahedral elements (1 mm). A deterministic and spatially homogeneous Poisson's ratio (0.3) was assumed. Young's modulus (10 GPa) was deterministic everywhere except in a 90˚ segmental region (height, 0.007 m) where it was spatially homogenous but normally distributed within the population (mean, 10 GPa; coefficient of variation 10%). The bottom face was held fixed, and the upper face was compressed by 10% of the height.

Results & Discussion
The propagated uncertainty through bone strength was quantified and compared with the corresponding result obtained by the converged Latin hypercube sampling of the Monte Carlo method, LHMC, with 2000 samples. The variance in bone strength obtained by the sFE solver has a 1.5% error compared with the one determined by LHMC. Moreover, the total computational time of the sFE approach was ~124x lower than LHMC.

Conclusion
The present evaluation demonstrates the correctness of implementation and provides an initial demonstration of the accuracy of the sFE solver.

UNDERSTANDING THE MECHANICS OF RANDOM FIBER NETWORKS VIA NETWORK TOPOLOGY

Peerasait Prachaseree[1] and Emma Lejeune*[1]

[1]*Boston University*

ABSTRACT

Architected materials exploit geometry to obtain novel mechanical properties and functionalities. A common strategy to engineer architected materials is to design a unit cell with desired properties, and then assemble these unit cells into a periodic array [1]. However, natural and biological systems often have aperiodic microstructure that leads to interesting emergent global mechanical behavior. Designing aperiodic structures is challenging because they can both correspond to a larger design space, and contain complex mappings between structure and mechanical properties. As such, there has been significant recent interest in understanding the interplay between geometry and the global mechanical behavior of materials for designing architected materials with aperiodic microstructures.

One class of metamaterials with aperiodic microstructure that is ubiquitous in biological and natural systems is random fiber networks. Compellingly, most random fiber networks in nature exhibit nonlinear strain-stiffening behavior under uniaxial tension. The strain-stiffening effect arises from fibers in the network transitioning from a softer bending dominated regime to a stiffer stretching dominated regime [2]. The strain-stiffening effect is also accompanied by the emergence of load paths in the fiber network, akin to force chains in granular systems [3]. However, the connection between force chains, fiber network kinematics, and the nonlinear mechanics of fiber networks are not well understood. In this work, we aim to link network topology and kinematics (structure) to the stress-strain response of discrete random fiber networks (function). First, we examine the mechanics of single fiber chains and relate the kinematics of these fiber chains to the mechanical response under loading. With the intuition from the mechanics of single fibers, we then look into the mechanics of random fiber networks. Specifically, we identified potential force chain candidates from the initial stress-free network structure and associated the emergence of these force chains to the strain-stiffening functional behavior of random fiber networks.

TOPOLOGY OPTIMIZATION OF TIME DEPENDENT CONCENTRATED SOLID CHANNELS WITH INTERNAL HEAT GENERATION

Diego Prado[*1], Emilio Carlos Nelli Silva[1], José Luís de Paiva[1] and Marcelo Martins Seckler[1]*

[1]University of São Paulo

ABSTRACT

This work presents a novel topology optimization formulation for the Euler-Euler model applied to concentrated solid channels. Concentrated solids in fluid flow modeling are used in many relevant engineering areas, such as carbon capture and storage, electrochemical reactors, and fuel cells. One of these applications is a temperature swing adsorption (TSA) system. This system employs several stages to improve its efficiency. Inside these stages, adsorption takes place and generates heat. As adsorbent material temperature rises, its adsorption capacity decreases; thereby, temperature management is needed. Optimizing the topology of heat exchangers may reduce the operational cost and energy required for such a system. This investigation addresses fluid dynamics and thermal analysis, aiming to enhance the thermal efficiency of such systems by reducing thermal gradients and optimizing heat distribution within the channels. The forward problem is solved using a finite elements model, and sensitivities are obtained utilizing automatic derivation for the adjoint equations. The objective function is designed to minimize the internal energy inside the domain simultaneously. One example is presented to demonstrate the effectiveness and robustness of the proposed method. The example, an adsorption domain, demonstrates the formulation ability to handle time-dependent problems with internal heat generation. The results show that the optimized design can achieve significant improvements in performance over the initial designs, indicating the potential benefits of incorporating topology optimization and automatic differentiation into the design of systems based on Euler-Euler models. Additionally, results show that the design must be adjusted as solid density increases, which is relevant since most applications, such as fluidization, employ high-density solid materials.

PHASE-FIELD METHOD AS APPROXIMATION OF THE SHARP INTERFACE THEORY WITH THE ORDER PARAMETER AS INTERNAL STATE VARIABLE

Andreas Prahs[*1], Daniel Schneider[12] and Britta Nestler[12]*

[1]*Karlsruhe Institute of Technology (KIT)*
[2]*Karlsruhe University of Applied Sciences*

ABSTRACT

The phase-field method is a well-established technique for simulating microstructure evolution in computational materials science [1]. It enables the numerically efficient tracking of material surfaces by means of an order parameter. The evolution equation of the order parameter is typically derived using a variational approach or by exploiting a corresponding principle of virtual power. In both cases, the order parameter is treated as an additional degree of freedom. In addition, both approaches consider a diffuse interface region from the outset. In this contribution, following the remark by [2], the order parameter is considered as an internal state variable instead of an additional degree of freedom. Moreover, the phase-field method is considered as approximation of the sharp interface theory of a continuum containing a singular surface [3]. The evolution equation for the order parameter is consistently derived within the framework of continuum thermodynamics through the exploitation of the Clausius-Duhem inequality. In this context, for the diffuse interface region, the heat conduction equation, the thermomechanical coupling, and the role of latent heat due to phase evolution are discussed. A comparison with the evolution equation obtained by the classical variational approach is carried out.

DYNAMIC CHARACTERIZATION OF ARCHITECTED METAMATERIALS USING REAL-TIME HYBRID SIMULATION

Tao Zhang[1], Luz Maria Agudelo Urrego[1], Sun-Beom Kwon[1] and Arun Prakash[1]*

[1]Purdue University

ABSTRACT

Architected metamaterials are an emerging class of materials with extraordinary properties that can be tailored to achieve specific objectives by customizing their microstructural configurations. Further, the growth of additive manufacturing has enabled 3D printing of complex microstructures and has further stoked interest in this area. Applications areas of such architected metamaterials include mechanical, thermal, electrical, chemical, optical, magnetic and numerous others.

In this study, we focus on characterizing the dynamic performance of architected metamaterials such as energy absorption and wave attenuation under low velocity impact. We consider both, auxetic and nonauxetic microstructures, and study their response under plane wave propagation. A parametric study is conducted to evaluate how different microstructures perform and how their properties may be tailored to maximize wave attenuation.

A key objective of this study is to enable the use of real-time hybrid simulation (RTHS) for studying the dynamic characteristics of architected materials. With RTHS, that part of the metamaterial domain that is subjected to impact and undergoes large deformations and damage is modelled physically and other parts of the domain that remain linear are modeled numerically. A single actuator transfer system is used to connect the physical and numerical subdomains using an in-house Linux-based real-time execution platform. This effort is ongoing and challenges with conducting such RTHS and lessons learned will be presented.

REDUCED ORDER MODELING OF INCOMPRESSIBLE FLOWS

Aviral Prakash[*1] and Jessica Zhang*[1]

[1]*Carnegie Mellon University*

ABSTRACT

Advancements in computational hardware and physical simulation techniques have pushed the envelope of complexity of scientific applications that can be modeled with adequate accuracy. However, these high-fidelity simulations of many challenging applications are expensive for multi-query applications, real-time simulation and dynamics forecasting. In such situations, reduced order models (ROMs) are an attractive alternative as they can simulate engineering systems at a lower computational overhead without a significant loss in accuracy. Projection-based ROMs rely on offline-online model decomposition, where the data-based energetic spatial basis is used in the expensive offline stage to obtain equations of reduced states that evolve in time during the inexpensive online stage.

The online stage requires a numerical scheme for the dynamic evolution of the coupled system of pressure and velocity states for incompressible fluid flows. Furthermore, the dynamic evolution of a large number of these reduced states in the online stage can be expensive. In contrast, the accuracy significantly decreases if only a few reduced states are considered and the interactions of the unresolved states with the resolved states are not accounted for. Ideally, ROMs should be consistent with the underlying full order model, which requires an appropriate strategy for the construction of operators. In this talk, we will present advancements in three areas of ROMs for incompressible flows: 1) solution method for the coupled continuity and momentum equation, 2) appropriate closure modeling for interactions between unresolved and resolved states, and 3) maintaining consistency between ROM and corresponding full order model. For the last area, we will discuss the trade-off between consistency and intrusiveness for continuous, discrete and data-driven approaches for constructing ROM operators.

ANALYSIS OF ENERGY DISSIPATION IN PARTICLE DAMPERS VIA THE DISCRETE ELEMENT METHOD EMPLOYING THE COMPLEX POWER METHOD

Braj Bhushan Prasad[*1], Tommy Luft[1], André Katterfeld[1], Elmar Woschke[1] and Hermann Rottengruber[1]*

[1]*Otto-von-Guericke-University Magdeburg*

ABSTRACT

A particle damper is a passive damping system, which relies on the high dissipation properties of granular materials. The particle dampers can be mounted on the structure or can be inserted in existing cavities of the vibrating structure often without causing significant changes in the mass or stiffness of the original structure. The collisions of the particles with each other and with the cavity walls lead to friction-based dissipation and result in a reduction of the vibration amplitude of the carrying structure. The particle damping mechanism is highly non-linear and depends on several parameters, such as particle size, the number of particles, particle materials, and particle packing ratio, which restrict its real-world application. This contribution aims to present preliminary work in the development of models for assessing the damping characteristics of particle dampers utilizing the complex power method, which enables the analysis of energy dissipation in particle dampers without the need for an underlying vibrating structure. In general, the complex power is connected to a harmonic excitation cycle, and its computation involves using the velocity of the particle container and the force driving its excitation. The numerical investigation of the energy dissipation mechanism in particle dampers is conducted through the discrete element method (DEM) using the open-source code LIGGGHTS. This study employs a particle damper consisting of steel balls, chosen with the objective to expediting the calibration process, facilitated by the availability of material characteristics for steel balls in a data handbook. The methodology proposed in this study will undergo validation through an experimental investigation.

UNCERTAINTY REDUCTION WITH MULTI-MODEL MONTE CARLO FOR CRYSTAL PLASTICITY SIMULATIONS OF ADDITIVELY MANUFACTURED METALS

Joshua Pribe[*1], Patrick Leser[2], Saikumar Yeratapally[3], George Weber[2] and Edward Glaessgen[2]*

[1]*Analytical Mechanics Associates*

[3]*Science and Technology Corporation*

ABSTRACT

In this work, multi-model Monte Carlo estimators are developed to reduce uncertainty in quantities of interest (QoIs) extracted from crystal plasticity simulations of additively manufactured (AM) metals. A significant concern in AM parts is uncertainty in mechanical properties caused in part by complex microstructures that arise from the AM process. Quantifying uncertainty in microstructure-sensitive behavior using experiments alone is costly, especially when mechanical allowables must be established. Quantitative relationships among microstructure, micromechanical metrics like slip accumulation, crack initiation, and failure are also difficult to capture with limited experiments. Crystal plasticity material models instead enable computational prediction of micromechanical stress and strain fields given a discretized microstructure. However, high-fidelity finely discretized crystal plasticity simulations are computationally expensive, while lower-fidelity models are less accurate and generally biased, making uncertainty quantification and reduction computationally difficult as well.

Multi-model Monte Carlo methods leverage correlations between high- and low-fidelity models to produce unbiased estimators for QoIs with reduced uncertainty relative to standard Monte Carlo. Crystal plasticity QoIs considered in this work include yield strength and the mean and extreme values of micromechanical fields that are relevant to crack initiation. Multi-model Monte Carlo estimators are developed for each individual QoI and several groups of QoIs. The results of this work establish relationships among model correlations, sample allocation, and uncertainty reduction for different combinations of QoIs and demonstrate a trend of less uncertainty reduction as QoIs become more sensitive to local microstructure. Limitations from using pilot samples to estimate model covariances and train low-fidelity models are also addressed. The uncertainty reduction achieved by multi-model Monte Carlo is an important step toward using computational mechanics models to predict microstructure-sensitive crack initiation and failure in AM parts.

A PROBABILISTIC GRAPHICAL MODEL APPROACH TO DECOUPLE MULTI-PHYSICS SYSTEMS

Ricardo Baptista[1], *Teo Price-Broncucia**[2] *and Rebecca Morrison*[2]

[1]*California Institue of Technology*
[2]*University of Colorado - Boulder*

ABSTRACT

Complex multi-physics systems, like those used in weather prediction and spacecraft simulation, often require coupling of subdomain models. However, this coupling is expensive - due to feedback, heavy communication overhead, and the need to ensure the delicate consistency of scenario parameters across domains. With the increased cost of running the model, downstream tasks like model calibration and uncertainty quantification can also become impractical. Thus, modelers aim to decouple these models as much as possible, while maintaining high accuracy in the model predictions. In this work, we demonstrate a method to decouple multi-physics models by learning an undirected graphical model corresponding to the system state variables. The edges in the learned graph represent conditional dependence between variables, which indicates the need for coupling between two models. This approach leverages information in available data - from either the real system or a high-fidelity model - to identify the most important couplings, and those which may be safely neglected.

TOWARDS THE EXAMINATION OF PROCESS-PROPERTY RELATIONSHIPS OF WIRE ARC DED VIA THERMO-MECHANICAL FE SIMULATIONS

Matthew Priddy[*1], J. Logan Betts[1] and Matthew Register[1]*

[1]*Mississippi State University*

ABSTRACT

The as-built internal residual stresses and part-level distortions from the wire arc DED process are highly dependent on machine process parameters and tool path. While multiple experiments are commonly performed for process parameter optimization, these experiments are typically limited in part volume and thus do not provide much information related to residual stresses or distortion. Additionally, the build up of multiple part replicates of sufficient volume for such an examination would be labor and cost intensive. Therefore, this work seeks to examine the process-property relationships of wire arc DED via thermo-mechanical FE simulations. Abaqus/standard with a moving heat source and material deposition are used to mimic the wire arc DED process. This work introduces modeling the substrate fixturing in addition to component being additively manufactured. Multiple variables of the printing process (e.g., process parameters, inter-layer dwell time, tool path) and as-built component (e.g., residual stresses, distortion) are studied. Additionally, material model fidelity is examined to determine the relative role of the material model on the mechanical predictions. The thermo-mechanical FE simulation results are compared with experimental data for model calibration/validation purposes. Preliminary results indicate a significant role of inter-layer dwell time on the as-built component's residual stresses and modeling the substrate fixturing leads to significantly different thermal responses in early layer printing of components.

GEOMETRIC MULTIGRID METHODS FOR A MATRIX-FREE STABILIZED SOLVER FOR THE INCOMPRESSIBLE NAVIER-STOKES EQUATIONS

Laura Prieto Saavedra[*1], Peter Munch[2] and Bruno Blais[3]*

[1]*Polytechnique Montreal*
[2]*Uppsala University*
[3]*Polytechnique Montréal*

ABSTRACT

The fully-coupled finite element discretization of the incompressible Navier-Stokes equations requires the solution of a sequence of linear systems of equations that are saddle-point problems difficult to solve with traditional iterative methods. Geometric multigrid methods can be used as monolithic preconditioners for the linearized system if a stabilized finite element discretization is used. In this study, we compare two variants of geometric multigrid preconditioners, local smoothing and global coarsening, within a matrix-free solver [1, 2]. The multigrid variants are implemented in Lethe, an open-source computational fluid dynamics (CFD) software, which uses the deal.II finite element library and a continuous Galerkin discretization with SUPG/PSPG stabilization [3]. Multigrid levels are defined using the mesh hierarchy obtained by the refinement of the original mesh. While the global coarsening approach considers the entire domain for each level, the local smoothing approach uses only the most refined cells at each stage of the mesh refinement. This leads to different multigrid hierarchies when adaptive mesh refinement (AMR) is used. We compare the results of two benchmarks that benefit from AMR: the flow around a sphere and the backward-facing step, using different Reynolds numbers and equal-order velocity-pressure discretizations. The comparison is made in terms of iterations and parallel performance, using both strong and weak scaling. Preliminary results indicate that the global coarsening algorithm shows better parallel scalability than the local smoothing algorithm. Moreover, this study demonstrates that geometric multigrid preconditioners are promising for strongly nonlinear coupled problems and matrix-free implementations.

FINITE ELEMENT TECHNIQUES FOR MODELING HURRICANE STORM SURGE

Jennifer Proft[*1], Clint Dawson[1], Eirik Valseth[21], Mark Loveland[1] and Benjamin Pachev[1]*

[1]The University of Texas at Austin
[2]Norwegian University of Life Science

ABSTRACT

Storm surge due to hurricanes and tropical storms can result in significant loss of life, property damage, and long-term damage to coastal ecosystems and landscapes. Computer modeling of storm surge can be used for two primary purposes: forecasting of surge as storms approach land for emergency planning and evacuation of coastal populations, and hindcasting of storms for determining risk, development of mitigation strategies, coastal restoration and sustainability.

Storm surge is modeled using the depth-averaged shallow water equations coupled with wind forcing. Tides, riverine forcing, atmospheric pressure, bottom friction, the Coriolis effect and wind stress are all important for characterizing the inundation due to surge. The problem is inherently multi-scale, both in space and time. To model these problems accurately requires significant investments in acquiring high-fidelity input, accurate discretization of the computational domain using unstructured finite element meshes, and numerical methods capable of capturing highly advective flows, wetting and drying, and multi-scale features of the solution.

The combined effects of continuous and discontinuous Galerkin finite element methods allows for many of the features necessary to accurately capture storm surge physics. We describe the application of the computational techniques to hurricane storm surge.

SELF-DIAGNOSIS OF ADAPTIVE STRUCTURES BASED ON THE REDUNDANCY CONCEPT

Tamara Prokosch[*1], Jonas Stiefelmaier[1], Christina Tarín[2] and Manfred Bischoff[1]*

[1]*University of Stuttgart*
[2]*Universtiy of Stuttgart*

ABSTRACT

Sustainability calls for new technologies and saving resources. Due to the huge impact on global resource consumption, energy demand and waste production, adaptive civil structures might contribute to the answer to this calling. By incorporating sensors, actuators, and a control unit into the design of civil structures, active shape changes and stress redistribution become possible. This way, the structure can react efficiently to typically high, varying loads. Embodied energy in the high masses of bridges and high-rises can be purposefully used or reduced. However, as with any new technology, safety considerations are important, particularly when it comes to structural failure. The sensors and actuators in adaptive structures offer a unique opportunity, not only to monitor structural health and detect potential failure at an early stage but also to actively test the structure for damage. This allows for timely repair and support measures as well as a sustainable and long service life.

The first challenge for structural analysis lies in modeling the actuation and developing analysis methods with fundamental insight and high applicability. The redundancy matrix as such has been of particular importance for adaptive structures. By quantifying the constraint on each element exerted by the surrounding structure, the redundancy matrix provides insight into the response of the structure to actuation, modeled as an imposed actuator stroke. Gade et al. [1] proposed a generic matrix formulation for efficiently updating the redundancy matrix with application to truss and frame structures. This lays the foundation for investigations on the detection of structural failure of elements and changes in element properties due to changes in the redundancy distribution.

We conducted studies on various systems with different topologies and materials and implemented the redundancy distribution both for the original systems, as well as for variants with missing or damaged elements. Aiming for detectability measures, we analyzed changes in stress distribution and deformations for general load cases and changes in the redundancy distribution of the system. To validate the resulting measures, we implemented the model-based fault diagnoses for an adaptive high-rise structure and tested the efficiency.

This work is conducted in the framework of the Collaborative Research Centre 1244 funded by the Deutsche Forschungsgemeinschaft (DFG - German Research Foundation). The authors are grateful for the generous support.

ABSTRACT

We propose a graph neural operator that enables efficient uncertainty quantification for macroscale quantities of interest due to changing geometries. Our graph-based framework, in contrast to typical mesh-based approaches to PDE modeling, addresses the challenges of uncertainty quantification on random domains and alleviates the mesh dependency of many alternative methods. We will present the application of our method for ice-sheet dynamics that enables efficient quantification of the uncertainty related to glacial mass loss and allows for increased flexibility based on the ice sheet geometry, grounding line, and basal friction.

MARKOV CHAIN MONTE CARLO CAPABILITIES IN DAKOTA

Ernesto Prudencio[*1] and Adam Stephens*[1]

[1]*Sandia National Laboratories*

ABSTRACT

This talk will be divided in four parts. We will first go through an overview of the different Markov chain Monte Carlo (MCMC) algorithms and companion Bayesian analysis functionalities that Dakota provides by interfacing itself with different external packages, such as the MIT Uncertainty Quantification (MUQ) and the Quantification of Uncertainty for Estimation, Simulation, and Optimization (QUESO) libraries. In the second part, we will have a more detailed exposition on the methods most recently added to Dakota through MUQ: the Metropolis adjusted Langevin algorithm (MALA) and the likelihood informed subspace (LIS) methods. The third part will present a comparison of the application of some MCMC algorithms to a set of problems, highlighting pros and cons of the different algorithms being compared. We will finalize the talk with a presentation of potential directions we might take in the future regarding (i) the improvement of current MCMC methods already available in Dakota, (ii) the addition of new methods, and (iii) the use of python to access MCMC capabilities in Dakota.

SOME OF PROFESSOR ODEN'S INVESTIGATIONS ON MODEL VALIDATION AND BAYESIAN ANALYSIS OF COMPLEX ENGINEERING AND SCIENTIFIC MODELS

Ernesto Prudencio[*1]*

[1]*Sandia National Laboratories*

ABSTRACT

In this talk I will present some of the investigations I had the pleasure to conduct in collaboration with Professor Oden and other colleagues at The Oden Institute for Computational Engineering & Sciences at the University of Texas at Austin. More specifically, I will briefly talk about three different efforts: one in material damage control, one in nonlinear elatostatics, and one in tumor growth. Just this small sample of Professor Oden's work already gives us a glimpse on the breadth and depth of his investigative mind. These three different efforts cover areas such as uncertainty quantification, model calibration, model validation, model ranking, information gain analysis, optimal experimental design, and filtering.

VERIFICATION AND VALIDATION IN COMPUTATIONAL MECHANICS

*Serge Prudhomme**[1]

[1]*Polytechnique Montréal*

ABSTRACT

Verification and Validation are essential activities for predictive modeling in computational sciences and engineering. I will briefly describe some recent progress on related topics, for example, the verification of neural network approximations of solutions to boundary-value problems, the optimal design of experiments for validation of mathematical models, or a goal-oriented formulation for model calibration. More specifically, I will present a multi-level neural network approach capable of reducing the approximation error to machine precision. The method consists in estimating a correction in a previously computed neural network approximation by solving the problem for the residual error using a new network of increasing complexity. I will also describe a novel methodology to design an optimal validation scenario to assess the predictivity of a model in the cases where experimental data at the prediction scenario are unavailable and the quantity of interest cannot be observed. The method relies on solving two optimal design problems that best match sensitivity indices that one would obtain at the prediction scenario. Finally, I will present a novel approach for model calibration that simultaneously identifies the model parameters and the modeling errors. The novelty of the proposed calibration method lies in the fact that the values of the model parameters are now inferred with respect to the intended use of the model, which is expressed in terms of a given quantity of interest.

NONLINEAR MODEL ORDER REDUCTION WITH SMOOTH NEURAL FIELDS

Vedant Puri[1], Aviral Prakash[1], Jessica Zhang[1] and Levent Burak Kara[1]*

[1]*Carnegie Mellon University*

ABSTRACT

There has been heightened interest in model order reduction for predictive modeling in light of recent advances in machine learning (ML). Reduced order models (ROMs) follow a separation of variables approach. First a reduced state representation is learned from data. Then, the reduced state vector is evolved in time following the physics of the problem. ML-ROMs, which apply nonlinear transformations to obtain powerful ROM representations, have been shown to outperform projection-based PCA-ROMs in advection-dominated fluid-flow problems [1, 2]. ML-ROMs, however, incur limitations as they are trained using autoencoders that learn to map high-dimensional simulation data from fixed grids to a reduced space [1, 2, 3].

In this work, we cut the training time in the offline stage by half by employing an encoder-less training approach where a decoder is learned along with reduced representations corresponding to trajectories in the training set. The decoder, a continuous neural field model, then learns a mapping from the reduced space to the space of continuous vector fields in a discretization-invariant manner [3]. Our model is therefore able to learn ROMs from simulations on adaptive and evolving grids where interpolation to a fixed mesh may be infeasible.

Once a reduced representation is learned, the problem is time-evolved per the governing PDE system, which involves computing spatial derivatives of the solution field. Prior works suffer from nonsmooth neural representations whose derivatives are corrupted by noise, and resort to low-order finite differencing on a supplementary coarse mesh [3]. We sidestep this problem by developing methods to learn smooth neural representations that can be differentiated exactly with automatic differentiation. Our key observation behind this improvement is that smooth neural representations can be learned by applying regularization to the decoder model during the offline training process.

In this presentation, we discuss our contributions which lead to faster offline-stage, and improved accuracy, performance during the online-stage. We demonstrate the efficacy of our methods on several 1D and 2D advection dominated traveling shock problems.

ANALYTICAL FRAMEWORK AND NUMERICAL VALIDATION FOR FLUID-STRUCTURE INTERACTION OF FLEXIBLE COAXIAL CYLINDERS

Maria Adela Puscas[1] and Romain Lagrange*[1]

[1]*CEA, DES, ISAS*

ABSTRACT

This study delves into the analysis of small-amplitude forced beam vibrations of two coaxial finite-length cylinders separated by a viscous Newtonian fluid. To tackle this complex phenomenon, we introduce a novel theoretical approach rooted in the Helmholtz expansion of the fluid velocity vector. This method enables us to derive a comprehensive analytical expression for the fluid forces, subsequently providing insight into the modal added mass and damping coefficients [1].
Our theoretical framework reveals a noteworthy finding: the fluid forces exhibit linearity with respect to the Fourier harmonics of the vibration modes. Importantly, the coefficients governing these linear combinations are found to be contingent upon the aspect ratio of the cylinders, the separation distance, and the Stokes number. Consequently, the linear fluid forces do not invariably mirror the shape of the forced vibration mode. Instead, the fluid introduces the intriguing possibility of coupling vibration modes with distinct wave-numbers.

In contrast to prior research efforts, our current theory surpasses limitations by incorporating viscous effects of the fluid, accounting for the finite length of the cylinders, avoiding reliance on the assumption of a narrow annulus, and encompassing all classical boundary conditions for an Euler-Bernoulli beam within a unified formulation.

To validate our theoretical predictions, we conduct numerical simulations (TrioCFD [2] open source code with an ALE module) considering various boundary conditions such as rigid, pinned-pinned, and clamped-free vibrations. The results not only support the proposed theoretical framework but also shed light on the nuanced interplay between fluid dynamics and structural vibrations under diverse boundary conditions. This comprehensive approach advances the understanding of forced vibrations in complex systems involving fluid-structure interactions.

ON A STRUCTURE PRESERVING IMPLICIT DYNAMICS CONTACT ALGORITHM.

Michael Puso[1] and Cosmin Petra*[1]

[1]*Lawrence Livermore National Laboratory*

ABSTRACT

A newly developed contact algorithm [1] that exactly conserves discrete energy and momentum has been developed. In addition, the new approach avoids the chatter typically encountered with most contact algorithms during persistent contact. Standard time integration schemes such as Newmark's method are well known to have stability issues and chatter in the event of unilateral contact. This is due to inherent smoothness built into these time integration schemes and the lack of control of the energy due to the nonlinear nature of the impact. A large body of literature has been devoted to treat these inherent issues of implicit contact but few if any conserve a discrete form of energy and momentum, eliminate chatter whilst enforcing both gap and velocity constraints by way of Lagrange multiplier. This is accomplished here by developing a new mortar projection scheme that conserves angular momentum by construction The chatter is eliminated by modifying the midstep time integration such that the updated velocity satisfies a biliteral gap velocity constraint. The discrete energy of the contact is conserved by employing a time integrated algorithmic gap. The gap calculation is exact in 1D, doesn't drift and the error can be bounded by the time step. Examples that demonstrate the robust character, accuracy and unbiased contact are demonstrated.

NON-DESTRUCTIVE STRESS WAVE AMPLITUDE TESTING FOR INTERFACE BONDING STRENGTH OF 3D PRINTABLE CONCRETE

Cheng Qi[*1], YuChing Wu[1] and Peng Zhi[1]*

[1]*Tongji University*

ABSTRACT

This study aims to explore the impact of interface bonding properties of the concrete on non-destructive testing. Various concrete samples with different numbers of layers and time intervals were printed. Non-destructive testing was conducted using an ultrasonic device. Because of the presence of interface layers, 3D printable concrete exhibits slower wave propagation velocity and smaller wave amplitude than casted concrete. Moreover, the amplitude considerably increased while the number of printing layers and intervals increased. The amplitude attenuation could be attributed to losses caused by stress wave transmission between the transducer and the test piece. It was also resulted from the height of the concrete, as well as the printed interface layer. It shown a linear relationship with the interface bonding strength of the cement-based material. The interface bonding performance of 3D printable concrete was investigated through the observed pattern of amplitude attenuation using the non-destructive testing approach. It is demonstrated that the interface bonding properties exhibit anisotropic mechanical performance resulted from the layer-by-layer additive printing technique employed in 3D printable concrete. In comparison to casted concrete, the interface layer in 3D printable concrete considerably affected the transmission of stress waves. It could be a fundamental factor resulted in differences in non-destructive testing.

ABSTRACT

Fiber-reinforced polymer composite systems have been replacing traditional metallic materials at an unprecedented rate for airframe structures, driven by the essential needs for lightweight and improved structural performance to achieve high demands on aircraft sustainability objectives. Meanwhile, damage tolerance assessment of composite structures presents significant difficulties for airworthiness certification and aircraft sustainment due to their complex damage and failure mechanisms. Although considerable research has been devoted over the past decades to developing high-fidelity composite damage computational models, having the capability to effectively and efficiently predict complex composite damage and failure behavior is still a daunting challenge. All existing modelling strategies for composite damage evolution suffer from either inaccuracy, modelling cumbersomeness, or formidable computational cost. This study aims to develop an improved hybrid computational mechanics framework to capture the major failure modes of each composite ply and predict their progressive damage evolution in a composite laminate. An integrated modelling approach is proposed, combining continuum damage modelling (CDM), the extended finite element method (X-FEM), and the cohesive zone modeling (CZM) technique, to capture fiber fracture, matrix cracking, and interlaminar delamination. The Schapery theory (to address polymer matrix viscoelastic behavior) is incorporated with the 3-D Hashin failure criteria to accurately simulate the pre-peak nonlinearity of the load-bearing response due to matrix microcracking. The proposed hybrid model is developed and implemented using Abaqus with user-defined subroutines. Multidirectional composite laminates with open-hole notch configurations under tension (OHT) and compression (OHC) loading scenarios are examined. The simulation results are compared with the physical experiments and numerical models in the open literature and demonstrate the effectivity and practicability of the modelling methodology for composite progressive damage analysis. In conclusion, such a modelling and simulation methodology shows a noticeable improvement in composite damage modelling. It represents a practical paradigm, which not only drastically reduces the pre-processing workload to build a physics-based high-fidelity damage model, but also largely decreases the computational cost.

PREDICTING FAR WAKE INTERACTION IN WIND FARM BY HIGH RESOLUTION 2D LES SIMULATION WITH POROUS DISK MODEL

Ji Qi[1], Kenji Ono[1], Koichiro Shibuya[1] and Takanori Uchida[1]*

[1]*Kyushu University*

ABSTRACT

Numerical fluid dynamics has become an essential tool in wind turbine design, and recent large-scale simulations using LES models have provided highly detailed information. In the design of large offshore wind farms, accurately simulating the interaction of wake flows behind wind turbines is crucial for predicting the overall power generation performance of the wind farm. However, conducting LES simulations on such a large scale across the entire wind farm requires impractical huge computational resources, even when using state-of-the-art supercomputers. To mitigate computational costs, various surrogate models such as Actuator Line Model / Actuator Disk Model and light-weight engineering models for approximating wake flows have been employed. We have proposed a simple porous disk model as a surrogate model and confirmed its excellent reproducibility in replicating the mainstream velocity distribution when compared to actual measurement data [1,2]. The advantage of the porous disk model lies in its ability to be implemented in two dimensions, distinguishing it from other surrogate models. Therefore, by implementing the porous disk model into a 2D LES code and conducting high-resolution simulations, we were able to simulate interference scenarios of wake flows from multiple wind turbines that cannot be replicated by engineering models, enabling us to perform unsteady wind condition analysis for the entire wind farm. The code is capable of efficient computations through parallel processing using OpenMP/OpenACC. In this presentation, we will demonstrate not only showcase a comparison between the results of 2D LES simulations and experimental data but also provide insights into comparisons with engineering models, computational time considerations, and the characteristics of wake flow interactions.

A FRAMEWORK OF CONVOLUTIONAL HIERARCHICAL DEEP NEURAL NETWORK FOR NONLINEAR FINITE ELEMENT AND MESHFREE ANALYSIS

Yingjian Liu[1], Jiachen Guo[2], Chanwook Park[2], Wing Kam Liu[2] and Dong Qian[*1]*

[1]The University of Texas at Dallas
[2]Northwestern University

ABSTRACT

In this presentation, we introduce a framework for the Convolutional Hierarchical Deep Neural Network (C-HiDeNN) designed for nonlinear finite element and meshfree analysis. Building upon the structured foundation of HiDeNN [1], which encompasses the evaluation of shape function derivatives, adaptivity, and material derivatives [2], C-HiDeNN [3] incorporates a convolution operator to enhance the HiDeNN approximation. The distinctive feature of C-HiDeNN lies in its provision of an expanded set of optimization parameters, including the polynomial basis number 'p,' dilation parameter 'a,' patch size 's,' and mesh position 'x.' These parameters serve as the weights and bias parameters of the C-HiDeNN patch. To underscore the effectiveness of this framework, we present numerical examples within the context of nonlinear finite element and meshfree analysis. The results demonstrate that our approach achieves significantly higher accuracy compared to the regular Finite Element Method (FEM) with a substantially reduced computational cost.

GENERALIZED STRENGTH REDUCTION METHOD FOR DETERMINING THE FACTOR OF SAFETY OF CONCRETE STRUCTURES

Xiangdong Qian[*1] and Renjie Shen*[2]

[1]*Hohai University*
[2]*Jiangsu University of Science and Technology*

ABSTRACT

The strength reduction method (SRM) was originally used in a slope stability analysis, and it was applied by reducing the shear strength of geomaterial. However, in case of concrete, damage occurs due to not only exceeding the shear strength, but also exceeding the tensile strength or compressive strength, SRM should be modified and adapted to concrete strength criterion. The paper presents a modified SRM for determining the factor of safety (FoS) of concrete structures with multi-parameters strength criterion. Instead of reducing the material strengths directly, the limit length of deviators (ρL) which describes the failure surface of material is reduced. In this way, the strength reduction is indirectly implemented by the isotropic shrinkage of the failure surface in deviator plane. The modified SRM can be generally applied on all strength criteria, so called generalized strength reduction method□GSRM. For GSRM, a numerical algorithm was developed and implemented into the self-developed software. The algorithm was verified through test examples and the obtained results were compared with analytically calculated FoS. The global FoS of a concrete dam is calculated by applying GSRM.

3D TOPOLOGY OPTIMIZATION OF TWO-FLUID HEAT EXCHANGERS

Xiaoping Qian[*1] and Sicheng Sun[1]*

[1]*University of Wisconsin-Madison*

ABSTRACT

In this study, we introduce an approach to topology optimization (TO) for a two-fluid heat exchanger, specifically designed for additive manufacturing. The design is bifurcated into the header and the core. The header aims to enhance flow uniformity and reduce the pressure drop, while the core is focused on improving heat transfer efficiency. In the core optimization, a concurrent optimization of three materials – hot fluid, cold fluid, and solid – is undertaken using two density fields. An overlap constraint on the dilation fields of these densities ensures the formation of a solid layer between the fluids. The minimal thickness of this layer and the self-supporting angle of the design are regulated by two optimization parameters and a Projected Undercut Perimeter (PUP) based overhang angle constraint [1], respectively. A numerical example showcases the use of a two-density method in designing a heat exchanger core unit cell. Compared to a benchmark straight pipe heat exchanger, our TO design, with a similar volume fraction, demonstrates a significant increase in heat transfer rate. This improvement is credited to the TO design's solid fins which increase the contact area, enhance mixing by splitting and merging flow streams, and reduce pressure drop with aerodynamically efficient structures. In optimizing the header, a hierarchical scheme distributes hot and cold fluids from their single inlet pipes to multiple outlets, optimizing from macro to micro scales. This results in a composite design of varying scales. The same two-density method and PUP constraint are applied, with the modification being a cost function focused on minimizing pressure drop. The final assembly of the heat exchanger integrates the optimized core and header, exemplifying the efficacy of multi-scale, multi-material, multi-component TO in additive manufacturing. This approach not only significantly enhances heat transfer rates but also demonstrates the potential of topology optimization in complex thermal management systems.

ABSTRACT

The technique of identifying Lagrangian Coherent Structures (LCSs) has emerged as a powerful tool for studying incompressible flows. Yet, the discrepancies arising from incompressibility assumptions often compromise the accuracy of LCSs constructed using Lagrangian particle methods. In this study, we introduce a modified framework to compute Finite-Time Lyapunov Exponents (FTLEs), addressing the misalignment between the fully incompressible assumption of LCS theory and the inherent incompressibility loss in simulations of particle methods. We begin by examining the correlation between the minimum and maximum FTLEs. By incorporating the deformation gradient and Cauchy-Green strain tensor which account for the time-advancing errors of incompressibility based on continuum theory, we enhance the computational accuracy of FTLEs. Moreover, we introduce the modified FTLE algorithm to the incompressible particle-in-cell (PIC) method for resolving free surface flows and fluid-structure interaction problems. Finally, numerical examples including the Tayler-Green vortices, water sloshing with baffles, an eccentric box sinking in water, and three-dimensional shear-driven cavity problems with high Reynolds numbers are tested to validate the effectiveness of the modified FTLE algorithm and the improved LCSs. These results demonstrate that the proposed modification scheme adeptly counteracts the errors caused by incompressibility loss, enabling accurate computation of FTLEs and detection of LCSs.

INVESTIGATION OF CAVITATION BUBBLE DYNAMICS NEAR A SOLID WALL WITH PRE-SET BUBBLE BY THREE-PHASE SHARP-INTERFACE METHOD

Tianyang Qiao[*1], Wangxia Wu[1] and Honghui Teng[1]*

[1]*Beijing Institute of Technology*

ABSTRACT

Cavitation near a solid wall might induce erosion due to the strong pressure and the high-speed jet emanating from the collapse. Previous studies demonstrated that the pressure distribution and the jet pattern during cavitation collapse changed significantly in the presence of a pre-set bubble, offering a potential strategy for reducing surface erosion [1]. In this work, a three-phase sharp-interface method is employed to investigate the dynamic behavior of a single cavitation bubble in the vicinity of a horizontal wall during its expansion and collapse [2]. In contrast to diffusion interface methods, the level set method for handling three-phase topological changes is considered, where surface tension can naturally be taken into account during collapse without considering diffusion effects [3]. A pre-set air bubble is further positioned near the horizontal wall to investigate its effect on the jet during collapse. The influence of the distance between the cavitation bubble and the preset bubble is studied. It is found that the jet generated by cavitation bubble collapse will be away from the wall when the cavitation bubble is distant from the pre-set bubble. However, if the cavitation bubble is close to the pre-set bubble, a high-pressure region is formed in interstitial fluid and the direction of the jet reverses. In addition, the transition mechanism of different collapse mode of the cavitation bubble and the critical distance are analyzed in detail.

LATTICE BOLTZMANN STUDY OF VAPOR CONDENSATION IN 2D POROUS MEDIA

Feifei Qin[*1] and Zelong Zhang*[1]

[1]*Northwestern Polytechnical University*

ABSTRACT

Vapor condensation in porous media is widely applied in engineering fields, such as heat exchangers, seawater desalination, proton exchange membrane fuel cells, etc. It is a complex process involving coupled multiphase flow, phase change, heat/mass transfer in pore structures. In this work, we study the mechanisms of vapor condensation in 2D porous media at pore-scale by utilizing the hybrid lattice Boltzmann method. First, film condensation on flat surfaces considering various Prandtl and Jacob numbers is simulated and compared with Nusselt's theory, to validate the model. Then, vapor condensation in 2D porous media is studied, considering the influences of temperature difference, porous media structure and surface wettability. The mechanisms of heat transfer, condensation speed, liquid configurations are analyzed and compared under different conditions. This study benefits to improving the understanding of vapor condensation processes in porous media, as well as providing insights to alleviate certain application problems such as water flooding in proton exchange membrane fuel cells, etc.

AN IMPROVED FLUX VECTOR SPLITTING METHOD FOR CHARACTERISTIC-WISE WENO SCHEMES OF THE EULER EQUATIONS

Jianyu Qin[*1] and Yiqing Shen*[1]

[1]*Chinese Academy of Sciences*

ABSTRACT

The weighted essentially non-oscillatory (WENO) schemes based on the Steger-Warming (SW) [1] or Lax-Friedrich-type (LF) [2] flux vector splitting methods are extensively applied in simulations of compressible flow fields. Due to the less dissipation, SW method is preferred in flow calculations that require fine scale structures such as direct numerical simulation of turbulence. However, this paper shows that, even if the characteristic-wise WENO scheme is used, SW method may still exhibit oscillations near contact discontinuities. We give a similar analysis as in [3] and show that, in certain situations, the SW method may make the characteristic-wise WENO scheme become close to the component-wise WENO scheme. Then, we propose an improved flux vector splitting method. Its basic idea is that, in the characteristic-wise WENO procedure, an adjusted characteristic speed is used for the flux splitting. Numerical experiments show that the proposed method can keep the non-oscillatory property near discontinuities as LF method and maintain the low dissipation as original SW method in other regions.

UNDERSTANDING THE INTERFACIAL CREEP OF FIBER-MATRIX INTERFACE USING MOLECULAR DYNAMICS SIMULATIONS

*Renyuan Qin**[1]

[1]*Dongguan University of Technology*

ABSTRACT

Creep performance is a crucial parameter for evaluating the long-term effectiveness of composite materials. The interface between fibers and the epoxy matrix significantly influences creep resistance and stress transfer within the composite structure. Over the service life, carbon fiber-reinforced polymer (CFRP) and glass fiber-reinforced polymer (GFRP) exhibit distinct creep resistance properties under sustained loads. This study aims to elucidate the nanoscale mechanism underlying the differences in creep performance between CFRP and GFRP. Interface models of carbon fiber/epoxy and glass fiber/epoxy composites are constructed, the creep evolution of CFRP and GFRP interface models are compared under various loading levels using molecular dynamics simulations. The results reveal that CFRP demonstrates a higher shear threshold under equivalent holding load conditions. Additionally, an energy method and bond autocorrelation function are employed to characterize the differing creep response processes of CFRP and GFRP at the microscopic scale. These findings provide insights into the molecular-level distinctions in interfacial creep behavior between carbon fiber/epoxy and glass fiber/epoxy systems, contributing to an enhanced understanding of creep resistance properties in CFRP and GFRP composites.

[4]*Duke Kunshan University*

ABSTRACT

We present a Poisson–Nernst–Planck–Navier–Stokes–Cahn–Hillard (PNP–NS–CH) model for an electrically charged droplet suspended in a viscous fluid under an external electric field. Our model incorporates spatial variations in electric permittivity and diffusion constants, as well as interfacial capacitance. Based on a time scale analysis, we derive two approximations of the original model: a dynamic model for the net charge (assuming unchanged conductance) and a leaky-dielectric model (assuming unchanged conductance and net charge). For the leaky-dielectric model, we perform a detailed asymptotic analysis to demonstrate the convergence of the diffusive-interface leaky-dielectric model to the sharp interface model as the interface thickness approaches zero. Numerical computations are conducted to validate the asymptotic analysis and demonstrate the model's effectiveness in handling topology changes, such as electro-coalescence. Our numerical results from these two approximation models reveal that the polarization force, induced by the spatial variation in electric permittivity perpendicular to the external electric field, consistently dominates the Lorentz force arising from the net charge. The equilibrium shape of droplets is determined by the interplay between these two forces along the direction of the electric field. Moreover, in the presence of interfacial capacitance, a local variation in effective permittivity results in the accumulation of counter-ions near the interface, leading to a reduction in droplet deformation. Our numerical solutions also confirm that the leaky-dielectric model is a reasonable approximation of the original PNP–NS–CH model when the electric relaxation time is sufficiently short. Both the Lorentz force and droplet deformation decrease significantly when the diffusion of net charge increases.

DATA-EFFICIENT ONE-STEP MECHANICAL DESIGN OF COMPOSITES USING GENERATIVE AI

Milad Masrouri[1] and Zhao Qin[*1]*

[1]Syracuse University

ABSTRACT

The distribution of material phases is crucial to determine the composite's mechanical properties. While the entire structure-mechanics relationship of highly ordered material distributions can be studied with a finite number of cases, this relationship is challenging to reveal for complex irregular distributions, preventing the design of such material structures from meeting specific mechanical requirements. The noticeable developments of artificial intelligence algorithms in material design enable the discovery of hidden structure-mechanics correlations, which is essential for designing composites of complex structures. It is intriguing how these tools can assist composite design. Here, we focus on the rapid generation of bicontinuous composite structures and the stress distribution in loading. We find that generative AI, enabled through fine-tuned Low-Rank Adaptation models, can be trained with a few inputs to generate synthetic composite structures and the corresponding von Mises stress distribution. The results show that this technique is convenient in generating massive composite designs with useful mechanical information that dictates stiffness, fracture, and robustness of the material with one model, and such has to be done by several different experimental or simulation tests. This research offers valuable insights for improving composite design to expand the design space and automatic screening of composite designs for improved mechanical functions.

MACHINE LEARNING-DRIVEN OPTIMIZATION DESIGN OF HYDROGEL-BASED METAMATERIALS

Yisong Qiu[*1], Hongfei Ye[1], Shuaiqi Zhang[1], Hongwu Zhang[1] and Yonggang Zheng[1]*

[1]Dalian University of Technology

ABSTRACT

The deformation of hydrogel-based metamaterials is a complex nonlinear problem involving soft material contact and large deformation. Numerical simulation of such structures is very time-consuming, and the sensitivity is difficult to derive during optimization design, which makes it difficult for traditional gradient and non-gradient optimization methods to achieve efficient design of such structures. To address this problem, an optimization method based on the combination of back-propagation neural network (BPNN) and multi-population genetic algorithm (MPGA) is proposed to rapidly design hydrogel-based metamaterials with specific mechanical properties in this paper. In this method, several dimensionless design parameters are introduced to describe the structural characteristics of the metamaterial. The initial dataset is constructed based on finite element method simulation results, the mapping relationship between design parameters and metamaterial mechanical properties is constructed by BPNN, and the metamaterial with specific effect is efficiently optimized by combining the MPGA. Based on the proposed method, the design of hydrogel-based metamaterials with specific negative hydration expansion effects as well as hydrogel-based metamaterials with zero/negative Poisson's ratio and adjustable stress-strain curves is achieved. Moreover, this method can significantly reduce the amount of calculation, and can effectively avoid falling into local optimum. The results show that machine learning-driven optimization method is an effective means to design hydrogel-based metamaterials.

Key Words: hydrogel-based metamaterial, machine learning, optimization design, negative hydration expansion, negative Poisson's ratio

ENTROPY STABLE REDUCED ORDER MODELING OF NONLINEAR CONSERVATION LAWS USING DISCONTINUOUS GALERKIN METHODS

Ray Qu[*1] and Jesse Chan*[1]

[1]*Rice University*

ABSTRACT

We generalize the construction of entropy stable reduced order models (ROMs) for nonlinear conservation laws from finite volume methods (FVM) to high order discontinuous Galerkin (DG) methods. This generalization preserves entropy stability while simplifying the hyper-reduction step by utilizing the Caratheodory pruning for the hyper-reduction of boundary conditions.

TRANSIENT TOPOLOGY OPTIMIZATION METHOD FOR VISCOELASTIC STRUCTURES BASED ON TIME-FREQUENCY DOMAIN CONVERSION TECHNIQUE

Quhao Li[1] and Yongxin Qu[1]*

[1]Shandong University

ABSTRACT

Abstract: In engineering design, precision instruments are often required to realize vibration suppression or amplification within a specified time to ensure the rapidity, accuracy and sensitivity of structural response. Therefore, it is of great significance to carry out transient topology optimization design. Viscoelastic materials are often utilized for vibration control because of their excellent damping properties. However, due to the time-dependent nature of the material properties, when the transient response is solved based on Newmark method, its calculation formula and sensitivity analysis are complicated and difficult to achieve. In this paper, the time/frequency domain conversion technology is put forward to solve the problem of transient topology optimization of large-scale viscoelastic structures. Based on the positive/inverse Laplace transform, the transient problem can be solved efficiently in the frequency domain. The specific research work is as follows:
1) Considering the convolution characteristics of viscoelastic constitutive in time domain, Laplace transform is used to convert transient analysis into frequency domain, and the order reduction model and multigrid preconditioned iterative method are adopted to achieve efficient solution;
2) The fast Fourier transform combined with algorithm is used to construct the numerical Laplace inverse transformation to realize the rapid conversion from the frequency domain solution to the time domain solution. The influence of truncation error and algorithm parameters on the conversion accuracy and computational efficiency is studied, and the solution speed, accuracy and stability are analyzed by comparing with the Newmark method in the time domain.
3) The method of first differentiation and then discretization is adopted to solve the sensitivity of the objective function in the frequency domain based on the adjoint method, and then the sensitivity of the objective function in the time domain is solved by the inverse Laplace transform. Finally, the transient response topology optimization design for viscoelastic structure is realized.

A DECOUPLED, STABLE, AND LINEAR FEM FOR A PHASE-FIELD MODEL OF TWO-PHASE INCOMPRESSIBLE SURFACE FLOW

Yerbol Palzhanov[1], *Annalisa Quaini**[1] *and Maxim Olshanskii*[1]

[1]*University of Houston*

ABSTRACT

We consider a thermodynamically consistent phase-field model of a two-phase flow of incompressible viscous fluids. The model allows for a non-linear dependence of the fluid density on the phase-field order parameter. Driven by applications in biomembrane studies, the model is written for tangential flows of fluids constrained to a surface and consists of (surface) Navier–Stokes–Cahn–Hilliard type equations. We apply an unfitted finite element method to discretize the system and introduce a fully discrete time-stepping scheme with the following properties: (i) the scheme decouples the fluid and phase-field equation solvers at each time step, (ii) the resulting two algebraic systems are linear, and (iii) the numerical solution satisfies the same stability bound as the solution of the original system under some restrictions on the discretization parameters. We will provide numerical examples to demonstrate the stability, accuracy, and overall efficiency of the approach. Our computational study of several two-phase surface flows reveals some interesting dependencies of flow statistics on the geometry.

NONLOCAL DIFFUSION IN HETEROGENEOUS MEDIA

Petronela Radu[*1]

[1]*University of Nebraska-Lincoln*

ABSTRACT

The wide applicability of nonlocal models in different areas of science (continuum mechanics, biology, image processing, neural networks) has catapulted them to the center of many analytical investigations. In this talk I will present some recent results on nonlocal systems that exhibit heterogeneous behavior via domain operators or boundary conditions. Of particular interest is the study of the limiting behavior of the nonlocal system as the horizon of interaction shrinks to zero. For the emergent system we identify the classical (differential) counterparts and their physical interpretation.

UNCERTAINTY QUANTIFICATION IN LINEAR DYNAMICAL SYSTEMS BY SPLINE CHAOS EXPANSION

Sharif Rahman[*1]*

[1]*The University of Iowa*

ABSTRACT

This paper leverages recent progress on orthonormal splines for solving uncertainty quantification (UQ) problems from linear structural dynamics. The resulting method, premised on spline chaos expansion (SCE) [1], construes Fourier-like expansion of a dynamic system response of interest with respect to measure-consistent orthonormalized basis splines in input random variables and standard least-squares regression for estimating the expansion coefficients. The SCE proposed is similar to existing polynomial chaos expansion (PCE), but by swapping polynomials for B-splines, SCE achieves a greater flexibility in selecting expansion orders and dealing with subdomains. For this very reason, SCE can effectively tackle stochastic responses that contain locally high fluctuations and that are non-smooth. However, due to the tensor-product structure, SCE, like its polynomial sibling, also suffers from the curse of dimensionality. Numerical results from frequency response analysis of a two-degree-of-freedom dynamic system indicate that a low-order SCE with fewer basis functions eliminates or substantially mitigates the spurious oscillations generated by high-order PCE in calculating the second-moment statistics and probability distributions of frequency response functions [2].

VISCOPLASTIC FLOWS IN GROOVED SUPERHYDROPHOBIC CHANNELS: EFFECTS OF ANISOTROPIC SLIP DYNAMICS

Hossein Rahmani[*1], Ian Frigaard[1] and Seyed Mohammad Taghavi[2]*

[1]*University of British Columbia*
[2]*Université Laval*

ABSTRACT

Poiseuille flow dynamics of a viscoplastic fluid in channels equipped with a groovy superhydrophobic (SH) wall is revisited. It is assumed that air (gas) fully fills the SH wall grooves, while forming a flat interface with the overlying viscoplastic liquid. The pressure gradient direction can make any arbitrary angle θ with the groove direction, allowing formation of the longitudinal (θ=0), transverse (θ=90) and oblique (0<θ<90) flows. Anisotropic slip dynamics governs the slippery motion on the formed liquid/air interface, for modeling of which a tensorial slip number is used along with the Navier slip law to correlate the shear stress and the slip velocity tensors on the interface. The Bingham constitutive equation is used to model the viscoplastic rheology. Semi-analytical, explicit-form and numerical models are developed to address the flow problem through quantifying the velocity profile, the effective slip length tensor, and the secondary flow field. The effects of the anisotropic slip dynamics on the flow are evaluated by defining an anisotropy number α, which represents the ratio between the components of the slip number tensor. Considering a creeping flow motion, we define six dimensionless parameters for our flow, i.e. the Bingham (B), slip (b) and anisotropy (α) numbers, the groove periodicity length (l), the slip area fraction (φ), and the groove orientation angle (θ). We find the largest/smallest slip velocity for the longitudinal/transverse flow. In addition, the effective viscosity varies with θ, causing an independent problem at any angle θ; this implies that the oblique flow dynamics cannot be directly obtained using the longitudinal and transverse flow solutions (in contrast to the Newtonian flow). For oblique flows, a secondary flow appears normal to the direction of the applied pressure gradient. We calculate the values of θ_max that correspond to the maximum of the secondary flow rate and the effective slip shear component and quantify their variation versus the Bingham number. The increase in the Bingham number is found to cause a continuous decrease in θ_max. Finally, we quantify the onset of no-shear condition at the liquid/air interface, i.e. when an unyielded plug zone appears on the interface.

MELT POOL TEMPERATURE PREDICTION USING VISIBLE LIGHT CAMERA AND MACHINE LEARNING TECHNIQUES IN METAL ADDITIVE MANUFACTURING

Mostafa Rahmani Dehaghani[*1], Pouyan Sajadi[1], Yifan Tang[1] and Gary Wang[1]*

[1]*Simon Fraser University*

ABSTRACT

Metal additive manufacturing (AM) is increasingly significant in fabricating complex geometries unattainable with conventional manufacturing techniques. This technology, however, faces challenges in achieving uniform mechanical properties due to uneven microstructures resulting from substantial heat input during the process. Researchers try to model the thermal behavior and then the process-microstructure-property relationship in order to better control the manufacturing process. The melt pool temperature plays a pivotal role as the temperature dictates the cooling rates and thermal gradients, which directly affect the microstructure and thus the product's mechanical properties like strength and ductility. Therefore, knowing the melt pool temperature is crucial in the modeling of the process-microstructure-property relationship and control of the metal AM process.

To measure the melt pool temperature, pyrometers or thermal cameras are most often used. These methods, however, have limitations. Pyrometers often struggle with accuracy due to emissivity variations and their installation can be challenging. Thermal cameras, on the other hand, can be prohibitively expensive and difficult to integrate into existing AM setups.
To overcome the difficulties of these methods, this study innovatively employs visible light cameras as a cost-effective, versatile alternative to conventional temperature monitoring methods. Approximately 24,000 coaxial visible light images were captured from the Laser wire directed energy deposition machine, equipped with a coaxial visible light camera and a pyrometer to record the melt pool temperature, under varying settings of laser power, travel speed, and deposition rate. These images were then used to train and validate convolutional neural networks (CNN), Gaussian process regression (GPR), and artificial neural networks (ANN) models.

The CNN model processed the images directly, while the GPR and ANN models utilized key features extracted from the images, such as melt pool dimensions and intensity, for regression analysis. The CNN model achieved an R-squared value of 0.718, whereas the ANN and GPR models reached higher R-squared values of 0.863 and 0.835, respectively.

In conclusion, this study not only demonstrates the practicality of using visible light cameras in temperature prediction for metal AM processes but also suggests a more cost-effective approach to quality control in manufacturing. The ability to accurately predict melt pool temperature using this method can significantly impact the metal AM industry by providing a reliable and efficient means to link process parameters with the final microstructure and properties of the manufactured parts, ensuring consistent product quality.

A NUMERICAL INVESTIGATION OF THE EVOLUTION OF TENSILE STRENGTH OF OIL WELL CEMENT DURING CURING PROCESS

Zahra Rahmanihamzehkolaei[*1], Ian Frigaard[1] and Sardar Malek[2]*

[1]*University of British Columbia*
[2]*University of Victoria*

ABSTRACT

Well cementing involves injecting cement in the annular space between the steel casing and the geologic formation. Maintaining the mechanical integrity of the cement sheath is of high importance throughout the entire lifespan of wells. It ensures the success of the primary cement job, which involves providing structural support to wells and ensuring zonal isolation to prevent oil leakage.
Mechanical failure of the cement sheath within well cement is influenced by several factors including cement characteristics and development of its strength and elastic constants. The knowledge of the early-age properties (e.g. stiffness and strength) of cement sheath throughout curing time, is essential for failure analysis of the cement sheath during its service life. Although the International Organization for Standardization (ISO) and the American Petroleum Institute (API) proposed recommended methods for assessing compressive strengths of oil well cement, there are currently no equivalent standards for evaluating the tensile strength of oil well cement. Without the ability to assess tensile strength of oil well cement accurately and consistently, it becomes very challenging to estimate induced stresses and determine if a given cement mix offers sufficient tensile strength to resist failure and subsequently well leakage. Previous studies have shown that the tensile strength of the cured? cement is about 30 to 50% of its flexural strength. A correlation factor between the tensile strength of cured cement and its flexural strength has been proposed in the form of a coefficient.

To study the correlation between tensile strength and flexural strength of cement during the curing process, a detailed 3D finite element (FE) model has been developed and is presented in this paper. Considering pre-determined Young's and shear moduli, along with measured compressive and flexural strength values from available experiments in the literature, the tensile strength of cement can be estimated and compared with test data. Once validated, the FE model could be used as virtual testing framework (digital-twin) to related tensile strength of cement to its flexural strength throughout the curing process. Application of the developed FE model in assessing the overall integrity of oil wells will be discussed.

A UNIFYING FINITE STRAIN MODELING FRAMEWORK FOR ANISOTROPIC MIXED-MODE FRACTURE IN SOFT MATERIALS USING A PHASE-FIELD APPROACH

Mrunmayee Shiradhonkar[1], Pranavi Dhaladhuli[1] and Amirtham Rajagopal[*1]*

[1]Indian Institute of Technology Hyderabad

ABSTRACT

Materials like composite and elastomers have widespread applications in the automobile, aerospace, and civil engineering. The materials are subjected to mixed-mode loading in real-time applications. These materials have anisotropic and hyperelastic nature. The factors influencing mixed-mode fracture in the materials are studied in the study. This study presents a unifying thermodynamically consistent phase field approach with finite strains for mixed-mode fracture modeling in hyperelastic soft materials. The initiation of the crack and its propagation process are modeled using the adopted phase field method based on a power law criterion. A coupled Neo-Hookean model with orthotropic anisotropy is adopted considering volumetric-deviatoric and a tension-compression decomposition. This helps to model the mixed-mode fracture of anisotropic hyperelastic materials. This model is suitable for capturing the overall response of soft fiber-reinforced elastomeric composites and soft biological tissues. The proposed model is validated by conducting fracture tests on elastomers and elastomeric composites. The results obtained are compared with experimental and numerical investigations from literature.

TIME-DEPENDENT RESPONSE OF UNSATURATED POROELASTIC SOILS UNDER SURFACE LOADING

K Prapinpanich[1], Teerapong Senjuntichai[1] and Nimal Rajapakse[2]*

[1]Chulalongkorn University
[2]Sri Lanka Institute of Information Technology

ABSTRACT

Poroelastic materials are two-phased materials consisting of a solid skeleton with voids saturated with water. These materials accurately represent the time-dependent response of geomaterials, which settle gradually over time under externally applied loading, known as soil consolidation. Poroelastic model considers the fluid flow, and the pressure change within pore spaces during the consolidation process. Typically, poroelastic soils are saturated with water, and the pore air is treated as a part of the fluid phase. However, for unsaturated soils, the air phase could play an essential role in soil consolidation, and it has to be considered separately from the water phase. This paper analyses the time-dependent response of an unsaturated poroelastic half-space under axisymmetric surface loading. The equilibrium equations of unsaturated soils are expressed in displacements, pore water pressure, and pore air pressure. The seepage equations of pore water and pore air obey the generalised Darcy's law. The general solutions of displacements, stresses, pore water and pore air pressure are derived by applying Hankel and Laplace transforms with respect to the radial and time coordinates, respectively.
Numerical solutions are obtained by employing an accurate numerical quadrature scheme for the Hankel transform inversion and Stehfest's scheme for the numerical inversion of the Laplace transform. The accuracy of the present solution is verified by comparing it with existing results for a saturated half-space. Selected numerical results are presented for an unsaturated poroelastic half-space under a vertical patch load applied on its surface to illustrate the influence of the degree of saturation on time-dependent responses of unsaturated soils. In addition, a set of influence functions corresponding to an annular load and an annular fluid pressure applied on the half-space surface is then derived to demonstrate the applicability of the present solution for the analysis of consolidation settlement of a rigid circular foundation.

PERSONALIZING NON-INVASIVE BRAIN STIMULATION TREATMENTS USING IMAGE-BASED ANATOMICAL AND COMPUTATIONAL MODELS

Divya Rajasekharan[*1], Leanne Williams[1] and Ellen Kuhl[1]*

[1]*Stanford University*

ABSTRACT

Non-invasive brain stimulation (NIBS) technologies are rapidly gaining traction as novel therapies for treatment-resistant psychiatric disorders. NIBS protocols involve administering electrical pulses to the exterior of the head in order to induce therapeutic changes in neural activity. Despite consistent reports of clinical efficacy over the past two decades, NIBS outcomes vary widely across individuals. This has led to questions about the possibility of increasing remission rates by personalizing the site of stimulation (Klooster et al., 2022). Without practical means to directly measure electric fields within the human brain, research efforts to pinpoint stimulated regions have relied on computational modeling. However, the computational cost of constructing personalized anatomical representations of the head, which consists of the scalp, skull, cerebrospinal fluid, meninges, and brain, have challenged these modeling efforts, forcing them into one of two categories: i) reduced-order geometric models, such as multilayer spherical shells, or ii) image-based finite element models of a small number of subjects. Here, we present an automated pipeline for generating personalized finite element models of the head from magnetic resonance imaging (MRI), which we successfully apply to a cohort of 50 individuals with major depressive disorder participating in a clinical trial of transcranial magnetic stimulation (TMS). Our pipeline combines established cortical surface-based image segmentation tools for the brain with recent tools for atlas-based segmentation of the surrounding tissues in order to derive a three-dimensional geometric representation of individual head anatomy from an MRI scan (Dale et al., 1999; Puonti et al., 2020). In addition to ongoing finite element simulation of induced electric fields, we successfully leverage our models to generate subject-specific, first-order estimates of the TMS treatment site on the cortex. During imaging, study participants wear a specially fit cap with a high-contrast gel capsule attached at the target stimulation site. We project the imaged stimulus location orthogonally across the scalp and onto the cortex using the modeled anatomical surfaces. Making repeated estimates from three imaging timepoints, we demonstrate the ability to efficiently localize the treatment center to an average 5.4 mm radius. Furthermore, using established neuroanatomical methods for registering subject-specific brain anatomy to standardized atlases, we provide descriptive anatomical labels of the effective cortical treatment site to aid clinicians and increase interpretability. Together, our automated image-based pipeline provides a framework for adapting treatment protocols in clinical settings and retrospectively studying the effect of treatment site on NIBS outcome.

MODELLING THE EFFECT OF CURRENT COLLECTORS ON STRUCTURAL BATTERY PERFORMANCE

Karthikayen Raju[*1], Sihan Dong[1], Vincent B C Tan[1] and Tong-Earn Tay[1]*

[1]National University of Singapore

ABSTRACT

Structural batteries [1] promise multi-functional performance of simultaneous structural load bearing ability and energy storage. This opens an opportunity to maximize volume utilization and mass savings at the system-level for electric vehicles, UAVs, drones and electric flight applications. Structural batteries being relatively new, research on developing electrodes, electrolyte, device architecture, encapsulation that gives the battery load bearing capability are ongoing. In addition, another important aspect to development of structural batteries are their current collectors onto which the active anode and cathode are coated or integrated directly.

The current collectors considered in this work are carbon fibre and their composites. Carbon fibres being a structural reinforcement in polymer composites and being electrically conductive make it an ideal candidate for structural battery current collectors. The resistivity of the current collectors is not uniform due to the distribution of polymer in the composite. The work focuses on numerical study of the effect of current collector parameters such as geometry, resistivity, and imperfections due to manufacturing on the structural lithium-ion battery behaviour. The imperfections due to manufacturing of the current collectors are measured as local resistivity along the various directions of the current collectors. These local resistivity values are input as spatially varying resistivity of the current collectors to the models.

The work investigates the effect of local resistivity on the cell performance with the Doyle Fuller–Newman (DFN) and the Single Particle Model with electrolyte (SPMe) models [2] and compare the results with experimental observations on structural battery pouch cells. The non-uniform distribution of matrix that causes high resistivity in certain regions leads to some low resistance paths for current to flow and resulting in non-uniform lithium intercalation. These models help in understanding the effect of current collectors on structural battery's performance and hence aid in their design.

ACCURATE MULTISCALE SOLUTIONS TO QUASI-STATIONARY THERMAL PROBLEMS INVOLVING A HETEROGENEOUS HEAT SOURCE

Isabelle Ramiere[*1], Louis Belgrand*[12] and Frédéric Lebon*[3]

[1]*CEA*
[2]*Aix-Marseille University*
[3]*Aix-Marseille Université, Centrale Marseille*

ABSTRACT

We address the multiscale resolution of a (quasi-)stationary thermal problem with source term on a heterogeneous material. This situation differs from the mechanical computational homogenization framework in that a precise primal solution (temperature) is sought on the Representative Volume Element (RVE) and that a source term (possible heterogeneous at the microscale) is considered. Various Finite Element square (FE2) approaches are reviewed, differing mainly in their treatment of the source on the microstructure. These approaches are analyzed, in particular through a possible parallel with methods based on double-scale asymptotic expansion.

For this problem, the classical FE2 method [2] respects the Hill-Mandel principle and does not impose a source on the microstructure. This approach is of order 1. In the case of low or no insulated inclusions, these approaches are proving to be sufficiently precise. In counterpart, for insulating inclusions, it is essential to consider the local influence of the source to obtain accurate solutions on the microstructure [1]. Recently introduced, the generalized Hill-Mandel [3, 4] principle makes it possible to consider the source on the microstructure in a FE 2 framework. We show that, thanks to this strategy, methods of order greater than 1 can be constructed.

The accuracy of the numerical results obtained by these different approaches is assessed using a direct simulation of the structure discretizing the heterogeneities. This study allows us to conclude that it is essential to consider the complete heat source on the microstructure [4], and not just its fluctuations [3], to obtain a reliable estimate of temperature variations at this scale. Finally, a quasi-stationary FE2 calculation with temporal loading and nonlinear behavior has been successfully carried out. This simulation confirms the importance of considering the generalized Hill-Mandel principle for avoiding underestimating the temperature in the microstructure inclusions.

EXPLORING NON-LOCAL ELASTICITY: A COMPARATIVE STUDY OF NATURAL VIBRATION FREQUENCIES IN NANOSTRUCTURES

Fernando Ramirez[*1] and Arturo Rodriguez-Herrera*[1]

[1]*Universidad de los Andes*

ABSTRACT

Classical local elasticity theory (CLET) is widely recognized as effective for modeling large scale structural mechanics problems. Nevertheless, at the nanoscale clear discrepancies arise between CLET predictions and empirical observations, since it does not take into account long range interaction contributions. To bridge this gap, the non-local elasticity theory (NLET) emerges as an alternative, a theory proposed advanced by Eringen and Edelen [1]. In this theory, the stress-strain relationship of a particle within the solid not only depends on itself, but the collective assembly of particles in the material aggregate.

Based on Eringen's theory, Polizzotto [2] introduced a two phase non-local elasticity theory. In this formulation, the volume is composed of CLET and NLET phases. The latter uses an attenuation function to include the long range cohesive forces. This function depends on the internal length of the material (l) which is the main non-local parameter. This approach is convenient as it facilitates the finite element formulation of the problem (NL-FEM). In the present work, the non-local natural vibrations behavior for different structures is studied. For this purpose, the first natural vibration frequency using NLET (ηnl) and CLET (ηl) are calculated using a custom implementation of NL-FEM. The simulations include different geometries (cubes, spheres, plates, and beams), domain sizes (R), materials, non-local parameters (l), and boundary conditions.

The obtained normalized frequency response considering the non-local theory (ηnl) does not depend on the material. Furthermore, it does not depend on l or R independently, but instead on their ratio l/R. Therefore, the behavior of ηnl only depends on domain geometry. Additionally, threshold l/R values are determined. A minimum value l/Rmin, from which the CLET holds for vibration analyses, and a maximum l/Rmax when the size of the domain is no longer feasible compared to the internal length of the material. For the range [l/Rmin, l/Rmax] the response for ηnl presents a linear behavior, and the corresponding regressions are presented.

MLS-SPH-ALE: AN IMPROVED MESHLESS FORMULATION BASED ON RIEMANN SOLVERS

Luis Ramírez[1], Antonio Eirís[2], José Maciñeira[1] and Xesús Nogueira[1]*

[1]*Universidade da Coruña*
[2]*Spanish Naval Academy*

ABSTRACT

Nowadays, advances in engineering and CFD have led us to face problems with more complex geometries and higher accuracy needs. Mesh-based and meshless discretizations are usually considered as two completely different strategies to solve partial differential equations, and each comes with its own advantages and disadvantages.
Traditionally, mesh – based methods have been employed to solve this CFD problems, but with today's computational facilities, meshless methods have become very popular for dealing with large deformation or complex geometries problems, like free-surface or wave breaking problems.
In this work, we present a high-accurate, stable and low-dissipative meshless method for CFD applications, the MLS-SPH-ALE method. This method can be seen as a generalized meshless method that under certain circumstances and parameters recovers other well-known methods, such as the Smoothed Particle Hydrodynamics method (SPH). Moreover, there is a relation between the MLS-SPH-ALE method and the finite volume method.
The method was developed to overcome some of the grand challenges [3] of traditional Lagrangian SPH methods, like boundary conditions, accuracy and the treatment of the free surface.

The accuracy and robustness of the proposed method are demonstrated by performing tests cases. In these test cases the new methodology will be compared to the traditional kernel-based method of Vila [4].

ABSTRACT

Fiber formation of polymeric materials is an industrial relevant process that involves shear, extensional, and elastic material response. The polymer solution is compressed and sheared in a die and then exhibit die swell, a predominantly elastic response, as the fibers are extruded. Computational fluid dynamics (CFD) models are needed to describe these flows, to inform process design and perform process optimization. However, CFD of viscoelastic flows have both increased complexity and increased computational costs compared to Newtonian flows, since a polymer stress constitutive equation is necessary to describe the polymer rheology. These stress-constitutive equations introduce a tensor unknown to the CFD calculation. Furthermore, constitutive equations that perform well in shear such as an Oldroyd-B model, become undefined at high extension rates.

In this paper, we investigate die swell and CaBER flows of polymeric solutions where there is also a free surface. The viscoelastic equations are discretized using DEVSS-G method with LBB-stable elements for the velocity and pressure spaces and bilinear interpolation for the stress and velocity gradient space. A multimode Phan-Thien-Tanner (PTT) constitutive equations is used for the viscoelastic response. An arbitrary-Lagrangian-Eulerian (ALE) implementation with pseudo-solid mesh motion is used to solve for the location of the free surface. The velocity, pressure, stress, and velocity gradient equations are discretized and solved with a finite element method. A kernel transformation of the conformation tensor for the stress equations is used to improve stability of the method as the fluid elasticity is increased. Die swell data is available for a number of model fluids, with varying viscosities, elasticities, and shear and extensional thinning. Some preliminary work investigating scientific machine learning into our rheological measurements will also be discussed. Physics-informed neural networks (PINNs) are a recently developed numerical technique that augments traditional approaches to fluid mechanics modeling with high-dimensional and heterogeneous data. PINNs provide a robust framework for both forward and inverse problems, spanning problems where the underlying physics are well-described and data is limited, to problems where physics are partially or largely unknown, but rich datasets are available. We will apply a PINNs framework to utilize data from an idealized CaBER experiment.

ABSTRACT

A digital twin couples computational models with a physical counterpart to create a system that is dynamically updated through bidirectional data flows as conditions change. Data Assimilation and Optimal Experimental Design (OED) provide a systematic means of updating the computational model and acquiring information as the physical system evolves. This talk will describe scalable preconditioners and solvers for Bayesian inversion using different randomization techniques. The proposed techniques are amenable to parallelization and drastically reduce the required number of model evaluations. We also develop theoretical guarantees on the condition number. Additionally, the talk will describe connections between OED for Bayesian linear inverse problems and the column subset selection problem (CSSP) in matrix approximation and derive bounds, both lower and upper, for the D-optimality criterion via CSSP for the independent and colored noise cases. We demonstrate the performance and effectiveness of our methodology on a variety of test problems such as Burgers and quasi-geostrophic equations.

CONTACT REPRESENTATIONS IN REDUCED INTERFACE MODELS

Ali Raoofian[*1], Xu Dai[1] and Jozsef Kovecses[1]*

[1]McGill University

ABSTRACT

Contact interactions play a significant role in the dynamic analysis of non-smooth mechanical systems. Yet, incorporating these contacts into the system dynamic model is challenging due to the numerous ways to account for them. This study introduces and evaluates various approaches to contact modelling techniques, emphasizing how different approaches can lead to differences in the results. To this end, a co-simulation setup serves as the primary framework to address the differences in the contact modelling and the corresponding formulations.

In a co-simulation framework, a system is divided into subsystems that exchange information at pre-determined communication points via the interface. Real-time simulations for virtual environments and prototyping would need non-iterative co-simulation, for which stability is often the main problem. The stability behaviour is controlled by how the system elements are coupled. Model-based coupling offers a potential solution for enhancing simulation accuracy and efficiency. It involves using a reduced model of a mechanical subsystem, with the interfacing subsystem, whether mechanical or from another domain, interacting only with this model. A key element is that the reduced model must accurately represent the mechanical subsystem's behavior.

In this context, the reduced model is developed to represent some specific behaviour of a larger-scale system. In the case of interfacing, we are interested in a specific behaviour that is associated with the interface, i.e., how the other subsystem sees the system we intend to represent with the reduced model. Such a reduced interface model (RIM) is usually defined based on the modes of motion, i.e., degrees of freedom, that are characterizing the interface and the way how these degrees of freedom are expressed and parameterized.

The main challenge in developing the reduced models often emerges when the system is non-smooth, i.e., unilateral contacts/articulations and friction are also important to model. In this work, we address challenges in developing a representative reduced order model for a non-smooth mechanical subsystem and propose solutions to incorporate changes in contact states in the RIM. It will be demonstrated how fundamental assumptions in the contact dynamic incorporation can affect the simulation outcome. We will use examples with interfacing mechanical-mechanical subsystems to illustrate these findings.

INVERSE DESIGN OF SPINODOID STRUCTURES THROUGH BAYESIAN OPTIMIZATION

Alexander Raßloff[*1], Paul Seibert[1], Karl Kalina[1] and Markus Kästner[1]*

[1]TU Dresden

ABSTRACT

In this contribution, we propose a general framework to inversely designing mesostructures using structure-property linkages. Typically, large datasets are necessary. Experiments alone are prohibitively expensive. Therefore, computational augmentation is employed to allow for data-driven approaches even in this data scarce regime.

In an iterative procedure (1) mesostructures are characterized by descriptors, (2) effective properties are derived from numerical simulations, (3) structure-property linkages are set up using a Gaussian process, (4) descriptors of new candidate mesostructures are proposed by Bayesian optimization and (5) mesostructures are reconstructed. Steps 2 through 5 are repeated until a desired convergence criterion is reached, e.g., the uncertainty of the structure-property linkage is decreased or a mesostructured with preferable properties is found.

This framework is applied and presented at the example of spinodoid structures. Augmenting a small initial data set by in silico reconstructed spinodoid structures and their simulated effective properties allows for deriving improved structure-property linkages and, thus, finding potentially optimal structures or predicting properties.

LIP-FIELD REGULARIZATION OF SECOND-ORDER ANISOTROPIC DAMAGE MECHANICS MODELS

Bruno Masseron[1], Giuseppe Rastiello[1], Rodrigue Desmorat[2] and Nicolas Moes[3]*

[1]Université Paris-Saclay, CEA Paris-Saclay
[2]ENS Paris-Saclay
[3]Ecole Centrale de Nantes, Institut Universitaire de France

ABSTRACT

Softening stress-strain responses lead to strain and damage localization. In a numerical context, this translates into an undesirable dependency of the structural response on the spatial domain discretization. Nonlocal enhancements and regularization techniques are employed to address this issue and recover the mesh independence of the structural response.

The "Lip-field" approach [1, 2] falls into the second category of techniques. In this approach, the unknown displacement and damage fields are determined through the alternate minimization of an incremental potential during each time step. In contrast to phase-field models, the "Lip-field" formulation relies on minimizing a local energy potential and incorporates regularization by imposing a Lipschitz regularity constraint on the damage field. This constraint guarantees the boundedness of the damage gradient across the domain and naturally introduces an internal length parameter.

Although this method is appealing for its robust mathematical foundation, only isotropic damage formulations were considered in [1, 2]. However, when modeling quasi-brittle materials (e.g., concrete), it is crucial to account for damage-induced anisotropy. Addressing this within Continuum Damage Mechanics framework can be achieved, for instance, by representing material degradation through a tensorial damage variable [3].

This contribution introduces the first "Lipfield" formulation tailored for anisotropic damage. To characterize the induced anisotropic material behavior, a convex free-energy potential is defined according to [3]. A crucial aspect of the model lies in defining a dissipation potential. This choice is directly linked to choosing a suitable scalar variable subject to Lipschitz continuity. Here, a "cumulative damage" variable λ is introduced, and the potential is expressed in terms of this variable. Spurious localizations are prevented by enforcing the Lipschitz constraint of a function $g(\lambda)$ chosen appropriately, while the anisotropic nature of damage growth is considered through the evolution law.

To demonstrate the feasibility and advantages of an anisotropic damage formulation over a purely isotropic approach, the proposed model is implemented in a finite element code, and several test cases are illustrated.

PHASE-FIELD MODELING OF CONTACT BETWEEN DEFORMABLE SOLIDS IN FLUID FLOW

Biswajeet Rath[*1], Xiaoyu Mao[1] and Rajeev Jaiman[1]*

[1]*University of British Columbia*

ABSTRACT

Elastic contact in hydrodynamic environments is a complex multiphysics phenomenon and can be found in applications ranging from engineering to biological systems. The motivation for the current work derives itself from ship-ice interactions in Arctic regions during the collision of ships with large ice sheets, the drifting of ice floes and crack propagation in ice. A fully coupled continuum mechanics formulation is a necessity if we wish to capture the dynamic response of the marine vessel navigating ice-covered Arctic waters. This entails the development of a generalized framework capable of handling topological changes and transitioning implicitly from fluid-structure interaction conditions to solid-solid contact conditions.

Given the physical demands of the problem, we adopt a phase-field based fully Eulerian approach to resolve the multiphase and multibody interactions in the system. We employ a stabilized finite element formulation and a partitioned iterative procedure to solve the unified momentum equation comprising solid and fluid dynamics coupled with the Allen-Cahn phase-field equation [1]. The evolution of solid strain in the Eulerian reference frame is governed by the transport of the left Cauchy Green deformation tensor. We introduce a contact force [2] approach to handle smooth elastic-elastic contact based on the overlap of the diffused interfaces of two colliding bodies. The diffuse interface representation ameliorates the issue of discontinuous contact forces in conventional approaches. The implemented model is validated against the classical Hertz model for smooth dry contact and sensitivity studies are carried out for the model parameters involved. We extend the model to resolve contact between multiple elastic bodies immersed in a surrounding fluid. The developed approach obviates the need for solving multiple phase-field equations or reconstructing the solid boundaries at every time step. Using the proposed framework, we demonstrate the collision dynamics between multiple immersed bodies of varying sizes. We also showcase scenarios where active motion control of a specific body allows us to replicate ship-ice interactions.

PHYSICS INFORMED MACHINE LEARNING (PIML) FRAMEWORK FOR AIR QUALITY PREDICTION

Kalani Ranathunga[1], YuanTong Gu[2] and Charith Rathnayaka[*12]*

[1]The University of The Sunshine Coast
[2]Queensland University of Technology

ABSTRACT

Air pollution leaves a significant impact to both human health and the global climate, requiring robust predictive models for accurate simulation of pollutant dispersion. The concentration of air pollutants exhibits considerable variability across short spatial distances due to diverse emission sources, meteorological conditions, and chemical processes. Existing models, including mechanism-based methods, statistics-based machine learning methods, and chemical transport models, often facing with limitations in capturing the complex atmospheric dynamics. This research aims to evaluate the Physics Informed Machine Learning (PIML) framework for accurate air quality prediction by integrating physical principles and diverse real-world data. The primary objective of the research is to develop a comprehensive PIML model for simulating air pollutant dispersion and transport. Furthermore, a secondary objective involves incorporation of real-world data sources to enhance the model's applicability. Those can be achieved by leveraging the advection-diffusion equation as the governing equation and employing the Eulerian method for spatial predictions. By integrating physical constraints into the learning process, the proposed model aims to improve accuracy by capturing the intricate dynamics involved in the dispersion of atmospheric pollutants. The expected results anticipate a substantial advancement in predictive accuracy for spatial distributions of air pollutants compared to traditional machine learning models. The significance of this research lies in the integration of advection-diffusion equations with PIML, representing a ground breaking approach that combines data-driven techniques with a strong foundation in physics. This innovation holds promise for refining atmospheric pollutant dispersion predictions, contributing to a better understanding of air quality dynamics, and facilitating more effective mitigation strategies for environmental and public health. Overall, the proposed research represents a pivotal step toward developing comprehensive and accurate models to address the increasingly pressing challenges posed by air pollution.

ABSTRACT

A fundamental challenge in neuroscience is the general lack of governing laws relating macroscopic variables. With recent strides in the ability to obtain high-dimensional, multimodal recordings from awake animals, there is growing need for physiologically motivated, low-dimensional descriptions of the effective dynamics. Following recent themes in the experimental literature, we have hypothesized the existence of an intrinsic, arousal-related dynamical process whose organism-wide regulation underpins fluctuations observed across diverse neural, physiological and behavioral measurements (Raut et al. 2021 SciAdv; Raut et al. 2023 biorxiv). Motivated from this perspective, we describe a computational framework aimed at constructing probabilistic mappings between such measurements (e.g., pupillometry and brain images) from a latent, low-rank representation of their shared dynamics.

Specifically, we introduce a data-driven approach to parsimoniously link observables that evolve according to a common but unknown dynamical mechanism. This approach is motivated from Takens' embedding theorem, which permits the (topology-preserving) reconstruction of a full-state attractor manifold from a single observable and its time history. Takens' theorem enables a strong prediction – and thus, a challenging test – of our framework: in theory, a single arousal-related observable (e.g., pupil size) should suffice to reconstruct high-dimensional observables, to the extent that a dynamical mechanism is shared. We test this prediction by performing simultaneous pupillometry and widefield calcium imaging in awake mice. The latter reports the large-scale spatial structure of cortical activity, which we hypothesize to be tightly regulated in accordance with arousal dynamics (Raut et al., 2021). We train neural networks (namely, a variational encoder-decoder architecture) to approximate the hypothesized mapping from delay-embedded pupil time series (i.e., a scalar measurement) to (high-dimensional) widefield measurements.

Following this procedure, we are able to reconstruct a surprising extent of cortex-wide spatiotemporal dynamics in awake mice from simultaneously measured pupil diameter. We achieve similar success using a scalar index of behavioral arousal (whisker movement), and in predicting widefield measurements of brain metabolism or hemodynamics, suggesting the ability of our procedure to elucidate low-dimensional generative factors that underlie physiologically diverse, high-dimensional measurements. Finally, we extend this architecture to multimodal, state-of-the-art behavioral and electrophysiological measurements publicly released through the Allen Institute Brain Observatory—successfully demonstrating our ability to integrate diverse experimental data into a unified generative model via mappings from an intrinsic manifold. Our data-driven approach may find application to other settings in which a coarse-grained

process involving a small set of macroscopic variables may parsimoniously capture the dynamics of high-dimensional, nonlinearly-coupled observables.

PARALLEL–ADAPTIVE MESHING IN A SPACETIME DISCONTINUOUS GALERKIN SOLVER FOR WAVE PROBLEMS

Pavan Ravi[*1], Christian Howard[1], Jeff Erickson[1] and Robert Haber[1]*

[1]*University of Illinois Urbana-Champaign*

ABSTRACT

We present recent progress at the University of Illinois in implementing parallel–adaptive spacetime meshing techniques in ParaSDG, a scalable spacetime solver for wave problems based on the causal Spacetime Discontinuous Galerkin (cSDG) method. cSDG solvers feature local conservation properties, linear computational complexity in the number of spacetime elements, unconditional stability without stabilization, and powerful space-time adaptive meshing capabilities. In lieu of synchronous time marching, cSDG solvers construct unstructured spacetime meshes according to a causality constraint that localizes the solution process to small clusters of spacetime elements called patches such that the solution on each patch depends only on adjacent, previously-solved elements and initial/boundary data.

This presentation focuses on formulation and implementation of new capabilities for causal adaptive meshing in up to E^3 x R, previously only available in up to E^2 x R. We present localized, dimension-independent algorithms for tent-pitching, refinement, smoothing and coarsening as well as dimension-specific schemes for flip operations, including four distinct forms of flip operations in E^3 x R. A harmonic triangulation procedure governs adaptive meshing to generate quality meshes in the 3D setting with fewer sliver elements. We present a new meshing scheme that delivers a more compact localization with zero refinement propagation.

EXPLORING THE HELIX-COIL TRANSITION IN DNA: A GEOMETRIC THERMODYNAMIC APPROACH

Asif Raza[1] and Debasish Roy*[1]

[1]*Indian Institute of Science, Bangalore*

ABSTRACT

The helix-coil transition in DNA is a fundamental process that involves the transformation of the DNA molecule from a double-stranded helical state to a single-stranded coiled state. This essential phenomenon plays a pivotal role in various biological processes, such as DNA replication and transcription. A comprehensive understanding of this transition is crucial for obtaining valuable insights into the functionality and behavior of DNA. This study introduces an innovative method for investigating the helix-coil transition by employing the principles of geometric thermodynamics.

Geometric thermodynamics is a branch of thermodynamics that uses geometric and mathematical principles to describe the behavior of thermodynamic systems. In geometric thermodynamics, the thermodynamic properties of a system, such as entropy and free energy, are represented as geometric entities. Ruppeiner geometry [1] is a specific type of thermodynamic geometry that associates thermodynamic fluctuations of a system with the curvature of the thermodynamic manifold. In this study, metric and curvature are determined using the free energy derived from the Zimm-Bragg Model [2] of the helix-coil transition which incorporates nearest-neighbor cooperativity. The coordinates of the thermodynamic manifold are defined as temperature and the number of helical segments. Factors such as temperature, pressure, and external forces can significantly alter the geometric configuration of the DNA molecule, thereby influencing the transition. The variations of curvature with temperature and fractional helicity are examined, providing insights into microstructural changes and interaction dynamics during the transition.

The study reveals that Ruppeiner geometry can provide new insights into the underlying physics of helix-coil transition. It enables us to explore the interplay between the physical structure of DNA and the energetic properties that drive its behavior. This interdisciplinary approach not only enhances our understanding of DNA behavior but also opens new avenues for advanced DNA manipulation techniques. Significantly, it proves instrumental in elucidating the intricate connections between microscopic interactions and macroscopic behavior. This framework equips us with a scalar curvature that proves valuable in enhancing our knowledge of life at the molecular level. This study underscores the importance of interdisciplinary approaches in scientific exploration.

ADAPTIVE NONLINEAR REDUCED-ORDER MODELS FOR THREE-DIMENSIONAL TRANSONIC FLOWS

Alireza Razavi[*1] and Masayuki Yano*[1]

[1]*University of Toronto*

ABSTRACT

We present a registration-based nonlinear model-order reduction (MOR) method for parametrized three-dimensional transonic flows. For many parametrized partial differential equations (PDEs), linear MOR methods provide rapidly converging solutions; however, for PDEs with discontinuities whose position depends on the parameter, linear MOR methods are ineffective due to the parametric solution manifolds with slowly decaying Kolmogorov N-widths. To mitigate this issue, we introduce a registration-based nonlinear ROM (NLROM) method that uses nonlinear reduced approximation spaces. Our formulation builds on the following ingredients. The first ingredient is transformed solution manifolds associated with transformed PDEs defined on parameter-dependent warped domains where the discontinuities are aligned. The method finds appropriate transformations in the offline stage by locating discontinuities using statistics of a dilation-based shock sensor and then optimizing transformation parameters to align the discontinuities. The second ingredient is the elements of linear MOR---reduced basis, reduced quadrature constructed using the empirical quadrature procedure, and dual-weighted residual error estimate---but crucially applied to the transformed PDEs and manifold. The third ingredient is an adaptive NLROM training procedure which simultaneously constructs adaptively refined meshes, transformations, reduced basis, and reduced quadrature to meet the user-prescribed output error tolerance in an automated manner. We demonstrate the efficacy of the method using three-dimensional transonic flow problems.

MAPPING STIFFNESS LANDSCAPE OF HETEROGENEOUS AND ANISOTROPIC FIBROUS TISSUE

*Mir Jalil Razavi**[1]

[1]*State University of New York at Binghamton*

ABSTRACT

Biological tissues are complex materials that play essential roles in the structure and function of living organisms, making their characterization a crucial aspect of many fields of study 1. The accurate characterization of mechanical properties of biological structures is vital for understanding the healthy functioning of tissues and diagnosing diseases 1,2. Alterations in mechanical properties, such as stiffness and elasticity, can provide important insights into disease progression, tissue damage, and other pathological conditions. However, due to the heterogeneity and anisotropy of biological fibrous tissues, this task presents challenges and significant uncertainty when characterized only by single-mode loading experiments. In this study, we propose a new method to accurately map the stiffness landscape of fibrous tissues, specifically focusing on brain white matter tissue. Initially, a finite element model of the fibrous tissue was subjected to six loading modes, and their corresponding stress-strain curves were characterized. By employing multiobjective optimization, an equivalent anisotropic material model (Holzapfel-Gasser-Ogden (HGO)) was inversely extracted to best fit all six loading modes simultaneously. Subsequently, large-scale finite element simulations were conducted, incorporating various fiber volume fractions and orientations, to train a convolutional neural network capable of predicting the equivalent anisotropic material model solely based on the fibrous architecture of any given tissue. We adopted a 3D Resnet to predict the strain-stress curve with simulation data from the finite element models. We aimed to map the stiffness landscape of a small part of the white matter tissue by dividing it into homogenized cubes with equivalent directional properties individually determined according to the tissue microstructure by using the developed deep learning model. The method was applied to local imaging data of brain white matter tissue, demonstrating its effectiveness in precisely mapping the anisotropic behavior of fibrous tissue. In the long-term, the proposed method may find direct applications in traumatic brain injury, brain folding studies, and neurodegenerative diseases, where accurately capturing the material behavior of the tissue is crucial for simulations and experiments.

THERMOELECTROMECHANICAL TOPOLOGY OPTIMIZATION: NON-CONVEXITY STUDIES FOR MULTIPHYSICS PROBLEMS

Guillermo Reales[*1], Alejandro Aragón[1], Johannes F. L. Goosen[1] and Fred van Keulen[1]*

[1]Delft University of Technology

ABSTRACT

Thermoelectric devices, capable of harnessing energy from temperature differentials or serving as efficient cooling solutions, have garnered attention for their potential to revolutionize energy recovery and cooling technologies. In comparison to traditional compressor-based counterparts, these devices offer advantages such as miniaturization, lower associated CO2 emissions, and operation under static conditions, resulting in reduced mechanical complexity. Despite these benefits, the current cost per watt - up to 75$/W [1] - of thermoelectric devices surpasses that of compressor-based technologies, hindering their widespread adoption in the market.

While prior studies have employed the SIMP method and assumed the validity of literature pertaining to mechanical systems [2], our investigation reveals that different physics exhibit distinct behaviors under identical optimization parameters. We delve into the evaluation of non-convex objective functions for thermoelectric devices, offering insights applicable to various physics domains and emphasizing the unique considerations for cooling technologies.

The material removal from the TO can lead to mechanical issues during operation or installation. Our study incorporates stress constraints to ensure the reliability of thermoelectric devices after optimization. The interplay between material removal and stress constraints further influences the convergence of the optimization algorithm, a critical that we further analyze.

Throughout the presentation, we discuss the intricacies of applying density-based topology optimization to thermoelectromechanical systems, highlighting algorithm particulars, convergence studies, and showcasing application examples with tangible results. By presenting our findings, we aim to contribute to the advancement of thermoelectric technology, making it more attractive to the market by concurrently improving efficiency and reducing overall costs.

AN OVERVIEW OF ADVANCED ISOGEOMETRIC SIMULATIONS INVOLVING COMPLEX GEOMETRIES

Alessandro Reali[*1]

[1]*University of Pavia*

ABSTRACT

Isogeometric Analysis (IGA) is a successful simulation framework originally proposed by T.J.R. Hughes et al., in 2005, with the aim of bridging Computational Mechanics and Computer Aided Design. In addition to this, thanks to the high-regularity properties of its basis functions, IGA has shown a better accuracy per degree-of-freedom and an enhanced robustness with respect to standard finite elements in many applications - ranging from solids and structures to fluids, as well as to different kinds of coupled problems - opening also the door for the approximation in primal form of higher-order partial differential equations. After a concise introduction of the basic isogeometric concepts, this lecture aims at presenting an overview of some recent advances in IGA with a special focus on problems involving complex geometries, where the characteristics of IGA seem to be of great advantage. In particular, applications that will be discussed include structural and fluid-structure interaction simulations in different contexts ranging from Civil and Mechanical Engineering to Biomechanics, electro-mechanical simulations for biological tissues, and studies on the effect of mechanically-induced stresses on cancer growth.

LOCAL CONSERVATION LAWS OF CONTINUOUS GALERKIN METHOD FOR THE INCOMPRESSIBLE NAVIER–STOKES EQUATIONS IN EMAC FORM

Leo Rebholz[1] and Maxim Olshanskii*[2]

[1]*Clemson University*
[2]*University of Houston*

ABSTRACT

We consider {\it local} balances of momentum and angular momentum for the incompressible Navier-Stokes equations. First, we formulate new weak forms of the physical balances (conservation laws) of these quantities, and prove they are equivalent to the usual conservation law formulations. We then show that continuous Galerkin discretizations of the Navier-Stokes equations using the EMAC form of the nonlinearity preserve discrete analogues of the weak form conservation laws, both in the Eulerian formulation and the Lagrangian formulation (which are not equivalent after discretizations). Numerical tests illustrate the new theory.

MECHANICAL PROPERTIES OF GLASSY POLYMER NANOCOMPOSITES VIA ATOMISTIC AND CONTINUUM MODELS: THE ROLE OF INTERPHASES

Hilal Reda[*1] and Vangelis Harmandaris*[1]

[1]*The Cyprus Institute*

ABSTRACT

The effect of interphases property on the mechanical behavior of silica–polybutadiene polymer Nanocomposite (PNC) is investigated via combined homogenization and molecular dynamics simulation. In the current work, we propose a multi-scale computational methodology consisting of detailed microscopic simulations and continuum modelling (homogenization) approaches for predicting the spatial distribution of the mechanical properties in polymer nanocomposites (PNC). The homogenization methodology is based on a systematic nano/micro/macro coupling between detailed atomistic molecular dynamics (MD) simulations and the variational approach based on the Hill-Mandel lemma. The model system we studied glassy-PB/silica NC's for different volume fraction of NP. Using MD simulations, the polymer/NP interphase in PNCs is directly examined by probing the distribution of the density and the stress profile at equilibration. The effective Young modulus and poison ratio of the interphases are calculated from the relation between the local stress and strain showing high rigidity in compared to the bulk material . The mechanical properties at the interphases and the polymer matrix are used, together with homogenization approach, to develop a continuum model for the prediction of mechanical properties of the PNC. A good agreement be-tween the calculated effective mechanical properties through MD and continuum models is observed. Although using an appropriate interphase model within micromechanical model is of high importance, the high accuracy should also be considered. To address such challenge and requirements, we present a closed-form analytical model to estimate the mechanical properties of interphase zone, through the molecular dynamic simulation without the aid of any continuum model. Moreover, the mechanical properties of interphases are investigated at different position between the NP and the matrix region in order to ensure the continuously changes from the nanosilica properties to the polymer matrix properties.

ROLE OF COMPUTATIONAL MECHANICS AND RECENT ADVANCES

J.N. Reddy[*1]*

[1]*Texas A&M University*

ABSTRACT

This lecture will focus on the role of computational mechanics in research and applications, followed by an introduction to the Dual Mesh Control Domain Method (DMCDM) that the author has conceived and advanced in recent years. The development of realistic mathematical models of physical phenomena is a part of scientific investigation, which requires the translation of the mathematical models into meaningful discrete models that enable us to systematically evaluate various parameters of the mathematical model and hence the physical process. Mathematical model development and numerical simulations are aids to designers, who seek to maximize the reliability of products and minimize the cost of production, distribution, and repairs. Computational methods can be used to investigate the effects of various parameters of the system on its response to gain a better understanding of the system being analyzed. Thus, the role of computational mechanics is vital to the technological advancement of any society. Currently, the finite element method (FEM) and finite volume method (FVM) are the most commonly used numerical methods for the solution of differential equations, with FEM dominating solid and structural mechanics and FVM witnessing popularity in heat transfer and fluid mechanics. Both methods suffer from certain drawbacks. In 2019, Reddy [1] introduced a numerical approach termed the dual mesh control domain method (DMCDM), which utilizes the desirable features of the FEM and FVM. In the DMCDM the dependent variables are approximated using finite element interpolation functions (as in the FEM), and the governing equation is satisfied in an integral sense over a typical control domain of the dual mesh (as in the FVM). In this lecture, the DMCDM is explained and its application to a variety of linear and nonlinear problems is presented to illustrate the workings of the DMCDM [2].

DISCONTINUOUS FAILURE IN MICROMORPHIC ELASTIC-DEGRADING MODELS

Pamela Reges[*1], Roque Pitangueira[1], Leandro Silva[1] and Lapo Gori[1]*

[1]Federal University of Minas Gerais

ABSTRACT

Structural rupture is triggered, typically, by a localized failure that corresponds to a loss in the material continuity within a specific region of the body. This localized failure is preceded by a well-known phenomenon so-called localization of deformations. This phenomenon holds particular significance in the numerical modeling of the physically non-linear behavior of quasi-brittle materials, which exhibit a strain-softening behavior. Localization is traditionally analyzed from the perspective of acceleration waves, also referred to as waves of weak discontinuities. The existence conditions for the propagation of acceleration waves are linked to the strong ellipticity condition of the equilibrium equations, which can be reduced to an algebraic problem: the spectral problem for an acoustic tensor. This study investigates discontinuous failure within the framework of micromorphic media [1, 2], which is well suited for modeling microstructured materials and also recognized in the relevant literature for its regularization properties due to its non-local formulation. Based on the concepts of propagation of acceleration waves, the acoustic tensor for the micromorphic medium is here derived. The acceleration wave is treated as a propagating surface across which, within small deformations, the second spatial and time derivatives of the displacement vector and the small micro-motion second-order tensor may undergo jump discontinuities. A generalized tangent acoustic tensor is here proposed building upon a recently proposed formulation for elastic degradation in micromorphic media [3], defined in terms of a loading function, generalized secant relations, degradation rules, and a hardening-softening law. The derived acoustic tensor is also specified for the particular case of associated scalar-isotropic damage models. The localization condition for micromorphic media is based on the analysis of the proposed generalized acoustic tensor and the numerical investigation is conducted in the open-source software INSANE, with the development code freely available at the Git repository http://git.insane.dees.ufmg.br/insane/insane.git).

WIND FARM STRATIFIED FLOW SIMULATIONS WITH ACTUATOR LINE METHOD AND VARIATIONAL MULTISCALE FRAMEWORK

Aabhushan Regmi[*1] and Artem Korobenko*[1]

[1]*University of Calgary*

ABSTRACT

In this work we present the extension of the actuator line method coupled with the residual-based variational multiscale (ALM-VMS) formulation, originally developed in [1], to model multiple wind turbines under atmospheric flow conditions. Finite element method is used for spatial discretization. The stratified flow formulation in a context of VMS was originally developed in [2]. The ALM-VMS formulation for stratified flows is first validated by comparing velocity deficit and turbulence kinetic energy in the wake region of a NREL 5MW turbine. Multiple cases with varying rotor and wake refinement regions are studied to explore the sensitivity of the results to mesh size. Next, back-to-back turbine simulation is performed under both stratified and non-stratified flow conditions. A precursor simulation is used to generate realistic turbulent inflow conditions. Finally, the simulation of the Lillgrund farm is performed with wind flow from 222° direction at various turbulent intensity levels. The power generated for each row is compared with available data, and an in-depth analysis of the wake dynamics between the turbines is also examined.

[1]*Mohammed V University*

ABSTRACT

The effects of selenium and tellurium substitution on structural, electronic, optical, and thermoelectric properties of FeS compound are investigated using the first-principal calculations and Hubbard potential (U). The phonon dispersion of each structure is simulated to examine the feasibility of the synthesis and evaluate the relative stability. FeS2 is an indirect semiconductor with an energy gap of 1.058 eV. The electronic properties can be tuned by substituting sulfur element with chalcogenide. The outcomes suggest that the band gaps are signifi cantly reduced from 1.058 eV to 0.215 eV after substitution. The absorption ability is improved in various wavelength ranges by exceeding 1.10-6 cm1 for FeTe and FeSTe compounds. Other optical properties such as optical band gap, Urbach energy, and dielectric function in both (xx) and (zz) directions are studied. The thermoelectric features of the studied compounds are strengthened and weakened under the temperature effect. The thermoelectric efficiencies are close to the unity ZT ~ 1. The findings prove that substituting is an extremely promising technique for expanding the predicted structure applications and boosting their thermoelectric devices.

FINITE ELEMENT BASED MICROMAGNETIC SIMULATIONS OF HETEROGENEOUS STRUCTURES

Maximilian Reichel[*1] and Jörg Schröder*[1]

[1]*University of Duisburg-Essen*

ABSTRACT

Cutting edge permanent magnetic materials such as neodymium-iron-boron (NdFeB) magnets play a crucial role in pushing the efficiency of power conversion devices, including wind turbines, sensors and electric motors to their limits, cf. [1]. Their huge potential to strongly influence current technological and social challenges such as the reduction of carbon dioxide emissions, provides a wide field of research, as their general increase in performance, the substitution of critical elements by harmless substances and the reduction of their required production energy. Here, microstructure engineering offers a promising approach, i.e., targeted influencing of sub-grain structures as grain boundaries or defects, to locally improve the magnetic properties. Thereby, finite element based micromagnetic simulations can be a strong technique to predict the magnetization behavior on fine scales. The FEM is characterized by a particularly flexible and not necessarily regular discretization, which is an advantage compared to other numerical methods for the discretization of heterogeneous microstructures, cf. [2]. The evolution of the magnetization vectors is determined by Gilbert's equation, which merely allows rotations, but no changes in length, cf. [3]. This constraint is enforced via a condensed perturbed Lagrange multiplier, cf. [4]. Within this contribution high-resolution micromagnetic simulations of strongly heterogeneous magnetic microstructures are presented. Thereby, the focus remains on analyzing the influence of grain boundary layers and inhomogeneities within the bulk material that often act as weak spots enabling premature reversal.

MICROSTRUCTURE-INFORMED, REGION-SPECIFIC VISCOELASTIC MODELING OF HUMAN BRAIN TISSUE

Nina Reiter[1], Lars Bräuer[1], Friedrich Paulsen[1] and Silvia Budday[1]*

[1]*Friedrich-Alexander-Universität Erlangen-Nürnberg*

ABSTRACT

Continuum-mechanics based computational models of the human brain can help to better understand mechanics-related processes of neurodevelopment, injury, and disease. A major challenge is, however, that brain tissue consists of many anatomical regions that strongly differ in their microstructural organization and mechanical response.

In a recent study, we have shown that considering the differences of those anatomical regions is essential to ensure the accuracy of whole-brain simulations [1]. However, calibrating material parameters for multiple brain regions remains challenging: firstly, tissue from all required anatomical regions needs to be characterized mechanically through reliable testing methods. Secondly, in phenomenological material models, the calibrated parameters are often highly sensitive to experimental boundary conditions and cannot be transferred to tissues that differ for example in age or health status from the ones used for calibration. This issue can be overcome with microstructure-motivated material models that have microstructural parameters with a physical meaning. Such parameters could be adapted to account for differences between individuals or changes associated with aging or neurological disease. Here, we present viscoelastic data from multimodal (i.e., compression, tension, and shear), large-strain experiments on healthy, postmortem human brain tissue from anatomical structures in the cerebrum, cerebellum, and brain stem and correlate those mechanical data with microstructural data of the same samples from histological examination. The insights gained from those correlations constitute a first step towards microstructure-informed constitutive models [2] for different anatomical regions of the human brain [3] and lay the groundwork for fully microstructure-based material models for human brain tissue.

X-MESH FOR MULTIPHASE FLOWS

Jean Francois Remacle[*1], Nicolas Moes[2], Antoine Quiriny[1] and Jonathan Lambrechts[1]*

[1]Universite catholique de Louvain
[2]Ecole Centrale de Nantes

ABSTRACT

The aim of this presentation is to introduce the X-MESH method applied to multiphase flows.

First, we'll look at the possibility of using elements with zero or near-zero measures in a finite element simulation. We will present results that go beyond the angle condition and show that there is a clear link between the use of zero-size elements and mortar methods.

We will then propose a new version of the X-MESH method, which uses a marker-and-cell representation of interfaces in both 2D and 3D. We will show that marker-and-cell coupled with X-MESH, is a very interesting alternative to the use of levelsets for representing complex evolution of interfaces, not only because it allows us to work on a computational mesh with a fixed topology, but also because, in the case of non miscible fluids, it is possible to guarantee the conservation of the mass of the different phases at machine precision.

NUMERICAL PROPERTIES AND APPLICATION POTENTIAL OF THE FINITE VOLUME METHOD WITH WALSH BASIS FUNCTIONS

Jiong Ren[*1], Gang Wang[2] and Yuan Gan[2]*

[1]Xi'an Aeronautical Institute
[2]Northwestern Polytechnical University

ABSTRACT

The finite volume method with Walsh basis functions (FVM-WBF method)[1] is a novel high-resolution numerical method recently developed by the author with the ability to capture discontinuity inside grid. An orthonormal basis set composed of Walsh functions that are characterized by square waves is used by this method to approximate the conservative variables in a control volume with Walsh series expansions which are discontinuous forms rather than the traditional continuous forms. Because of the square wave property of Walsh functions, FVM-WBF method breaks through the limitation on shock resolution imposed by the pre-condition that the flow variables vary continuously inside the control volume. A significantly improvement in resolution has been observed in FVM-WBF method when a sufficient amount of Walsh basis functions are used.

The numerical tests show that the new method not only has the high-resolution performance that captures discontinuities inside grid, but also can obtain higher computational efficiency than the traditional finite volume method. This illustrates that the character of square waves of Walsh functions enables FVM-WBF method to produce some new numerical properties that different from the traditional finite volume method. For example:

1) the scale characteristics similar to geometric multigrid can be observed in the FVM-WBF solution system, because the conservative variables are approximated by Walsh series step-by-step;

2) the compact stencils are provided by the Walsh function series in FVM-WBF method to perform high-order reconstruction;

3) the Walsh basis function coefficients has an inheritable nature. Therefore, the adaptive process can be realized by only involving the coefficients transfer, without introducing additional interpolation or reconstruction calculations.

This paper will analyze the numerical properties and application potential of FVM-WBF method, including naturally providing the compact stencils for high-order reconstruction, the dynamic adaptive and the multigrid acceleration convergence. Finally, several numerical examples are used to test the above numerical performance of Walsh function finite volume method.

INFLUENCE OF SEEPAGE SIMULATION METHOD OF WATER STORAGE PROCESS ON VALLEY DEFORMATION AND WORKING BEHAVIOR OF ARCH DAM

Qinwen Ren[*1], Xiang Yang[1] and Xuhua Ren[1]*

[1]*Hohai University*

ABSTRACT

During the construction of the high arch dam, the valley has obvious deformation, which affects the working state of the arch dam. How to reasonably simulate the construction and storage process of the arch dam to make the deformation law and magnitude of the valley closer to the actual situation is of great significance for understanding the actual working behavior of the arch dam and ensuring the safety of the arch dam. Take the arch Jinping Ⅰ arch dam as an example, in this paper, the seepage and stress-seepage coupling of dam abutment rock mass are simulated by different methods to study the effect of valley amplitude deformation on dam working state. The results show that when the traditional method is used to calculate the seepage force according to saturated seepage without considering the coupling of stress and seepage, the valley amplitude deformation shows an expanding state, which is opposite to the measured deformation. If the coupling effect of stress and seepage is considered, the valley amplitude deformation is contracted. At this time, if the conversion between unsaturated and saturated seepage in the initial water storage process is not considered, the shrinkage value is too large when the coupling analysis is carried out with saturated seepage. The correct simulation method should consider the stress-seepage coupling and the conversion between unsaturated and saturated seepage during the initial impoundment. The research in this paper shows the importance of selecting the correct simulation method.

SAMPLE EFFICIENT ESTIMATION OF RARE-EVENT PROBABILITIES WITH GAUSSIAN PROCESSES AND NORMALIZING FLOWS

Ashwin Renganathan[*1] and Annie Booth*[2]

[1]*The Pennsylvania State University*
[2]*North Carolina State University*

ABSTRACT

Simulating rare events and computing their probabilities find applications in various fields, including extreme weather event prediction and aircraft certification. In this context, we address the challenge of dealing with an expensive black-box computer model of a system in the estimation, which then involves an intractable integral requiring approximation, such as through Monte Carlo (MC) sampling. While naive MC sampling may incur high variance in the estimators, re-weighting with importance sampling (IS) can mitigate this issue, provided a suitable re-weighting, or "biasing," density is identified. A substantial body of work has focused on constructing biasing densities using a surrogate model. However, the overall probability estimation may still entail a considerable cost of O(1000-10000) queries to the model, which could be prohibitive for certain applications. In response to this challenge, we propose a novel method that demonstrate significantly improved sample efficiency. Specifically, by leveraging adaptive Gaussian process models and normalizing flows, we illustrate that accurate estimation of rare-event probabilities, as low as 1e-12, can be achieved with just O(100) queries to the model, while reducing variance. We validate our approach through experiments on several synthetic test functions and a gas turbine thermal stress analysis problem.

A NOVEL COMPUTATIONAL APPROACH FOR PREDICTING MICRO-BUCKLING SENSITIVITIES IN ARCHITECTED MATERIALS

David Restrepo[1], David Risk[1], Mauricio Aristizabal[1] and Harry Millwater[1]*

[1]*The University of Texas at San Antonio*

ABSTRACT

Architected Materials (AMs) have attracted attention due to their superior properties and functionalities obtained by exploiting elastic micro-buckling. However, the widespread adoption of AMs has been limited by the difficulty in predicting the onset of micro-buckling, which is highly sensitive to defects and imperfections. Current numerical models for analyzing and designing AMs are deterministic and do not account for unintended imperfections, leading to a lack of confidence in their performance. To address this issue, we present a new computational framework based on Hypercomplex Automatic Differentiation (HYPAD) that allows us to quantify local sensitivities in the onset of instabilities and post-buckling behavior of architected materials. In this talk, we will introduce this method to analyze the sensitivities of discrete structures exhibiting snap-through behavior and continuum elements such as geometrically non-linear shells. Our approach provides insights into the most significant factors affecting the onset of buckling and post-buckling behavior of AMs, enabling the development of surrogate models for uncertainty quantification and accounting for unavoidable uncertainties derived from fabrication, assembly, and actuation.

NUMERICAL ANALYSIS OF EVOLVE FILTER RELAX REDUCED ORDER MODELS (ERF-ROMS)

Jorge Reyes[1], Maria Strazzullo[2], Traian Iliescu[1] and Claudio Canuto[3]*

[1]*Virginia Tech*
[2]*Politecnico di Torina*
[3]*Politecnico di Torino*

ABSTRACT

This talk focuses on the development of the numerical analysis behind regularized reduced order models (ROMs) in computational fluid dynamics. Direct numerical simulations have long been understood to be computationally infeasible for day-to-day simulations in computational fluid dynamics. ROMs have been shown to provide an efficient low-dimensional model that enables fast and accurate simulations.

In the case of under-resolved flows, which is generally the case for turbulent flows, standard ROM accuracy tends to suffer. This results in a large variety of ROMs that use different methodologies to improve accuracy while still ensuring swift computations. Regularization, which is based on spatial filtering, increases the ROM stability and accuracy with negligible computational overhead. In this talk, we consider the evolve-filter-relax (ERF) ROM framework as it relates to implicit methods for the Navier Stokes equations. We analyze the numerical diffusion introduced by the scheme, as well as stability and convergence. Several numerical simulations are presented to support the analysis.

ABSTRACT

Physics-informed operator learning is a new tool for solving boundary value problems in a parametric way. We introduce a novel approach by defining loss functions for neural networks based on the discretized version of the weak form for the given PDEs and BCs. The loss function in this work is an algebraic equation that significantly enhances training efficiency. A distinctive aspect is our independence from classical solvers like finite element methods for data [1]. Additionally, we applied the concept of physics-informed NN to solve the constitutive relations for nonlinear, path-dependent material behavior. The trained network not only satisfies all thermodynamic constraints but also instantly provides information about the current material state under any given loading scenario without requiring initial data [2].

ESTABLISHING PROCESS-MICROSTRUCTURE-PROPERTY LINKAGES VIA DEEP LEARNING IN ADDITIVELY MANUFACTURED CERAMICS

Mohammad Rezasefat[*1] and James Hogan*[1]

[1]*University of Alberta*

ABSTRACT

Additive manufacturing techniques for ceramics provide several benefits compared to conventional manufacturing processes. These advantages include enhanced design flexibility, minimized material wastage, reduced manufacturing complexity, and the potential for accelerated prototyping and production phases. The goal of this study is to demonstrate how computational mechanics can be effectively used to correlate the processing parameters of additively manufactured ceramics (AMCs) with their microstructural characteristics and functional performance. Here, we develop and train deep learning models to interpret and predict the mechanical behavior of ceramics based on material's synthetic microstructure. This involves analyzing how different processing methods influence the internal structure of materials and how material’s microstructure, in turn, affect their mechanical properties (e.g., stiffness and strength). To achieve these objectives, our methodology consists of four primary components: i) the additive manufacturing of alumina ceramics using Stereolithography method, ii) experimental characterization and testing, employing various specimen geometries such as compression, indirect tension, and semi-circular bending, under both quasi-static and dynamic conditions, and microstructural analysis through EBSD, SEM, and X-ray computed tomography, iii) performing physics-based modeling (i.e., FEM and MD) to further understand of the material's mechanical and failure behavior, and finally iv) integrating manufacturing, microstructure, and mechanical performance using computer vision-based deep learning models, which are crucial for connecting the detailed aspects of the manufacturing process with the resulting material properties. This framework is notably effective for enabling efficient, high-throughput, and multiscale modeling, it is particularly tailored for application in the field of advanced ceramic materials. In summary, predictive modeling tools, validated and informed by current testing and characterization efforts, are aimed at the design of lightweight, high-performance, multifunctional structures made from additively manufactured ceramics. These advanced structures are anticipated to benefit key industrial sectors, including renewable energy, defense, manufacturing, aerospace, mining, and agriculture.

[3]University of Stuttgart

ABSTRACT

Abstract:
Human tissue imaging is essential in medical diagnostics for early illness identification and therapy planning [1]. Technological advancements have significantly improved the accuracy of diagnosis and expanded our understanding of physiological processes. Improving image quality is crucial for detecting fine details in biological structures. Photoacoustic imaging is a state-of-the-art method that provides exceptional clarity and depth in tissue visualization through the use of laser-induced acoustic waves. To accurately measure wave pressure in this imaging technique, a thorough understanding of the thermomechanical behavior of tissues is essential [2,3]. This study presents a new one-sided coupled thermo-mechanical model for human tissues in the context of photoacoustic imaging. The objective of this study is to improve image resolution. To achieve greater precision in tissue characterization, the model utilizes an incompressible Neo-Hookean uniaxial method. This approach lays the groundwork for future advancements in medical imaging technologies. The proposed model accounts for the complex interplay between thermal and mechanical effects by incorporating an incompressible Neo-Hookean model for heat-induced dynamic motion and a two-phase lag model for one-dimensional heat distribution. This contribution presents a precise and comprehensive method for simulating the complex interaction necessary for researchers investigating the thermomechanical behavior of human tissue in photoacoustic imaging.

DATA DRIVEN UNSUPERVISED CLUSTERING OF METAL ADDITIVE MANUFACTURING CRYSTALLOGRAPHIC TEXTURE DATA

Aashique Rezwan[*1], David Montes de Oca Zapiain[1], Daniel Moser[1], Michael Heiden[1] and Theron Rodgers[1]*

[1]Sandia National Laboratories

ABSTRACT

Metal additive manufacturing (AM) parts often have microstructural features (e.g., high-aspect ratio columnar grains, crystallographic orientation gradients, porosity, etc.) that are not well described by traditional microstructure quantification metrics (e.g., grain size and shape distributions). The large amount of microstructural variation that can occur within different features, thicknesses, and build orientations of an AM part can also be challenging to quantify. This work presents a data-driven approach to quantifying microstructures that incorporates grain morphology, crystallographic orientation and phase information. A combination of generalized spherical harmonics (GSH) to map the crystallographic texture, 2-point spatial autocorrelation for both GSH and phase discretization, and a dimensionality reduction technique (i.e., Principal Component/Auto-encoder) is used to discern the complex microstructural data into human-readable results for comparison. Application of this methodology to an experimental dataset of AM 316L stainless steel demonstrated that the method is sensitive to minor microstructural differences within specimens created with nominally identical processing parameters. The method can identify different part orientations, build batches and outliers present in the process. This method can potentially serve as a tool in detecting AM process changes from EBSD data for quality control applications.

Sandia National Laboratories is a multi-mission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

A HYBRIDIZABLE DISCONTINUOUS GALERKIN METHOD FOR COUPLED NAVIER-STOKES AND DARCY

Aycil Cesmelioglu[1], Jeonghun Lee[2] and Sander Rhebergen[3]*

[1]Oakland University
[2]Baylor University
[3]University of Waterloo

ABSTRACT

In this talk we will present a strongly conservative hybridizable discontinuous Galerkin (HDG) method for the coupled Navier-Stokes and Darcy problem with Beavers-Joseph-Saffman interface condition. These equations describe the motion of a freely flowing fluid coupled to flow of a fluid in porous media and are used to model, for example, surface/subsurface flows.

The HDG method has various appealing properties. First of all, HDG methods were introduced to reduce the large number of globally coupled degrees for freedom of standard higher-order discontinuous Galerkin methods. This is achieved through hybridization [1]. The HDG method is furthermore well suited for coupled problems: coupling between the Navier-Stokes equations and the Darcy equations across an interface is achieved naturally through HDG facet variables. In addition to these properties, the HDG method that we present is designed such that the discrete velocity is globally divergence-conforming and, in the absence of sources and sinks, pointwise divergence-free, i.e., the method is strongly conservative. These properties are appealing in their own right, but have further interesting consequences, namely, the velocity error is independent of the best approximation to the pressure.

In this talk we will show stability and prove existence and uniqueness of a solution to the discretized stationary [2] and time-dependent Navier-Stokes/Darcy [3] problems. Additionally, we present an optimal, a priori error analysis and demonstrate our theoretical results with numerical examples.

A WORLD OF PURE IMAGINATION? UNDERSTANDING THE DYNAMICS OF VERTICAL STIRRED MILLS WITHIN CHOCOLATE PROCESSING

Daniel Rhymer[*1], Andy Ingram[1] and Kit Windows-Yule[1]*

[1]*University of Birmingham*

ABSTRACT

While it would be nice to imagine a Willy Wonka world where perfectly smooth chocolate is produced by waterfall, the reality is very different. Cocoa liquor is a particle-laden slurry, and these particles need to be reduced in size to create the smooth texture and desired mouthfeel needed for tasty chocolate. A vertical stirred mill is often used to achieve this, as they have greater specific energy transfer and a smaller physical footprint than other grinding techniques [1]. However, there is still little understanding about its exact dynamics on an industrial scale. This is a problem not just within chocolate, but industry as a whole, as grinding is the most commonly used step in manufacturing. Over half of all manufactured products have at least one size reduction stage during processing [2], and up to 4% of global electricity consumption goes into reducing the size of materials [3].

Simulation has opened a new world of possibility to explore the detail of vertical mills and the talk presents a validated simulation using the Discrete Element Method (DEM) technique and experimental data from particle tracking data. The model is trained and optimised using machine learning and while there are limitations in trying to align complex multiphase systems, a good level of agreement with the experimental results can be reached. The model can also reproduce the dynamics of unseen trials to the same level of accuracy as the initial training set, further validating the optimal conditions and means the model can be used with confidence beyond the experimental trials. This truly unlocks a world of pure imagination in better understanding and optimising the process, improving efficiency and tackling the climate crisis.

[4]*EPF Ecole d'inge´nieurs*

ABSTRACT

Finite element analysis of damage in quasi-brittle materials implies using regularization approaches to obtain mesh-independent results. Non-local integral or gradient-type methods are usually applied. In most of these approaches, non-local interactions between material points are supposed to be constant and independent of the mechanical fields. Nevertheless, some pathological issues in these models (e.g., damage diffusion and boundary effects) may lead to incorrect descriptions of the damaging/cracking behavior. Non-local approaches with evolving interactions allow for a better description of damage processes and naturally model damage-to-fracture transition (Ribeiro Nogueira et al., 2022).
The present contribution aims to provide theoretical and numerical aspects concerning regularized anisotropic damage modeling in quasi-brittle materials. Particularly, attention is given to the gradient-enhanced eikonal (ENLG) damage model (Desmorat et al., 2015) based on the derivation proposed by Ribeiro Nogueira et al. (2024) using a micromorphic media framework. This approach considers that damage deforms the space where the non-local equivalent strain controlling damage evolution is computed (space curvature is represented through a damage-dependent Riemannian metric). Non-local interactions are thus reduced when damage occurs and vanish in highly damaged zones. Such an approach can be naturally applied to regularizing isotropic and anisotropic damage models.
Here, a second-order tensorial damage model is assumed, and induced anisotropic evolving interactions are naturally considered via the ENLG formation (both in 2D and 3D). This is essential for accurately describing damage/cracking initiation and propagation. After illustrating the main features of the ENLG formulation, its capabilities to represent experimental findings (e.g., size effect) are evaluated.

THERMODYNAMIC CONSISTENCY AND STRUCTURE-PRESERVATION IN A DISCONTINUOUS GALERKIN METHOD FOR THE MOIST COMPRESSIBLE EULER EQUATIONS

Kieran Ricardo[*1], David Lee[2] and Kenneth Duru[1]*

[1]*The Australian National University*
[2]*The Bureau of Meteorology*

ABSTRACT

We present a thermodynamically consistent and structure-preserving discontinuous Galerkin method for the moist compressible Euler equations. Our spatial discretisation satisfies the first and second laws of thermodynamics independent of the equation of state used, and additionally conserves tracer variance and energy. These properties are achieved by discretising a skew symmetric form of the moist Euler equations, using entropy as a prognostic variable, summation-by-parts properties of discrete operators and a careful choice of numerical fluxes. We experimentally verify our theoretical results with numerical simulations.

THE IMPORTANCE OF EXPERIMENTAL VALIDATION IN FSI PROBLEMS: RECENT AERO-SERVO-ELASTIC TESTS AT LARGE POLIMI'S WIND TUNNEL

Sergio Ricci[*1]*

[1]*Politecnico di Milano*

ABSTRACT

Born in the autumn of 2001, but fully operational since 2023, the large wind tunnel of Politecnico di Mlano turns 20 this year and today it is one of the 4 large research infrastructures of the University. Designed, from the point of view of fluid dynamics, entirely within Politecnico, it is close circuit wind tunnel characterized by a particular design that includes two test sections. The boundary layer section (14m x 4m x 38m), located in the return circuit, is particularly suitable for testing objects subjected to the action of the wind such as bridges, skyscrapers, stadiums and large roofing systems; this section is widely used for research in the wind energy sector. The low turbulence section (4m x 4m x 6m), located as usual between the convergent and divergent parts of the tunnel, is mainly used for aeronautical tests, such as airplanes and helicopters, but not only.
Two characteristics make this wind tunnel especially useful for FSI or more generally speaking aeroelastic testing. At first, the large test rooms allow for testing large scale models, in some cases components at full scale. Second, the flow generation system based on 14 fans for a total of 1.5 MW power is fully protected by a steel grid, so that it cannot be damaged by possible brake of aeroelastic models. During years of activity the wind tunnel has been equipped with dedicated equipment for aeroelastic tests that will be presented in the following. In the last 10 years of activity, a large experience has been acquired in different class of aeroelastic testing such as flutter identification and control, gust load alleviation, limit cycles oscillations. Relevant technologically advanced equipments have been developed to respond to complex aeroelastic problems, such as: a six vanes gust generator to produce the excitation profile to test gust load alleviation systems; a floating ground device embedded under a dummy floor to guarantee free plunge and pitch motions to test half models under 1g + gust loads; a photogrammetric system for motion capturing of large models based on 8 high speed cameras. On the side of this experimental capability, DAER POLIMI developed since many years a suite of different numerical tools at different fidelity level to analyze, optimize and control aeroelastic phenomena. The presentation will present the most relevant experiments carried out in the last years as well as the numerical-experimental correlation results obtained.

BAYESIAN OPTIMAL EXPERIMENTAL DESIGN FOR CONSTITUTIVE MODEL CALIBRATION USING FULL-FIELD DIC DATA

Denielle Ricciardi[*1], Daniel Seidl[1], Brian Lester[1], Amanda Jones[1] and Elizabeth Jones[1]*

[1]Sandia National Laboratories

ABSTRACT

Calibration and validation of constitutive models is an essential part of accurate computational simulations, which are increasingly being relied upon for engineering decision-making. Thus, there is a corresponding emphasis on the calibration process—both in terms of efficiency and accuracy—and in establishing confidence in predictions of the engineering problem with a quantified level of uncertainty. In practice, the calibration and subsequent validation of material models is often a discrete, multi-stage process that is decoupled from material characterization activities. As a result, the data which is collected does not always align with the data that is needed for calibration. To address this issue, an integrated workflow for delivering an enhanced characterization and calibration procedure—Interlaced Characterization and Calibration (ICC)—has been developed to improve constitutive calibrations with quantified and reduced parameter uncertainty. This framework leverages Bayesian optimal experimental design (BOED) to optimize the information content gathered from characterization experiments, thus minimizing parameter uncertainty.

This work presents results from a constitutive model calibration performed within the ICC framework. In this example, the load path of a metallic cruciform specimen is optimized in order to obtain the most informative data for calibration of an anisotropic yield surface and isotropic hardening material model. The selection of the optimal load path is segmented into the selection of individual load steps from a pre-determined load path tree. The specimen is deformed within a bi-axial load frame, and full-field digital image correlation (DIC) data and load data are collected for calibration. The high dimensionality of the field data is reduced via principal component analysis, and calibration is performed with Bayesian inference, which provides a quantitative measure of uncertainty on the unknown model parameters. Given a set of possible next load steps, BOED is used to determine which load step to take (i.e. on which arm of the cruciform specimen to impose a positive strain) using the expected information gain (EIG) as a measure of how informative each load step option is predicted to be. The experiment is actively driven through the load path with the highest EIG. Prior to beginning the characterization and calibration cycle, surrogate models are constructed to replace the expensive constitutive model and are built for both the load and displacement quantities of interest. The various advantages and disadvantages of the workflow are discussed along with the prospect for future application.

MODELING SMALL SCALE PROCESSES IN ANTARCTIC SEA ICE

Raghav Pathak[1], Tim Ricken[*1], Silke Thoms[2], Seyed Morteza Seyedpour[1] and Bernd Kutschan[2]*

[1]University of Stuttgart
[2]Alfred Wegener Institute

ABSTRACT

The Antarctic sea ice, subject to annual freezing and melting, holds a crucial role in the global climate cycle. Notably, satellite observations in the Antarctic region have revealed an unprecedented decrease in sea ice extent every year with lowest in 2023. Projections suggest that ongoing ocean warming and future environmental changes in the Southern Ocean will impact the Marginal Ice Zones (MIZ), BioGeoChemical cycles, and their coupled interactions. The 'pancake' floes are characterized by a porous sea ice matrix housing interstitial brine, nutrients, and biological communities within pores. Both ice formation and salinity are dependent upon ambient temperature. To realistically capture these multi-phasic and multi-component coupled processes, we employ the extended Theory of Porous Media (eTPM) presented in (Ricken et al., 2014). This approach enables the development of high-fidelity models adept at simulating diverse seasonal variations in the region. Crucial variables like salinity, ice volume fraction, and temperature, among others are considered, each having its equations of state. The phase transition phenomenon is addressed through a micro-macro linking scheme. Utilizing a Phase-field solidification model (Thoms et al., 2014) coupled with salinity, the micro-scale freezing processes are modeled and scaled up to the macro level using the eTPM model. The evolution equations for the phase field model follow Landau-Ginzburg order parameter gradient dynamics and mass conservation of salt, facilitating the modeling of salt trapped within the pores. In addressing the biological aspect, we establish a BioGeoChemical flux model for sea ice following (Vancoppenolle & Tedesco, 2017), to simulate algal species within the sea ice matrix. Ordinary differential equations capture environmental factors influencing the growth and loss of distinct BGC components. Processes like photosynthesis, dependent on temperature and salinity, are derived through an ODE-PDE coupling with the eTPM model. Academic simulations and results serve as validation for the mathematical model. These sophisticated models are poised to be integrated into large-scale global climate models, enhancing our understanding of the Antarctic sea ice's role in the broader climate system.

MULTIGRID-IN-TIME METHODS FOR NONLINEAR OPTIMIZATION OF DYNAMICAL SYSTEMS

Denis Ridzal[*1], Eric Cyr[1] and Radoslav Vuchkov[1]*

[1]*Sandia National Laboratories*

ABSTRACT

Fast methods for nonlinear optimization with differential equations are critical to the solution of optimal control, optimal design and inverse problems in fluid, flight, structural and electrodynamics. To compute a step, based on the derivatives of the cost function and the governing differential equations, conventional methods rely on the forward and backward (adjoint) time evolution of the dynamical system. The serial nature of time stepping introduces an inherent computational bottleneck, resulting in long solution times even for relatively simple problems governed by scalar ODEs. In contrast, matrix-free composite-step sequential quadratic programming (SQP) methods [1,2] offer an interesting alternative. Specifically, they solve a sequence of convex quadratic optimization problems that lead to Karush Kuhn Tucker (KKT) saddle-point systems in which the linearized forward and adjoint time evolutions are fully coupled. This time-domain coupling, combined with the convexity of the quadratic subproblems, enables a multigrid-in-time approach.

To develop our multigrid-in-time method, we express the KKT systems in their block-tridiagonal form, where the diagonal blocks maintain the saddle-point structure on each time interval, and the off-diagonal block expose the time coupling. From the tridiagonal form, we construct block-Jacobi and block-Gauss-Seidel fixed-point schemes. The block-Jacobi scheme is used as the pre- and post-smoother for the proposed multigrid method. This smoother is trivially parallelizable in the time domain. A Symmetric block-Gauss-Seidel (SGS) scheme is used as the preconditioner for a coarse-grid solver based on an inner GMRES iteration. The SGS scheme, which is also investigated in [3], serializes in the time domain, however it is applied to only a handful of coarse-grid time steps. We use the multigrid method as the preconditioner for an outer flexible GMRES (FGMRES) iteration.

We demonstrate excellent algorithmic scalability of the proposed multigrid-in-time approach on nonlinear optimization problems with ODE and PDE constraints. More concretely, scalability extends to (i) the inner coarse-grid SGS-preconditioned GMRES method, (ii) the outer multigrid-preconditioned FGMRES method, and (iii) the overall SQP method. Our results also point to a very mild influence of dynamical system coefficients on the number of FGMRES iterations.

NUMERICAL SIMULATION OF THE SWELLING AND DESWELLING PROCESS OF GEL

Isamu Riku[*1] and Koji Mimura*[1]

[1]*Osaka Metropolitan University*

ABSTRACT

It is well known that the entropy elasticity of rubberlike materials and Brownian motion are described by formally analogous equations as both originated from thermal fluctuations. In rubberlike materials, the shear modulus is conventionally considered to be proportional to the absolute temperature and the proportionality factor is the number density of the polymer chains for an affine polymer chains network model. On the other hand, the self-diffusion coefficient of Brownian motion is described as the product of the mobility and the absolute temperature.

However, for the polymer chains network in a solvent, the interaction between the polymer chains and the solvent molecules occurs and the collective diffusion coefficient of the solvent molecules should be different to the self-diffusion coefficient of Brownian motion. Moreover, the shear modulus of the resultant hydrogel should be dependent on the swelling ratio due to the nonaffine movement of the polymer chains.

Therefore, to investigate the analogy of the equations for the shear modulus of the nonaffine polymer chains network model and the collective diffusion coefficient of the solvent molecules, in this study, the swelling and deswelling process of hydrogel is investigated by the numerical simulations.

ENERGETIC MESH SMOOTHING

Julian Rimoli[*1], Alejandro Mota[2] and James Foulk[2]*

[1]*University of California, Irvine*
[2]*Sandia National Laboratories*

ABSTRACT

Mesh quality improvement is an integral part of finite element modeling, as the quality of the solution as well as the speed of the solution procedure are generally tied to the quality of the worst element in the mesh. Generally, a mesh improvement solution includes the introduction of a mesh quality measure followed by an optimization process, with most mesh quality measures being based on geometric parameters such as minimum angle, length, Jacobian, etc. In this work, we introduce an energetic measure of mesh quality given by the deformation energy of a reference element mapped to the current mesh configuration, assuming a hyperelastic constitution. In this way, the approach is analogous to a set of connected, equilateral, elastomeric elements subject to the topology of the given mesh and finding their equilibrium configuration. This formulation allows us to adopt traditional solid mechanics methods and techniques to optimize the mesh quality, significantly reducing the burden of the mesh improvement process. We will show results on how randomly generated meshes can be automatically improved using our approach.

AUTOMATED CALIBRATION OF CONCRETE MATERIAL MODEL WITH QUASI-STATIC EXPERIMENTS USING INVERSE APPROACH

Daniel Rios-Estremera[*1], Jean Santiago-Padilla[1], Jesse Sherburn[1] and Andreas Frank[1]*

[1]U.S. Army Engineer Research and Development Center

ABSTRACT

The U.S. Army's ERDC is the leader for the U.S. Department of Defense in the fields of blast and weapons effects on structures and geo-materials, and civil and military engineering. Recognizing the pivotal role of concrete in these critical domains and broader societal contexts, ERDC is dedicated to conducting thorough research aimed at advancements in numerical modeling for concrete materials. This study introduces an automated methodology for inverse parameter estimation and calibration of a complex concrete material model, utilizing quasi-static experimental data. The methodology involves the integration of the constitutive relationships and finite element numerical modeling to estimate optimal parameters. The constitutive relationships determine the failure surface and the non-linear shear modulus from a suite of triaxial loading experiments. Meanwhile, the numerical model consists of a single element under various loading/unloading conditions that induce a series of stress paths, which are compared to analogous experimental data. Parameter optimization is facilitated through the Dakota software [1] from Sandia National Laboratories. This methodology aims to reduce the time and subject matter expertise required for using and calibrating the material model, while maintaining flexibility to allow adaptation to requirement changes resulting from ongoing material model development. Lower barriers of entry will increase the model's availability and viability to a broader audience in the concrete and geo-materials modeling community.

STUDY OF WIND-INDUCED VIBRATIONS ON A TRELLIS PYLON CONTROLLED THROUGH AN ACTIVE MASS DAMPER SYSTEM

Francesco Ripamonti[*1], Stefano Cii[2] and Alberto Bussini[2]*

[1]*Politecnico di Milano*
[2]*Isaac srl*

ABSTRACT

In recent years, especially because of the diffusion of the 5G internet network, it has become increasingly necessary to develop new solutions (such as smart trellis pylons) to install a growing number of antennas for the transmission of the electromagnetic signals, and to implement or improve the monitoring of existing infrastructure.

Steel truss structures for telecommunications typically have very low damping values, even lower than 1%. Therefore, wind-structure interaction phenomena can generate significant oscillations, leading to structural deterioration, potential disturb of the network signal or, in the worst cases, the collapse of the system and a consequent total interruption of the service.

In this context, a detailed knowledge of the wind loads would allow to perform better structural analysis and estimate the beneficial effects of improvement interventions, such as the installation of a damping system or local structural reinforcements. Unfortunately, the modelling of wind actions induced on these structures is a complex and still open issue, and nowadays the national and international regulations introduce oversized safety factors in favour of safety.

In this article we analyse a 50-meter-high steel trellis pylon located on the top of a mountain, at 1300 meters above sea level, in Liguria (Italy). Several accelerometers and one anemometer on the top were installed on the structure. From the experimental measurements of the wind speed and the relative oscillation of the structure it was possible to estimate the wind loads. Then, a reduced modal model of the pylon, identified from the accelerometer measurements, was implemented in Matlab/Simulink considering only the most significant modes. Finally, an Active Mass Damper (AMD) was modelled, starting from the physical parameters of the motor and the control law, and added on the top node of the structure.

From the numerical simulations it is possible to study the structure behaviour with and without the AMD system, comparing the indexes in terms of tip displacement, most stressed structural elements and acceleration at the antennas (or other critical equipment) installation points.

HYBRID TWIN OF A VERTICAL AXIS ROTATING MACHINE: MODEL ORDER REDUCTION AND MACHINE LEARNING

Sima Rishmawi[*1], Souheil Serroud[1], Sebastian Rodriguez[2], Francisco Chinesta[2] and Frédérick Gosselin[1]*

[1]*École Polytechnique de Montréal*
[2]*École Nationale Supérieure d'Arts et Métiers*

ABSTRACT

Rotating machinery plays a crucial role in various industrial systems, including aircraft, vehicles, machine centers, and turbines. It is essential to evaluate the operational conditions of these machines to ensure safety and plan maintenance. Typically, most shafts in these machines are horizontal. In such cases, the bearing reaction forces can be determined by considering the static radial load resulting from the rotor's weight. However, when the shaft is vertical, the clearance between the shaft and the bearing leads to nonlinear bearing reaction forces that are challenging to calculate. Discretized partial differential equations can be used to represent the behavior of rotating machines, the solutions of which depend on various parameters. Creating accurate numerical models for multi-dimensional systems or systems with multiple parameters can be computationally costly, especially if the systems are non-linear. Therefore, the idea of having a pre-calculated library of solutions that can be used to efficiently calculate the system's response to a wide range of problem parameters is attractive. To accomplish this, we propose a two-step approach. Initially, we use a global solver that operates in the non-linear space-frequency domain. This solver generates a low-rank representation of the solution by employing the Harmonic-Modal Hybrid analysis and the Discrete Empirical Interpolation Method (DEIM). The DEIM technique creates a reduced basis for the non-linear function(s) using either calculated or experimental values, thereby enhancing the efficiency of the computations. Subsequently, the optimized solver is employed to perform rapid offline computations, enabling the construction of surrogate models. These models can then provide real-time predictions of the parameterized dynamic response by using the sparse proper generalized decomposition (sPGD) technique. In the second phase, we gather data from an experimental setup comprising a vertical rotating shaft. This shaft is connected to a fixed bearing at its lower end and a compliant bearing at its upper end. The collected data is then used to construct a correction model based on machine learning. This model aims to minimize the discrepancy between the experimental and simulated outcomes, resulting in an enhanced and more precise hybrid twin of the VARM. This twin finds uses in selecting the most favorable operational scenarios, anticipating malfunctions, and planning maintenance. Additionally, it can determine hard to measure parameter values by selecting a solution from this collection that corresponds to real-time measured data. In the future, this approach can be expanded to encompass the entire hydroelectric power generating unit.

TRACKING INTERFACE CONTACT AND PENETRATION IN EMBEDDED BOUNDARY FLUID-STRUCTURE INTERACTION SIMULATIONS

Erick Rivas[*1], Kevin Wang[1], Emily Guzas[2] and Edwin Lopez Ramos[2]*

[1]*Virginia Tech*
[2]*Naval Undersea Warfare Center, Division Newport*

ABSTRACT

Abstract:
Embedded and immersed boundary methods are effective tools for simulating fluid-structure interaction problems involving complex geometry and large structural motion. These methods eliminate the need of mesh motion computation and re-meshing. The tradeoff, however, is that the location of the wetted structural surface needs to be tracked within a non-body conforming fluid mesh at every time step. In this work, we tackle a special scenario involving multiple interfaces that may come into contact and penetrate each other. This type of topological change poses a significant challenge to the robustness of existing interface tracking algorithms that are based on projections and intersection detections. To overcome this challenge, we present a numerical method that applies ray-tracing and flood-fill algorithms to detect interface contact and penetration, directly using the fluid mesh for space discretization. Subsequently, existing interface tracking methods are extended to assign correct material/phase information within new disconnected subspaces resulting from interface penetration. For distributed parallel computation, k-d trees and a scoping strategy are employed at the subdomain level to improve efficiency and scalability. The new interface tracking method is capable of separating different fluid and structural domains, identifying edge-interface intersections within the fluid mesh, and computing the shortest distance from any point in the fluid domain to the fluid-structure interface. The performance of this method will be evaluated through academic benchmark tests and real-world engineering problems. In particular, it will be employed to simulate the unsteady hydrodynamics in dynamic underwater docking applications, where unmanned undersea vehicles are required to approach and interface with other undersea vehicles or submerged structures.

ABSTRACT

High-fidelity numerical models are commonly used to simulate physical phenomena in coastal and near-shore regions that involve nonlinear interactions between wave hydrodynamics, meteorological, and hydrological phenomena. Despite the tremendous progress in computational resources and methodologies, these high-fidelity models are still computationally expensive and require a significant amount of domain expertise. Moreover, in addition to the high computational cost, the challenges of capturing nonlinear spatial features using unstructured meshes across coupled models and the adoption of various empirical approximations render most of the existing high-fidelity, coupled wave-circulation models ineffective for use in ensemble-based forecasting systems and coastal hazard assessment studies.

In this talk, we will present a deep neural operator framework inspired by the deep operator network (DeepONet) philosophy that can generate fast and accurate predictions of various tidal and wind-driven flows arising in coastal environments. We will explore different neural operator model formulations and demonstrate their merits and drawbacks using a benchmark 1D analytical problem. A reduced-order emulator of a real-world example of 2D tide-driven flow in Shinnecock Inlet Bay, New York will also be presented. Such flows are typically simulated by a coupled system of the depth-averaged shallow water equations and the wave action balance equations, and are parameterized by various combinations of meteorological and morphological conditions. Moreover, a typical design and development pipeline for a model problem will be presented to highlight how such a framework might fit as a general approach for reduced order modeling in multi-physics engineering applications.

CONVERGENCE OF NUMERICAL METHODS FOR THE COUPLED CAHN-HILLIARD AND NAVIER-STOKES EQUATIONS

Beatrice Riviere[*1], Chen Liu[2] and Rami Masri[3]*

[1]Rice University
[2]Purdue University
[3]Simula

ABSTRACT

Modeling multicomponent flows in porous media is important for many applications relevant to energy and environment. Advances in pore-scale imaging, increasing availability of computational resources, and developments in numerical algorithms have started rendering direct pore-scale numerical simulations of multiphase flow in pore structures feasible. This talk presents recent advances in the discretization of phase-field models for systems of two-phase flows. Spatial discretization is based on the interior penalty discontinuous Galerkin methods. Time discretization utilizes a decoupled splitting approach. Both theory and application of the proposed methods to model flows in porous structures are discussed.

NEURAL-NETWORKS TO APPROXIMATE THE CONTACT LAW IN INTERFACE DYNAMICS

Daniel Rixen[*1] and Paolo Tiso*[2]

[1]*TU Munich*
[2]*ETH Zürich*

ABSTRACT

A detailed representation of the contact forces generated between components is essential when analyzing the dynamical behavior of complex structural assemblies. Even if the contact law is well understood, computing the contact forces during vibration remains a highly expensive task since opening/closing of contact and friction/stiction transitions can occur when vibration amplitudes are high. Capturing these phenomena precisely requires a very fine mesh to localize the contact and determine its nature. Therefore, a strategy to significantly reduce the computational cost of simulation for such problems would be highly desirable in order to use such simulation in design optimization or for health monitoring.

In this contribution, we propose to first apply a modal reduction on a vibrating system with friction contact. The friction forces conjugate to the modal amplitudes are influenced by the complex distribution of the stiction/friction regions and cannot be analytically derived from the contact law directly. Also, computing such modal friction forces is computationally expensive since, as a discontinuous, nonlinear needs to be evaluated at each degree of freedom at the interface. Hence, we propose to train a neural network in order to learn the contact law related directly to the modal amplitudes. We investigate which neural network topology is the most appropriate to represent the history dependent friction forces. We will then assess if the friction forces given by the trained neural network for the modes can properly reproduce the dynamics of the system with contact during a transient dynamics simulation.

The idea will be benchmarked on a simple academic example and the possibility to extend the method to real engineering problems will be discussed.

PERFORMANCE INCREASES OF HYPERCOMPLEX AUTOMATIC DIFFERENTIATION (HYPAD) IN PHYSICS INFORMED SYMBOLIC REGRESSION

Samuel Roberts[1], Mauricio Aristizabal[1] and Harry Millwater[1]*

[1]*The University of Texas at San Antonio*

ABSTRACT

Physics regularized genetic programming symbolic regression (GPSR) is a machine learning method for the discovery of symbolic solutions to differential equations. During the symbolic regression process, model outputs are verified by comparison with known analytical solutions for the differential equation(s) under study. As such, derivatives of candidate functions, typically 1st - 4th order, are required during the solution process. The OTI hypercomplex algebra is implemented to provide fast and accurate derivatives. Numerical experiments with second and fourth order differential equations indicate that OTI's provide up to 42X improvement in runtime compared to a PyTorch implementation with no loss of accuracy. Additionally, AD with the OTI hypercomplex algebra consumes less or comparable memory when compared with PyTorch. In addition, the coding implementation is simple and straightforward making the OTI hypercomplex AD method an excellent choice for implementation in PR-GPSR.

CALIBRATION OF STOCHASTIC AGENT BASED MODELS WITH GAUSSIAN PROCESS SURROGATES AND STEIN VARIATIONAL INFERENCE

Connor Robertson[*1], Jaideep Ray[1] and Cosmin Safta[1]*

[1]Sandia National Laboratories

ABSTRACT

Agent based models (ABMs) are procedures governing the evolution of many individual units (agents) which interact in a variety of discrete and nonlinear ways. Collectively, these interactions can yield a plethora of complex stochastic dynamics in individual and population level statistics. Additionally, their particle-based nature results in prohibitive computational costs for simulation. As such, they present a formidable challenge for model reduction, calibration, and uncertainty quantification.

In this presentation, we demonstrate techniques for model reduction and calibration of CityCOVID [1], an epidemiological ABM developed to capture the effects of interventions such as alternative schedules and individual protective behaviors on hospitalizations and deaths in the Chicago metropolitan area during the earliest phases of COVID-19. This ABM simulates several million agents moving and interacting in several million locations. To reduce the needed computational expense to calibrate this model, we present a Gaussian process surrogate and quantify its accuracy and shortcomings. We then outline its use in combination with Stein variational inference, a particle based approximate Bayesian calibration (ABC) technique, to provide approximate posterior distributions for key ABM parameters. We provide a comparison of this calibration approach with baseline ABC and MCMC calibrations. The resulting posterior and pushforward distributions are then presented.

ABSTRACT

Dynamical systems in engineering applications and epidemiology typically consider complex time-varying processes that are described mathematically by models consisting of time-invariant parameters. To alleviate difficulties in the implementation and computation of these models, simpler, semi-empirical models are often used. Such modelling approaches retain some basis in the physics of the problem, but also rely on data-driven components to accurately recreate the observed system behaviour. The nonlinear sparse Bayesian learning (NSBL) algorithm has been demonstrated as an efficient algorithm for the optimal model discovery in nested models of dynamical systems with time-invariant parameters and for general nonlinear models where the likelihood function can be computed [1].

There are, however, certain applications in damage detection or infectious disease modelling wherein a subset of the system parameters may vary in time. In such cases, robust algorithms that are capable of jointly estimating the system states, time-varying parameters and time-invariant parameters are required. It has been shown that the complementary use of nonlinear filters for the concurrent estimation of system states and time-varying parameters, and for the evaluation of the likelihood function alongside Markov chain Monte Carlo sampling for the estimation of time-invariant system parameters provides a robust and fully Bayesian framework for the concurrent estimation of time-varying and time-invariant parameters [2].

We consider two examples: (i) damage detection from aeroelastic oscillation data where the degradation of the structure may be manifested as a change in the stiffness while the remaining structural and aerodynamic parameters remain constant, and (ii) tracking the time-varying nature of infection rates of infectious diseases, where clinical parameters such as duration of infection remains relatively constant. Through these examples, we investigate for the first time, how the general Bayesian formulation of the two methods described in Ref. [1] and [2], respectively, permits the simultaneous estimation of time-invariant parameters, time-varying parameters, and optimal nested model structure.

ABSTRACT

Dynamical systems in engineering applications and epidemiology typically consider complex time-varying processes that are described mathematically by models consisting of time-invariant parameters. To alleviate difficulties in the implementation and computation of these models, simpler, semi-empirical models are often used. Such modelling approaches retain some basis in the physics of the problem, but also rely on data-driven components to accurately recreate the observed system behaviour. The nonlinear sparse Bayesian learning (NSBL) algorithm has been demonstrated as an efficient algorithm for the optimal model discovery in nested models of dynamical systems with time-invariant parameters and for general nonlinear models where the likelihood function can be computed [1].

There are, however, certain applications in damage detection or infectious disease modelling wherein a subset of the system parameters may vary in time. In such cases, robust algorithms that are capable of jointly estimating the system states, time-varying parameters and time-invariant parameters are required. It has been shown that the complementary use of nonlinear filters for the concurrent estimation of system states and time-varying parameters, and for the evaluation of the likelihood function alongside Markov chain Monte Carlo sampling for the estimation of time-invariant system parameters provides a robust and fully Bayesian framework for the concurrent estimation of time-varying and time-invariant parameters [2].

We consider two examples: (i) damage detection from aeroelastic oscillation data where the degradation of the structure may be manifested as a change in the stiffness while the remaining structural and aerodynamic parameters remain constant, and (ii) tracking the time-varying nature of infection rates of infectious diseases, where clinical parameters such as duration of infection remains relatively constant. Through these examples, we investigate for the first time, how the general Bayesian formulation of the two methods described in Ref. [1] and [2], respectively, permits the simultaneous estimation of time-invariant parameters, time-varying parameters, and optimal nested model structure.

ABSTRACT

Recent developments in acoustic metamaterials have been focused on broadening the attenuating bandwidth features towards lower frequency ranges, well below 1000 Hz, as well as tackling manufacturing issues. In this context, a multi-resonant layered acoustic metamaterial (MLAM) was proposed as a practical realization for addressing both challenges [1]. The MLAM's layered-based design makes it amenable to large-scale manufacturing and the periodic features of each layer enable the application of computational homogenization models to characterize the sound transmission loss (STL) response [2]. Combining these models with optimization techniques allows to determine realistic MLAM designs that trigger multiple resonances in broad frequency ranges. By exploiting coupling mechanisms these resonances translate into multiple STL peaks that produce a broadband continuous frequency range of attenuation, i.e., without transmission peaks in-between. In this work, the proposed computational homogenization model is presented and applied to the design of different MLAM configurations. The goal is to assess the influence of the number of coupled resonating layers in the STL response of the whole MLAM panel, in terms of increasing the attenuation intensity and the effective frequency bandwidth. The results demonstrate the STL enhancements features obtained from exploiting coupling mechanisms, compared to other acoustic metamaterial configurations based on local resonance phenomena. In this context, the proposed MLAM technology exhibits a great potential to provide an efficient, easy-to-manufacture solution to the sound insulation problem at low frequency ranges.

UNCERTAINTY ESTIMATION OF FOURIER NEURAL OPERATORS AS SURROGATES FOR CO2 STORAGE SIMULATION

Fernando Rochinha[*1], Alvaro Coutinho[1], Rômulo Silva[1], Rodolfo Freitas[1], Gabriel Barros[1] and Ezequiel Santos[1]*

[1]*Federal University of Rio de Janeiro*

ABSTRACT

Carbon Dioxide Capture and Storage (CCS) in underneath reservoirs plays an important role in mitigating global warming. It represents one key technology to reduce the amount of CO2 in the atmosphere. It involves complex multi-phase flows within a subsurface heterogenous medium, and its operational optimization and design rely on very expensive computational simulations. In order to cope with that, Scientific Machine Learning Surrogates [1] have been used, leading to affordable and accurate predictions on proper time. A critical component of reliable predictions is the ability to provide uncertainty quantification. Here, we systematically estimate uncertainties in such predictions due to building surrogates with limited data [2]. We concentrate the study on Fourier Neural Operators tailored for CCS, and some specific geological scenarios are explored, employing different concepts and algorithms for quantifying epistemic uncertainty [2].

PREDICTING LEUKEMIA EVOLUTION AND RESPONSE TO TREATMENT WITH STATE-TRANSITION THEORY

Russell Rockne[*1], David Frankhouser[1], Lisa Uechi[1], Sergio Branciamore[1], Denis O'Meally[1], Jihyun Izarriy[1], Yu-Hsuan Fu[1], Bin Zhang[1], Ya-Huei Kuo[1] and Guido Marcucci[1]*

ABSTRACT

We predict disease evolution and response to therapy using a state-transition model applied to bulk and single cell RNA sequencing data collected from murine models of acute and chronic myeloid leukemia. We demonstrate how the RNA transcriptome can be used as a sensitive, and patient-specific biomarker of disease by following gene expression profiles in the peripheral blood over time. Using a stochastic state-transition model which represents the transcriptome as a particle undergoing Brownian motion in a potential energy landscape, we estimate the model parameters from the transcriptome dynamics, and use the corresponding probability density function to predict disease manifestation and response to tyrosine kinase inhibitor and chemo therapies. We demonstrate that changes in the transcriptome precede detection of leukemia cells, and that very early changes in the transcriptome state are predictive of disease manifestation and response to treatment. Finally, we show how this mathematical approach may be applied to the clinical management of leukemia in the pre and post transplant settings.

The principal contribution of this work is the development and validation of a predictive, patient-specific model of disease progression and response to treatment derived from the dynamics of the peripheral blood transcriptome. This advances the field of precision medicine by moving beyond fixed sets of genes and provides a dynamic, individualized framework for patient-specific predictions.

ADAPTIVE ANALISIS FOR SCATTERING PROBLEMS IN THE CARTESIAN GRID DISCONTINUOUS GALERKIN METHOD

[2]Universitat Politècnica de Catalunya

ABSTRACT

The Cartesian grid Discontinuous Galerkin method, cgDG, [1] is a novel efficient simulation tool for phenomena governed by hyperbolic PDEs in the time domain. The NURBS-enhanced integration allows cgDG to automatically eliminate model approximation errors. However, the analyst must create appropriate meshes to deal with discretization errors. As the solution varies in time, so does the optimal mesh. Hence, creating optimal meshes is a difficult non-automated task.

In this work, we present a fully automated adaptive analysis strategy based on an explicit error indicator. This strategy considers both, refinement and coarsening of the spatial discretization over time and uses a set of rules to decide where to modify the element size and where to change the polynomial approximation.

Our numerical experience shows that the proposed technique can efficiently compute highly accurate results starting with uniform coarse meshes and with insignificant analyst intervention.

ABSTRACT

We have developed a multiscale finite element methodology to model dynamic shear localization and fracture in porous ductile metals subjected to high strain rates. Porous microstructures from various additive-manufactured materials, characterized using X-ray tomography analysis, have been integrated into computational models to simulate the collapse of thick-walled cylinders, the crushing of Shear-Compression specimens, and the torsion of thin-walled tubes. The simulations have been compared with experiments on additive manufactured AlSi10Mg and Ti6Al4V to identify the effect of porous microstructure on shear localization and fracture. The calculations have provided new insights on the role of size, shape and spatial distribution of voids on ductile failure under shear-dominated loading.

WEIGHT REDUCTION IN DYNAMICALLY LOADED SYSTEMS THROUGH THE EFFECT OF DAMPING IN BOLTED JOINTS

Silas Roediger[*1], Carsten Koenke[1] and Heiko Beinersdorf[1]*

[1]*Bauhaus-Universität Weimar*

ABSTRACT

In order to reduce vibration amplitudes, MFPA Weimar is investigating joint damping. The effect is based on the relative displacement between two components between which a surface pressure acts. In this case, the surface pressure is applied by a screw connection. The damping behavior is vibration-dependent and amplitude-dependent. The greater the excitation force, the higher the potential for relative movement and the higher the damping factor. In addition, experimental results show the dependence on the vibration mode. This does not apply to vibrations normal to the joining plane; a certain surface pressure must be applied here in order to maximize the damping factor. In decay tests it becomes clear that it is not possible to approximate the curves due to viscous behavior. Superposition with the friction according to Coloumb occurs particularly in the initial range. The aim is to set up a numerical model in order to be able to take the damping effects into account during the development of components. For this purpose, thin-layer-elements (TLE) are introduced into the joint in FE-simulation and provided with a material law that can represent the energy dissipation, non-linear local damping effects are taken into account. The thin-layer-elements are parameterized depending on the material, surface pressure and surface roughness. It is intended to replace damping, often done by a frequency shift of naturals frequencies via added masses, and thus contribute to lightweight construction.

HOMOGENIZATION BASED MODELLING OF ELECTRO-MECHANICAL INTERACTIONS IN FLUID SATURATED POROUS STRUCTURES

Eduard Rohan[*1], Vladimír Lukeš[1] and Fanny Moravcová[1]*

[1]*University of West Bohemia*

ABSTRACT

We have in mind metamaterials constituted by fluid saturated periodic electro-active microstructures and consider multi-physical interactions between an elastic or viscoelastic solids skeleton and viscous fluid in the channels. Such heterogeneous structures are exposed to electric field and incident acoustic waves. Due to its piezoelectricity [1], or electrostriction, the solid matrix can deform in response to the electric field locally generated by electrodes embedded in the microstructure. To respect dynamic effects of the flow in bulged pores, where the nonlinear advection term of the acceleration is non-negligible, two time scales are considered and an appropriate time scaling of the fast-slow dynamics is introduced in a proportion to the spatial scaling. To account for acoustic streaming, i.e. the mean flow induced by acoustic waves, the perturbation-based splitting method is employed which relies on the flow fields decomposition in the 0th, 1st, and 2nd order terms reflecting the steady, acoustic and time-averaged parts. Correspondingly this enables to decompose the Navier-Stokes equations into three subsystems. Under the small deformation and linear constitutive law assumptions at the heterogeneity level, the asymptotic homogenization method is applied to derive the macroscopic model and the local problems solved in the reference periodic cell.

The homogenized model can be used to explore functionality of the metamaterials which can serve for fluid pumping, or conversely to energy harvesting. In both cases, the electro-mechanic energy conversion is due to the peristaltic deformation. Using the homogenized model, functionality of such metamaterial structures can be explored, however the model must capture the phenomena associated with the fluid-structure interaction in deforming configurations. For this, the nonlinearity can be approximated by considering deformation-dependent homogenized coefficients. To reduce the computational efficiency, the sensitivity analysis of the homogenized coefficients with respect to deformation induced by the macroscopic quantities is employed, cf. [2]. This enables to avoid the two-scale tight coupling of the macro- and micro-problems typical for the ``FE^2" method. Nonlocal electro-mechanical dynamic interactions are concerned in the multi-scale in space-time, as an extensions of [3].

COMPUTATIONAL MODELLING OF MOISTURE TRANSPORT AND SWELLING IN PAPER THROUGH A MULTI-PHASE FLOW APPROACH

C. Rojas Vega[*1], Marc G.D. Geers[1] and Ron Peerlings[1]*

[1]*Eindhoven University of Technology*

ABSTRACT

Paper is a natural material composed of fibers and pores. This porous structure is highly sensitive to fluctuations in moisture content. When paper is used for digital printing, fluctuations in the moisture content may produce a hygroexpansion of the material. If the printing process is not properly controlled, unacceptable deformations may result. In this work, we implement a computational finite element-based model to study the moisture transport and swelling in paper. The porous structure is modelled as a multi-phase material by means of the hybrid mixture theory [1]. This methodology incorporates some characteristics of mixture theory and averaging procedures. Balance equations are presented at the microscale level, and by means of an averaging procedure, the corresponding balances at the macroscale are obtained. An application of the hybrid mixture theory can be found in [2], where a triphasic model was derived to study porous cellulose networks. We adapt this model to study paper. The novelty of our work is that the constitutive relations are derived from physical principles and assumptions at the microscale level. Moisture transport in fibers and pores is modelled using unsaturated flow theory, assuming flow to be driven by chemical potential. The pores are modelled as tubular structures with different radii. These are assumed to be parallel to each other. Water fills the smaller pores first and then the larger pores, which is consistent with the microscopic reality of the problem. By assuming that the moisture transport through the pores behaves according to Darcy's law, we derive the permeability of the porous structure. Moreover, a simple constitutive relation is proposed to study the moisture transport through the fibers. By solving analytically a single fiber problem, we found an expression for the mass exchange between fibers and pores. Swelling and mechanical deformations follow a linear elastic law. The performance of the model is verified by using experimental data on plain paper.

THE CRITICAL IMPACT OF ANTHROPOMETRIC PARAMETERS ON FRACTURE GAP MICRO-MECHANICS - A VIRTUAL TRIAL

Michael Roland[*1], Stefan Diebels[1], Bertil Bouillon[2] and Thorsten Tjardes[2]*

[1]Saarland University

[2]Cologne Merheim Medical Center, University Witten/Herdecke

ABSTRACT

The evidence base of surgical fracture care is extremely sparse with only few sound RCTs available. We hypothesize that anthropometric factors relevantly influence the local mechanical conditions inside the fracture gap, thereby interfering with the mechanoinduction of fracture healing. Therefore, we developed a finite element model of a tibia fracture, which acted as basis of an in-silico population (n = 300) by systematic variation of anthropometric parameters. Afterwards, simulations of the stance phase were performed and a correlation between anthropometric parameters and the mechanical stimulus in the fracture gap was investigated.

Analysis of the influence of anthropometric parameters on statistical dispersion between different in-silico trial cohorts with respect to the probability to generate two, with respect to anthropometric parameters statistically different trial cohorts, given the same power assumptions.

The mechanical impact inside the fracture gap correlates with anthropometric parameters; confirming the hypothesis that anthropometric factors are a relevant entity. On a cohort level simulation of a fracture trial showed that given an adequate power the principle of randomization successfully levels out the impact of anthropometric factors. From a clinical perspective these group sizes are difficult to achieve, especially when considering that the trials takes advantage of a „laboratory approach “, i.e. the fracture type has not been varied, such that in real world trials the cohort size have to be even larger to level out the different configurations of fractures gaps. Anthropometric parameters have a significant impact on the fracture gap mechanics. The cohort sizes necessary to level out this effect are difficult or unrealistic to achieve in RCTs, which is the reason for sparse evidence in orthotrauma. New approaches to clinical trials taking advantage of modelling and simulation techniques need to be developed and explored.

ADAPTATION OF A CELLULAR AUTOMATA-BASED GRAIN STRUCTURE EVOLUTION MODEL TO ADDITIVE MANUFACTURING CONDITIONS

Matt Rolchigo[*1], Jaime Stump[1], John Coleman[1], Gerry Knapp[1] and Alex Plotkowski[1]*

[1]Oak Ridge National Laboratory

ABSTRACT

The decentered octahedron-based cellular automata (CA) method pioneered by Gandin and Rappaz in the 1990s has been heavily utilized in recent years to predict grain structure and texture in metals produced via additive manufacturing (AM). Under unidirectional and bidirectional scan conditions the method has well-reproduced experimental trends, observed grain structures, and crystallographic textures. However, the predicted textures can be inconsistent with those from parts produced with the common AM scan strategy of rotating the raster scan direction between layers. In turn, this model error may lead to inaccurate prediction of important texture-dependent material properties such as yield stress anisotropy or creep performance. To address these shortcomings, we analyze the key assumptions made in the original decentered octahedron algorithm, which was applied to the solidification of castings. We show that these assumptions lead to error in the competition between solidifying grains at AM melt pool boundaries, as the cooling rates and thermal gradient magnitudes are much larger than those encountered in castings and the interface geometry much more complex. Corrections to the grain envelope advance algorithm are made to account for the large discontinuity in undercooling seen across cell boundaries under large thermal gradient conditions, allowing better resolution of the competition between grains. Additionally, modification of the octahedral grain envelope shape is shown to yield a variety of textures based on input variables governing the transient grain evolution and the grain anisotropy. The modified CA method is shown to enable more accurate texture evolution under complex thermal conditions with large temperature gradients at coarser cell sizes than previously possible. These developments enable more effective and computationally efficient use of CA models in AM process-microstructure workflows. A DATA DRIVEN MODEL FOR PREDICTING THE YIELD AND PLASTIC HARDENING BEHAVIOR OF METALS USING BRINELL INDENTATION TESTS

Nitzan Rom[*1] and Elad Priel*[23]

[1]*Israel Atomic Energy Commission*
[2]*Sami Shamoon College of Engineering*
[3]*Nuclear Research Center in the Negev*

ABSTRACT

When investigating the mechanical behavior of metals, particularly under large deformations, obtaining the yield and hardening behavior of the material is a crucial step. Usually, this behavior can be found using standard uniaxial tension or compression tests. However, when there is a need for a non-destructive investigation or when no standard specimen can be procured, other, indirect methods are sought after, such as the instrumented indentation test [1-2].

Although prediction of the plastic behavior of metals from instrumented indentation is not new, most modern methods require a continuous load-depth curve of the indentation test. When trying to predict the plastic behavior using a limited number of discrete indentation cases, no significant advancement is reported since the classical work of D. Tabor [3].

In this study, a two-stage data driven model has been developed for predicting the yield and plastic hardening behavior, based on 140 finite element based Brinell indentation tests. From these tests, several indentation force and trace diameter pairs were extracted for each material, and a database of a material's yield and hardening parameters, with its indentation information was constructed. Using this database, an empirical model was developed, which utilized minimization techniques to predict the material's plastic parameters based on their indentation results. The results of this empirical model were then fed to an Extreme Gradient Boosting algorithm to further refine the prediction capabilities. The trained two-stage model was then tested on 30 new numerical and experimental test cases, showing overall better accuracy than the classical Tabor method in predicting both the yield stress of a material, and its hardening curve.

THE ENERGY-STEPPING MONTE CARLO METHOD: A MARKOV CHAIN MONTE CARLO ALGORITHM BASED ON A SYMPLECTIC, ENERGY-CONSERVING TIME INTEGRATOR

Ignacio Romero[*12] and Michael Ortiz*[3]

[1]*Technical University of Madrid*
[2]*IMDEA Materials Institute*
[3]*California Institute of Technology*

ABSTRACT

Often, data-driven models require sampling complex, high-dimensional probability distributions. For that, Markov chain Monte Carlo (MCMC) methods are the standard tools. Naïve implementations of these algorithms have a huge cost and thus many optimized methods have been proposed. One of the most popular ones, the Hamiltonian Monte Carlo (HMC) method, transforms the sampling process into a surrogate dynamical problem that needs to be integrated in time. The discrete solution of these trajectories is then interpreted as proposal samples that are later accepted or discarded depending on detailed rules that achieve the desired distribution. The properties of the time integration employed have a crucial impact in the MCMC method, and thus structure-preserving (symplectic) integrators are usually selected.

In this talk, we will present the energy-stepping Monte Carlo (ESMC) method. It is an HMC method where the time-integration phase of the algorithm is performed using the energy-stepping scheme [1], a quasi-explicit structure-preserving method that is symplectic and energy-preserving. As a result of this choice, the new MCMC possesses remarkable properties: in particular, no proposed sample is ever discarded irrespective of the dimensional and complexity of the sampled distribution, hence being more efficient than other HMC.

The talk will describe the theory behind the method, numerical examples showcasing its favorable properties as compared with other MCMC methods, and how the latter can impact data-driven simulations.

A LAGRANGIAN COMPUTATIONAL METHODOLOGY FOR ASSESSING MIXING IN HEMODYNAMIC FLOWS WITH APPLICATION IN CAROTID ATHEROSCLEROSIS

Ricardo Roopnarinesingh[1], Neel Jani[2], Michelle Leppert[3] and Debanjan Mukherjee[1]*

[1]*University of Colorado Boulder*

[3]*University of Colorado Anschutz*

ABSTRACT

Key Words: Lagrangian method, Particle-based method, Hemodynamics, CFD

Plaque buildup within arteries, referred to as atherosclerosis, poses a critical threat for cerebral embolic events contributing to stroke, which remains the global leading cause of death. Hemodynamics plays a crucial role in etiology of diseases such as atherosclerosis with factors such wall shear stress commonly studied when analyzing the manifestation in local flow changes. However, the ability to gauge disease progression using quantitative hemodynamic factors remains limited. Quantification of mixing within the local region of the disease is widely regarded as an important factor underlying atherosclerotic disease and its susceptibility to progression. The carotid arteries are a common source of embolic events and are prone to the build-up of atherosclerotic plaques in varying degrees. Atherosclerosis results in the reduction of the arterial cross-sectional diameter due to the plaques build up, referred to as stenosis. Identifying quantitative descriptors of mixing in the stenotic arterial environment in a patient-specific vasculature can provide beneficial insights for atherosclerotic disease.

Here, we present a Lagrangian particle-based methodology to quantify mixing across varying degrees bilateral stenosis. Our methodology consists of two computations based on numerically integrated tracer particle trajectories: (a) an entropic measure of fluid mixing within the region of stenosis; (b) Lagrangian Coherent Structures (LCS) identified within Finite Time Lyapunov Exponent (FTLE) fields of the stenosis region. For both, careful resolution of vascular geometry is ensured by using a signed-distance field-based algorithm for particle dynamics. Our entropy descriptor is based on tracking the release of tracers from the surface and the cross-section of the start of the stenosis within the right and left carotid region across varying degrees of disease. The result quantifies the extent of mixing over the cardiac cycle within the stenosed region of the carotid artery. Conversely, LCS allows us to identify regions of deposition within the stenosis that are susceptible to disease progression. We will illustrate the underlying computational framework using a patient-specific case-study with varying bilateral carotid stenosis. Ultimately, our goal is to devise an in silico framework for evaluating atherosclerotic disease progression using Lagrangian-based hemodynamic factors.

MATERIAL CHARACTERISATION PARAMETERS EFFECTS ON TURBINE DISK RUPTURE SPEED PREDICTIONS

Tonya Rose[*1] and Zeineb Meskine*[1]

[1]*Safran Tech*

ABSTRACT

Given that turbine disks are massive and turn at high speeds, they contain a significant amount of kinetic energy. Consequently being able to predict when they rupture is important for minimizing fuel burn, and thus reducing emissions while still providing the maximum possible life of part. Thus being able to accurately predict the rupture speed and understanding the uncertainty of these predictions is an active source of study. Furthermore, since running one large turbine disk provides only one data point on the rupture speed with no indication of the margin of error in other highly stressed areas of the disk, experiments have been performed on smaller disks that are designed to fail at each at risk area, providing multiple comparisons to the fracture prediction calculations.

The damage model used in this study takes into account three different modes of rupture. One mode is based on the triaxiality of the stresses, another is a parabolic function of the Lode angle and the final discriminant is the level of necking the material undergoes. The material model is an isotropic continuum material law with an isotropic hardening and a nonlinear kinematic hardening. The material parameters explored are the plastic yield point in the isotropic hardening model and the hardening and saturation variables for the kinematic hardening. Since previous work (Staber, 2021) has indicated that the shape of the plasticity threshold has a significant effect on the prediction of failure a Hosford threshold was used to change between a von Mises threshold and a Hosford value of 6 and 8.

The effects of the material identification is explored using a Maximum projection Latin Hypercube design of experiments. Since the damage model includes the effects necking, lode angle and triaxiality several different geometries, both 2D and 3D were modeled to have a larger sample of stress triaxialities and load angles. The goal of this study is to characterise how the uncertainty in the material definition propagates to the prediction of the rupture speed.

A COMPARISON OF APPROACHES FOR THE INVERSE DESIGN OF SPINODOID METAMATERIALS WITH TAILORED STIFFNESS

Max Rosenkranz[1], Ivo F. Sbalzarini*[12] and Markus Kästner*[1]

[1]*TU Dresden*
[2]*Center for Systems Biology Dresden*

ABSTRACT

Mechanical metamaterials or architected materials are becoming increasingly popular due to rapid developments in additive manufacturing. These metamaterials are characterized by mechanical properties that differ greatly from those of the base material and may even exceed them. This is realized with a rationally designed spatial structure of the base material, which allows tuning the effective properties of the resulting solid. In order to efficiently design structures with desired features, it is necessary to invert the relationship between a structure and its properties. While the forward mapping from a given structure to its mechanical properties is well-defined, the inverse mapping from properties to a corresponding structure is ambiguous. This ambiguity makes the inverse problem difficult to solve.

This contribution addresses the solving of such inverse problems in the context of mechanical metamaterials, especially for the relationship between structure parameters and associated stiffness for spinodoid structures. The basis for the presented approaches is a sufficiently large data set of parameter-stiffness pairs obtained from homogenization calculations. Two different methods are examined, that make use of the Lp-adaptation algorithm [1] and invertible neural networks [2]. Lp-adaptation is a stochastic method, that allows to generate robust designs, i.e., designs that meet desired requirements while being as insensitive as possible to small changes in the space of structure parameters. For this purpose, the method only evaluates the forward process, which can be replaced by a standard feed-forward neural network, for example. Invertible neural networks, on the other hand, offer the advantage, that due to their internal architecture, the inverse mapping is automatically available as soon as the network has learned the forward mapping. By introducing additional latent variables in the output of the forward process, the originally ambiguous problem becomes unambiguous and thus invertible. This allows to determine all parameter combinations that result in a desired stiffness with only a single feed-forward network. The quality of the obtained results as well as conceptual advantages and disadvantages of these methods are demonstrated and compared with the literature results from [3].

SPARSE PROBABILISTIC TRAINING OF PHYSICS INFORMED NEURAL NETWORKS IN MECHANICS APPLICATIONS

Bojana Rosic[*1]*

[1]*University of Twente*

ABSTRACT

The discretization of parametric partial or ordinary differential equations describing complex physical phenomena leads to high-dimensional problems, the solution of which requires a massive computational effort. To address this challenge, the development of low-cost surrogates in a data driven manner is the main focus of this talk. To incorporate prior knowledge as well as measurement uncertainties in the traditional neural networks, an efficient sparse Bayesian training algorithm is introduced. By fine tuning specially designed priors the proposed scheme automatically determines relevant neural connections and adapts accordingly in contrast to the classical gradient-like solution [1]. Due to its flexibility, the new scheme is less prone to overfitting, and hence can be used to approximate both forward and inverse maps by use of a smaller data set. The optimal choice of the measurement data then can be easily achieved by maximizing the information gain. In this talk the new type of learning will be showcased on a high-dimensional stochastic partial differential equation describing the nonlinear mechanics problem. The neural network architecture is taken to be of hybrid type being able to describe both time and spatial dependency [2].

MODELING BONE MINERALIZATION AS A REACTION-DIFFUSION SYSTEM

Giacomo Rossato[*1], Mahdi Ayoubi[2], Peter Fratzl[1], Angelo Valleriani[1] and Richard Weinkamer[1]*

[1]*Max Planck Institute of Colloids and Interfaces*
[2]*Cornell University*

ABSTRACT

Newly formed bone consists of a fibrous, unmineralized collagen matrix. During bone mineralization calcium-phosphate mineral crystals are deposited in the matrix resulting in substantial changes of its mechanical properties. The basic structural units of newly formed bone in compact bone are osteons. These cylindrical structures are approximatively 300 μm in diameter and up to some millimeters in length, with a central Harversian canal accommodating blood vessels and nerves. Osteonal bone is permeated by a network of cavities (lacunae) and channels (canaliculi) housing a cell network (osteocytes) that – among other functions – allows the transport of mineralization precursors into the depth of the osteoid (Raguin et al. 2023) that forms during remodeling of the tissue.
The new osteon starts with the formation of a tunnel by resorption followed by the deposition of osteoid. This is followed by mineralization, which is described as a macroscopic mineralization front moving towards the Haversian canal. Three-dimensional high-resolution imaging using Focused Ion Beam-Scanning Electron Microscopy (FIB-SEM) revealed that the surrounding of canaliculi remains free of mineral over an extended period during mineralization (Ayoubi et al. 2021). This led to the hypothesis that a second microscopic mineralization front – nested in the macroscopic one – moves towards the canaliculus.
We analyzed in a first step the FIB-SEM images to quantify the mineralization pattern around single canaliculi. Different spatial positions along the canaliculi correspond to different time points in the mineralization process. In a second step we developed and explored a reaction-diffusion model generating mineralization patterns due to an interplay between a mineralization precursor and a mineralization inhibitor. Both diffuse simultaneously from the canaliculus, with the precursor turning into immobile mineral when its concentration exceeds the inhibitor's.
The mineralization pattern produced by the model agreed qualitatively with the patterns observed in FIB-SEM under the conditions of a constant flux of precursor and inhibitor from the canaliculus into the matrix. Both larger flux values for the precursor and a lower diffusion constant of the inhibitor ensured a start of the mineralization far away from the canaliculus. Noticeably, the model did not exhibit realistic results when precursor and inhibitor were kept at a constant concentration (as opposed to a constant flux) at the canaliculus. This description of time-dependent spatial mineralization patterns, will allow the interpretation of known mineralization disorders in the context of our model.

[2]*LAMEC (Laboratorio de Mecánica Computacional - IMIT - CONICET)*

ABSTRACT

Materials characterized by non-quasiconvex strain energies experiment microscale phase transitions when the strain state switches between different convex regions of the energy landscape. This type of phase transition offers a range of notable features, within which the repetitive energy release is of special interest for potential use in reusable energy dampers. It is well-known that non-quasiconvexity of the energy causes that, when the equilibrium of bodies composed by this kind of materials is resolved, it is possible to guarantee, in general, neither uniqueness nor existence. Additionally, the relaxation/quasiconvexification of the strain energies generates a closely related problem that is, contrarily, well-posed. This work exploits these concepts to address a comprehensive multiscale study of mechanical metamaterials with microscale elastic phase transitions. The emphasis is on phase transitions between two strain energy wells separated along volumetric strains, facilitating realistic applications in multidirectional energy release. At the macroscale, a generalized standard material model is proposed, defined through an energy potential and a dissipation potential. Both potentials derive from appropriate average calculations of microscale counterparts. In this sense, the relaxation of the microscale non-quasiconvex strain energy serves as the energy potential (see [1]), while the dissipation potential is obtained by homogenizing the microscale released energy. This methodology enables the examination of macroscopic hysteresis, in closed cycles of stress-strain responses when energy barriers of the energy landscape are not automatically surpassed, and the corresponding microstructure formation (highly oscillating strain fields). Numerical results are compared with theoretical estimations provided by [2]. The microarchitecture design of a 3D metamaterial capable of achieving volumetric phase transitions is also proposed. The metamaterial phase transitions result from elastic instabilities due to a geometrically non-linear deformation within the elastic range of the constituent material. The presented novel design builds upon microarchitectures previously introduced by [3] and extends them to three dimensions.

A FRACTIONAL FINITE ELEMENT FORMULATION FOR BENDING ANALYSIS OF VISCOELASTIC PROBLEMS

Jafar Rouzegar[*1] and Narjes Sanjarian Dehaghani*[1]

[1]*Shiraz University of Technology*

ABSTRACT

This article introduces a novel fractional finite element approach for the precise modeling of viscoelastic behavior in one-dimensional (rod) and two-dimensional (plane) problems. The viscoelastic properties of the material are represented using the fractional Kelvin-Voigt model, employing a combination of spring and fractional dashpot elements. While the fractional viscoelastic model demonstrates enhanced solution accuracy compared to conventional viscoelastic models, accurately defining the fractional derivative remains a challenge. To address this, a Gaussian Jacobi quadrature numerical method is integrated into the finite element formulation for calculating the fractional derivative of the fractional dashpot within the range of zero to one. The finite element discretization algorithm employs a polynomial Jacobi approach for computing the stiffness matrix and viscous loading. Notably, a recursive formulation updates the data at the end of each time increment, ensuring computational efficiency. A key advantage of this method is the reduced need for Gaussian points, leading to faster solutions and improved computational efficiency. The proposed model is validated against classical models to demonstrate its accuracy and precision.

MODELING BRITTLE FRACTURE IN EPOXY POLYMERS USING ATOMISTIC-CONTINUUM COUPLING OF MD WITH FEM

Samit Roy[*1] and Sankha Aditya*[1]

[1]*The University of Alabama*

ABSTRACT

The prediction of brittle fracture properties in polymeric materials using atomistic simulations is still a challenge. One of the main challenges is that the crack size in epoxy needs to be greater than 2590 nm to display full notch sensitivity, and that the fully developed fracture process zone size needs to be modeled contained within a zone of K-dominance. Consequently, , due to the intense computational cost of running atomistic simulations, the range of crack lengths simulated has been severely limited. In this work, we use the state-of-the-art multiscale modelling techniques to allow atomistic simulations to run with much larger crack lengths and study the effect of crack length variation on failure behavior. A thermosetting epoxy polymer system of EPON862/DETDA is modelled using the ReaxFF molecular dynamics (MD) force field, which allows for bond breakage. The MD system is concurrently coupled with a much larger continuum system modelled by the finite element method (FEM). The atomistic-continuum coupling is performed using a novel anchor-point based statistical method incorporating internal volume cells (IVCs), with displacement and strain continuity enforced in the handshake region using Lagrange multipliers. The combined system is used to simulate a double cantilever beam (DCB) specimen, with the MD domain surrounding the crack tip to capture nanoscale bond breakage. The critical strain energy release rate (SERR) is computed using the atomistic J-integral specifically developed by the authors for simulating fracture in amorphous polymers. The crack length of the system is varied and its effect on the SERR is studied. The atomistic J-integral contour is designed to include the crack tip in the MD region but can be allowed to extend well into the handshake region, if deemed necessary. The open-source LAMMPS code is used to run MD simulations at a finite temperature. The linear elastic in-house FEM code is integrated into an in-house concurrent coupling code, which iteratively executes the coupled MD simulations using a staggered solution scheme. Benchmarking of the code was carried out by simulating brittle fracture in monocrystalline graphene sheet. Our preliminary results for epoxy indicate a monotonic increase in notch-sensitivity with increasing subcritical crack length.

REDUCED ORDER MODELLING IN CFD: GEOMETRY, TURBULENCE AND COMPRESSIBILITY ENHANCED BY SCIENTIFIC MACHINE LEARNING

Gianluigi Rozza[*1]

[1]*SISSA*

ABSTRACT

We focus on some perspectives about Reduced Order Methods (ROM) for parametric Partial Differential Equations (PDEs) with a special interest in parametric problems arising in offline-online Computational Fluid Dynamics (CFD), with a special attention to the enhancement provided by Scientific Machine Learning (SML). Efficient parametrisations (random inputs, geometry, physics) are very important to be able to properly address an offline-online decoupling of the computational procedures and to allow competitive computational performances. Current ROM developments in CFD include: (i) a better use of stable high fidelity methods, to enhance the quality of the reduced model too, also in presence of bifurcations and loss of uniqueness of the solution itself, (ii) capability to incorporate turbulence models and to increase the Reynolds number; (iii) more efficient sampling techniques to reduce the number of the basis functions, retained as snapshots, as well as the dimension of online systems; (iv) the improvements of the certification of accuracy, established on residual based error bounds, and of the stability factors, as well as (v) the guarantee of the stability of the approximation with proper space enrichments. All the previous aspects are quite relevant -- and often challenging -- in CFD problems to focus on real time simulations for complex parametric industrial, environmental and biomedical flow problems, or even in a control flow setting with data assimilation and uncertainty quantification. Some model problems will be illustrated by focusing on few benchmark study cases, for example on simple fluid-structure interaction problems and on shape optimisation, applied to some industrial and environmental problems of interest.

THEORETICAL UNDERSTANDING OF CRITICAL ISSUES IN ALL-SOLID-STATE BATTERIES: SINTERING, CRACKING, AND DENDRITE PENETRATION

Haihui Ruan[*1] and Wei Wang*[1]

[1]*The Hong Kong Polytechnic University*

ABSTRACT

All-solid-state lithium metal batteries (ASSLMBs) are considered to be the most promising next-generation batteries because of their perceived electrochemical, mechanical, and thermal stability. The existing problems hindering their way to commercialization are the cracking of solid electrolytes (SEs) and cathodes and the penetration of dendrites. These issues are difficult to solve based soley on experiments and electro-chemo-mechanical Multiphysics models can set in to provide details bridging the fragmented experimental observations. This presentation introduced several ongoing endeavors in theoretical models. For the lithium penetration through SEs, we proposed a phase-field (PF) model to describe interfacial defects caused by electro-stripping, SSE cracking caused by chemical expansion/contraction during ion transport, and lithium penetration caused by an inhomogeneous electric field. With the model, we reveal the critical current density (CCD) and how it depends on material parameters. Additionally, it is found that the residual compressive stress at SE surfaces can effectively prevent SSE cracking. Using the PF formulations, we then studied glass fracture after a residual stress field is developed by the ion exchange, which may also be applied to strengthen SEs. A dense SE provides a compact surface in contact with an Li anode and it can lead to a small interfacial resistance with less interfacial defects for crack initiation. Nevertheless, SEs, e.g., LLZTO, after sintering at atmospheric pressure are likely porous due to decomposition and Li escape. Hence, a PF model of LLZTO sintering can be built to quantitatively investigate the competition between Li escape and LLZTO particle coalesce for optimizing the temperature profile to sinter dense LLZTO. Finally, we discussed the possible way to toughen NCM cathodes, of which the volumetric changes during lithiation and de-lithiation lead to catastrophic fatigue fracture. Based on a theoretical model, we argue that introducing soft polymeric interlayers between partially sintered NCM particles can improve the cyclic performance of NCM cathodes.

ROBUST VIRTUAL ELEMENT METHODS FOR STRESS-ASSISTED DIFFUSION PROBLEMS

Andres Eduardo Rubiano Martinez[*1], Ricardo Ruiz Baier[1] and Rekha Khot[1]*

[1]*Monash University*

ABSTRACT

This paper aims first to perform robust continuous analysis of a mixed nonlinear formulation for stress-assisted diffusion of a solute that interacts with an elastic material, and second to propose and analyse a virtual element formulation of the model problem. The two-way coupling mechanisms between the Herrmann formulation for linear elasticity and the reaction-diffusion equation (written in mixed form) consist of diffusion-induced active stress and stress-dependent diffusion. The two sub-problems are analysed using the extended Babuˇska–Brezzi–Braess theory for perturbed saddle-point problems. The well-posedness of the nonlinearly coupled system is established using a Banach fixed-point strategy and an assumption on small data. The virtual element formulations for the uncoupled sub-problems are proven uniquely solvable by a fixed-point argument, now in conjunction with appropriate projection operators. A priori error estimates are derived, and we test the accuracy and performance of the proposed method through computational simulations.

DATA-DRIVEN PREDICTION OF REDUCED-ORDER CARDIOVASCULAR MODEL PARAMETERS

Natalia Rubio[*1], Luca Pegolotti[1], Martin Pfaller[1], Eric Darve[1] and Alison Marsden[1]*

[1]*Stanford University*

ABSTRACT

Cardiovascular flow simulations have become a powerful tool for the study and management of cardiovascular in recent decades. They provide insight into the hemodynamic characteristics of diseased anatomies and the mechanisms by which they develop, aid in surgical planning by predicting the hemodynamic outcomes associated with proposed anatomical modifications, and support the development of medical devices. Unfortunately, traditional, high-fidelity finite element flow simulations that solve the unsteady Navier-Stokes equations in three dimensions (3D) are computationally expensive. This limits their use in many settings, including clinical applications, multi-query applications, and real-time simulators. In these use cases, reduced-order models (ROMs) that resolve the flow associated with simplified, but analogous systems are attractive alternatives to 3D simulations.

In this work, we focus on a popular zero-dimensional (0D) model in which the vasculature is represented as an idealized electric circuit where flow and pressure are analogous to current and voltage, respectively. Although computationally lightweight, the 0D ROM suffers from reduced accuracy due, in part, to the imperfect translation of the 3D flow problem into its 0D analog. To express a 3D vasculature as a 0D model, the vasculature is divided into vascular components (vessels and junctions), each of which is represented by an ideal wire populated with circuit elements (e.g. linear resistors, quadratic resistors, inductors) that describe the relationship between flow through the component and the pressure drop over the component. Traditionally, the characteristic values of these circuit elements are chosen based on the geometry using physics-based models that rely on simplifying assumptions that may not apply or heuristic techniques.
We propose data-driven techniques to construct improved 0D representations of vascular components. Specifically, we develop machine learning (ML) models that take the geometric features of the vasculature component as input and output characteristic values of the electric circuit elements. To construct datasets on which to train and test our models, we use an automated workflow in which we generate junction geometries, run a series of 3D flow simulations on each geometry, and extract the characteristic circuit element values for each geometry from its 3D simulation (ground truth) data. By supplying more accurate characteristic circuit element values to the 0D model, we improve its ability to model cardiovascular flows.

AN EXPLICIT TIME-MARCHING PROCEDURE FOR ELASTODYNAMIC ANALYSES BASED ON ADAPTIVE TIME-INTEGRATION PARAMETERS AND TIME-STEP VALUES

Lucas Ruffo Pinto[*1], Delfim Soares Jr.[2], Isabelle de Souza Sales[1] and Webe João Mansur[1]*

[1]*Federal University of Rio de Janeiro*
[2]*Federal University of Juiz de Fora*

ABSTRACT

This study discusses an explicit time-marching procedure that is designed for the time-domain resolution of elastodynamic models considering their physical properties and adopted spatial discretizations. The technique is entirely automated and proves itself to be highly effective, featuring second-order accuracy, adaptive algorithmic dissipation and extended stability limits. Additionally, the discussed methodology is truly explicit, truly self-starting, and it incorporates automated subdomain/sub-cycling splitting procedures to enhance its overall performance. Thus, the algorithm automatically divides the domain of the problem into different subdomains, adjusting their time-step values according to the properties of the discretized model, which allows improving the efficiency and the accuracy of the analysis, while ensuring stability. Locally-defined adaptive time-integration parameters are also considered, establishing an entirely self-adjustable formulation. In this case, expressions for the time-integration parameters are provided based on the local features of the discrete model, allowing to create a further link between the adopted temporal and spatial discretization procedures, better counterbalancing their errors. These parameters are locally formulated to nullify the bifurcation spectral radius of the method at pre-established sampling frequencies, providing maximal numerical damping at the highest sampling frequency of the elements of the adopted spatial discretization. This design optimizes the formulation to mitigate the influence of spurious high-frequency modes on the computed responses, allowing for enhanced analyses. In fact, the primary goal of introducing numerical damping is to eliminate non-physical spurious oscillations that may arise from the excitation of spatially unresolved modes. Therefore, the methodology not only tracks down the frequency range of the discretized model, but also it is designed to adaptively enforce significantly low values (close to zero) for the spectral radius of the method at the highest frequencies of the model, as well as it aims to provide relatively high spectral radius values (close to one, considering physically undamped models) in the important low-frequency range. Benchmark analyses are conducted at the end of this study to demonstrate the technique's effectiveness taking into account theoretical problems and complex models that are representative of real-world applications in the OIL & GAS industry.

FULLY MIXED FORMULATIONS FOR POROELASTICITY WITH STRESS-DEPENDENT PERMEABILITY

Arbaz Khan[1], Bishnu Lamichhane[2], Ricardo Ruiz Baier[3] and Segundo Villa Fuentes[3]*

[1]Indian Institute of Technology Roorkee
[2]University of Newcastle
[3]Monash University

ABSTRACT

We use fixed-point arguments to analyse the unique solvability of a nonlinear system of PDEs modelling poroelasticity equations with porosity-dependent permeability. The permeability is rewritten as a function of total poroelastic stress and fluid pressure. We construct fully mixed finite element methods and show their optimal convergence to weak solutions. A priori and a posteriori error bounds are established. Some numerical examples are provided to confirm the rates of convergence predicted by the theory, and we also illustrate the use of the formulation in some typical tests in Biot poroelasticity.

SIMULATING PULSATILE FLOW: TOWARDS UNDERSTANDING MICROVASCULAR DYSFUNCTION

Hans Christian Rundfeldt[1], Mario Gilberto Báez-Yáñez[1], Jaco Zwanenburg[1] and Natalia Petridou[1]*

[1]*University Medical Center Utrecht*

ABSTRACT

Pulsatile flow and pressure provide a proxy for vascular health. Increased pulsatility due to vascular stiffening is observed in different pathologies of the cerebrovascular system [1]. Pulsatility in larger vessels can be assessed in-vivo by medical imaging. In the microvasculature, pulsatility can only be assessed indirectly using functional MRI acquisitions [2]. However, the formation of MRI signal based on the underlying microvasculature and tissue remains elusive due to voxel-averaging, limiting the ability to investigate changes and dysfunction of small vessels severely.

To address this problem, we propose the generation of statistically informed microvascular models at the voxel level. These are used to simulate dynamic pulsatile blood flow and pressure changes in small arterioles, capillaries, and venules. A synthetic tree generation algorithm was utilized to generate two-dimensional realistic microvasculature covering an area of 3500x3500µm. The generated vasculature extends from the pial surface over six cortical layers to the gray-white-matter boundary. Penetrating arteries and veins are generated to varying depths. Capillary structures were generated using random bifurcations defined by a Delaunay triangulation. The statistical properties of the networks were matched to rodent data [3] and Murray’s law was enforced throughout the network. A 1D non-linear approximation of the Navier-Stokes equations is used to describe blood flow. The vessel wall deformation is assumed as purely elastic. Fluid-structure interaction is considered by coupling the computed blood pressure and wall deformations using a constitutive tube law. The governing equations were solved using a custom finite volume implementation. We conducted a sensitivity study of the model parameters, simulating the impact of vascular stiffening and changes in wall thickness on the pulsatility.

This work opens up the possibility to investigate pathologies that manifest themselves predominantly in the microvasculature such as small vessel disease and cerebral amyloid angiopathy (CAA). The simulated vessel pulsatility will be compared to fMRI data from diseased patients and healthy controls to further assess the validity of this approach.

SCALABLE OPTIMAL CONTROL FOR INEQUALITY-CONSTRAINED DISCRETIZATIONS OF CONSERVATION LAWS

Pavel Bochev[1], Denis Ridzal[1], Falko Ruppenthal[2] and Dmitri Kuzmin[2]*

[1]Sandia National Laboratories
[2]TU Dortmund University

ABSTRACT

A physically meaningful solution of a conservation equation has to satisfy certain constraints such as the validity of global maximum principles or the conservation of mass. If the analytical solution of the problem is bound preserving, closed-form limiters can be used to enforce appropriate inequality constraints for numerical approximations. However, if modeling errors or data errors are present, even exact solutions may violate global bounds that define the range of physically admissible approximations. To avoid such nonphysical behavior, we incorporate optimal control into discretized conservation laws. Following the methodology developed in [1], we consider inequality-constrained optimization problems in which the desired properties are enforced using graph Laplacian operators and flux potentials. The objective function penalizes deviations from nodal time derivatives corresponding to a high-order space discretization. The adjustable source term of the PDE constraint admits a decomposition into numerical fluxes, which enables us to achieve good local mass conservation properties.

In this presentation, we outline the derivation of the optimization problem and its connection to the optimization-based approaches developed in [2]. A potential drawback of formulations that use flux potentials as optimization variables is the lack of scalability for large-scale simulations. To develop an efficient alternative, we reformulate our optimization problem in terms of control variables from which flux potentials can be recovered by solving a linear system. The result is a quadratic optimization problem with box constraints and a linear equality constraint. For the corresponding system of optimality conditions, we use scalable trust-region solvers and scaling operators that serve as simple preconditioners. Besides, we discuss different choices of norms and seminorms for the objective function, as well as their influence on the convergence behavior. Further improvement is achieved by using multigrid preconditioning and inexact evaluations of objective, gradient and Hessian functions. To illustrate the viability of our new method, we present results for a linear advection problem (solid body rotation in 2D) and for the Cahn-Hilliard equation (merging droplets and spinodal decomposition in 3D).

MODELLING AND SIMULATION OF A FULLY ELECTRIC HYBRID PROPULSION SYSTEM FOR PASSENGER SHIPS USING AVL CRUISE-M SOFTWARE

Luca Micoli[1], Roberta Russo[1], Tommaso Coppola[1], Daniele Severi[2] and Giuseppe Corda[2]*

[1]University of Naples Federico II
[2]AVL Italia S.R.L.

ABSTRACT

The design and performance optimization of fully electric ships constitutes an integral goal of the maritime sector to meet the emission requirements and comply with the IMO environmental regulations.
Hybrid powertrains integrating fuel cell technology with energy storage systems are spreading worldwide in transportation. This research uses the AVL Cruise-M software to validate a PEM fuel cell power generation system integrated with a Li-based battery and the onboard propulsion mechanism. The proposed powertrain architecture and operating modes' working principles are presented from a system engineering perspective. The specifics of each component of the power train (e.g. the PEMFC module and its BoP, the battery pack, the electric motor, etc.) are taken from commercially available products.
As the scope of simulations, the ship's operating modes are tested over a predefined cruise cycle which is also used to size the power of each component and predict the fuel consumption. The objective is to assess the dynamic functionality of such a system and analyze the energy flows, including the corresponding Balance of Plant (BoP) subsystems. The cruise cycle is meant as a round trip lasting approximately 6.5 hours, with 44% of the total time spent in transfer mode at full speed, 35% in laytime, and the remaining 21% in maneuvering.
As a case study, we assume a passenger ferry with dimensions of approximately 30 meters in length and 10 meters in width. The ferry has a passenger capacity of 220 and a maximum cruise speed of 20 knots. The simulation results show that a PEM system with a maximum power of 1600 kWe can fulfil the ship's power demand, while a battery pack of about 200 kWh can support the PEM system during dynamic conditions, particularly during forceful accelerations. This enhances the ship's performance and increases the overall energy efficiency.
Considering the available space on board and the fuel consumption per cruise cycle, it is supposed to store about 350 kg of pure hydrogen in type IV cylinder tanks at 700 bars, which can be refilled daily.

MACHINE LEARNING-DRIVEN OPTIMIZATION OF 3D PRINTING COMPOSITE STRUCTURES AND PROCESSES

*Seunghwa Ryu**[1]

[1]*KAIST*

ABSTRACT

This presentation delves into the strategic application of artificial intelligence (AI) to enhance the capabilities and processes of 3D printing, illustrated through two distinct case studies. Initially, we present a data-driven design methodology that focuses on refining bio-inspired composite materials with a limited dataset. This approach results in an optimized set of composite designs that adeptly combine strength, durability, and lightweight characteristics. In the latter part, we introduce a simulation model for the Digital Light Processing (DLP) 3D printing method, which is pivotal in managing the residual stresses that emerge from the process. This model is key to foreseeing and mitigating unwanted warping in 3D printed objects following DLP printing. By integrating this simulation with real-world data in a data-optimized strategy, we showcase how to attain the desired structure with minimal distortion.

PEM FUEL CELL TOPOLOGY OPTIMIZATION WITH A PSEUDO 3D MODEL

Luís F. N. Sá[1], Fereshteh Razmara*[1], Julio Meneghini[1] and Emilio Carlos Nelli Silva[1]*

[1]*University of São Paulo*

ABSTRACT

The research related to clean energy sources is a growing topic nowadays. This work focuses on optimizing a hydrogen proton exchange membrane fuel cell to increase electric power generation. The model considers a pseudo-3d model to reduce the computational cost of the highly multi-physics problem across all cell layers. The model includes navier-stokes, energy conservation, chemical species transport, and water transport equations. The system is solved using a finite element formulation, and the sensitivities are calculated via automatic derivation. The optimization consists of a multi-objective function combining power generation and current density homogenization. An interior point gradient-based optimizer is used. The results show simultaneous optimized topologies for the cathode and anode flow fields.

ROLLING SHEAR SIMULATIONS IN CROSS LAMINATED TIMBER STRUCTURES USING A DOMAIN DECOMPOSITION METHOD

Karin Saavedra[*1], Jorge Fernández[2] and Felipe Núñez[1]*

[1]*Universidad de Talca*
[2]*Universidad del Bío-Bío*

ABSTRACT

Cross-Laminated Timber (CLT) is an engineered-wood product made of stacked lumber boards; each layer is usually oriented perpendicular to others and glued with structural adhesives. CLT are being increasingly used as structural materials due to environmental reasons and because of their remarkable mechanical strength. However, when designing CLT boards, the study of cracking propagation still requires further investigation due to the so-called rolling-shear failure [1] which is the inter-fiber cracking due to shear strains in the plane perpendicular to the longitudinal axis of the wood fibers. Indeed, the shear stiffness between radial and tangential directions is two hundred times lower than the stiffness in fibers' direction. The buckling of CLT walls is another important scenario – especially in mid-rise CLT building – where a weak rolling-shear strength could induce the apparition of cracks in cross layers. The combination of such anisotropy with thick sections is relatively new in the field of composite materials.

This work focuses on simulating the non-linear behavior of CLT structures using a computational strategy based on a mixed domain decomposition method [2]. We propose the integration of damage models at different scales (i.e. delamination between layers and crack propagation inside the layers) using cohesive zone models and parallel computing. Preliminary results show the beginning and spread of cracks in rolling-shear failure; the influence of the structural adhesive stiffness on the critical buckling load of the CLT walls is also analyzed [3]. Additionally, cohesive zone models – a bilinear, a trilinear and a potential one – are characterized using the equivalent linear elastic fracture mechanics (LEFM) R-curve. Such numerical-experimental methodology is studied considering double cantilever beam (DCB) tests performed in Chilean radiata pine specimens.

MINIMAL REMESHING VEM TECHNIQUE FOR COHESIVE FRACTURE NUCLEATION AND GROWTH

Elio Sacco[1], Sonia Marfia[2] and Elisabetta Monaldo[2]*

[1]*University of Naples Federico II*
[2]*Roma Tre University*

ABSTRACT

Recently, the virtual element method (VEM) has strongly developed and has proved to cope with a wide range of topics and problems. In particular, VEMs can be conveniently applied to the computational fracture mechanics applications.

The VEM formulation is characterized by the possibility to define polygonal meshes with elements characterized by any number of edges and by the flexibility in mesh generation that allow to introduce a crack just splitting the element in two different elements joined by a crack modelled with an interface element, requiring a minimal remeshing.

The present work proposes an algorithm for the nucleation and growth for fracture evolution in 2D cohesive media. The procedure is based on an enhanced virtual element method [1] specifically referred to a 4-side 12-node virtual element with piece-wise linear approximation of the displacement field on the edges. The large number of nodes and, consequently of degrees of freedom, is exploited to enrich the strain field evaluation. The proposed approach is framed within a generalization of the classic VEM formulation, obtained by introducing an energy norm in the projection operator definition. Various enhancements are proposed and tested through several numerical examples. The proposed procedures allow to avoid the stabilization of the element stiffness matrix.

Moreover a numerical technique is considered in order to introduce the crack in one virtual element splitting it in two elements joined by a cohesive interface [2]. An interface cohesive law, introducing a damage variable in mode I, in mode II and in mixed mode, and taking into account the unilateral effect due to the reclosure of the fracture in compression, is adopted.

Finally, different procedures are considered in order to evaluate the crack-tip stress field and the crack propagation direction.
The mixed-mode fracture examples are developed in order to assess the ability of the proposed procedure to satisfactorily reproduce the crack nucleation and growth observed in experimental tests.

FRACTIONAL DARCY'S LAW FOR POROELASTIC BEHAVIOUR OF SOFT BIOLOGICAL TISSUES: APPLICATION TO MENISCUS

Gunda Sachin[*1], Sundararajan Natarajan[1] and Olga Barrera[2]*

[1]*Indian Institute of Technology, Madras*
[2]*Oxford Brookes University*

ABSTRACT

The meniscus is an important part of the knee joint that helps with lubrication and shock absorption. Its porous structure and the flow of fluid through its pores are crucial for its functionality. Usually, poroelasticity is used to study this behaviour, which assumes Darcian flow. However, in reality, the fluid undergoes anomalous diffusion, which is non-Darcian [1]. To study this behaviour in the meniscus, researchers have used fractional Darcy's law for poroelasticity [2]. Confined consolidation creep experiments were conducted on the meniscus tissue to obtain its material properties, and the model was validated using stress relaxation tests and weight loss during consolidation. Results show that the fractional Darcy's law works better than the traditional one. Experimental data from different regions and orientations were used to study the anisotropic and inhomogeneous nature of the meniscus. The meniscus can be treated as a transversely isotropic poroelastic material, and its permeability is higher in the circumferential direction compared to the radial and vertical directions. A 3D fractional poroelastic model was implemented in 'Abaqus software [3], and simulations were performed on the whole meniscus, considering its functionally graded nature. The simulations studied quantities such as the flux of interstitial fluid during the consolidation process and energy absorption.

A HIGH-FIDELITY 3D MICROMECHANICAL MODEL OF VENTRICULAR MYOCARDIUM

Michael Sacks[*1]*

[1]*The University of Texas at Austin*

ABSTRACT

Right ventricular (RV) failure in response to pulmonary hypertension (PH) is a severe disease that remains poorly understood. PH-induced pressure overload leads to changes in the RV free wall (RVFW) that eventually results in RV failure. While the development of computational models can benefit our understanding of the onset and progression of PH-induced pressure overload, detailed knowledge of the underlying structural and biomechanical events remains limited, especially in the onset and progression of fibrosis in the RVFW. We have previously demonstrated the importance of myofiber-collagen mechanical interactions in modeling the passive mechanical behavior of right ventricle free wall (RVFW) myocardium. To gain deeper insights into these coupling mechanisms, we developed a high-fidelity, micro-anatomically realistic 3D finite element model of right ventricle free wall (RVFW) myocardium by combining high-resolution imaging and supercomputer-based simulations. We first developed a representative tissue element (RTE) model at the sub-tissue scale by specializing the hyperelastic anisotropic structurally-based constitutive relations for myofibers and ECM collagen, and equi-biaxial and non-equibiaxial loading conditions were simulated using the open-source software FEniCS to compute the effective stress-strain response of the RTE. To estimate the model parameters of the RTE model, we first fitted a 'top-down' biaxial stress-strain behavior with our previous structurally based (tissue-scale) model, informed by the measured myofiber and collagen fiber composition and orientation distributions. Next, we employed a multi-scale approach to determine the tissue-level (5 x 5 x 0.7 mm specimen size) RVFW biaxial behavior via 'bottom-up' homogenization of the fitted RTE model, recapitulating the histologically measured myofiber and collagen orientation to the biaxial mechanical data. Our homogenization approach successfully reproduced the tissue-level mechanical behavior of our previous studies in all biaxial deformation modes, suggesting that the 3D micro-anatomical arrangement of myofibers and ECM collagen is indeed a primary mechanism driving myofiber-collagen interactions. Through this approach, we determine that the interactions occurring at the tissue scale can be accounted for by accurately representing the geometry of the myofiber-collagen arrangement at the micro scale. Ultimately, models such as these can be used to link cellular-level adaptations with organ-level adaptations to lead to the development of patient-specific treatments for PAH.

AORTIC STENOSIS AND MYOCARDIAL REMODELING: INSIGHTS FROM FINITE ELEMENT ANALYSIS IN A RAT MODEL

Mohammad Javad Sadeghinia[*1], Henrik Nicolay Finsberg[1], Emil Espe[23], Ida Marie Hauge-Iversen[23], Lili Zhang[23], Einar S. Nordén[23], Ivar Sjaastad[23], Samuel Wall[1] and Joakim Sundnes[1]*

ABSTRACT

Aortic stenosis (AS) is a prevalent valvular heart disease characterized by the narrowing of the aortic valve, leading to increased cardiac afterload and myocardial remodeling. AS is also a common cause of heart failure with preserved ejection fraction (HFpEF), a condition where heart failure symptoms occur despite normal ejection fraction (EF) [1]. This condition undermines the effectiveness of conventional diagnostic measurements such as EF and global longitudinal strain (GLS) [2]. This study aims to use finite element analysis to investigate the alterations in myocardial mechanical behavior under the influence of AS and assess the diagnostic performance of myocardial work (MW) as an emerging index.

We utilized datasets from a rat model of increased afterload via aortic banding. Rat samples were subjected to three levels of constriction of the ascending aorta using o-rings with fixed inner diameters, ensuring precise aortic constriction [3]. This simulates aortic stenosis, leading to ventricular hypertrophy and myocardial remodeling. Additionally, a sham experiment was conducted to establish a control group. MRI was performed longitudinally on each group at two, four, eight, and twenty weeks post-operation. MR images were then used to create subject-specific geometries at end diastole. Employing the measured pressure-volume curves during the experiment, finite element (FE) models were created and tuned to estimate the passive and active material behavior of the myocardium throughout the development of induced AS and MW for each segment of the left ventricle calculated from the FE models.

FE models provide insights into the time-dependent mechanical remodeling of myocardial tissue due to increased afterload. Importantly, this research evaluates the potential of FE-based MW as an advanced metric for diagnosing HFpEF in cases of AS. While MW has been previously utilized based on echocardiography, these methods do not account for thickness, or curvature, all of which can be altered in the presence of abnormal afterload [1].

NUMERICAL INVESTIGATION INTO THE HYGRO-MECHANICAL RESPONSE OF SWELLING IMPLANTS AND THE BONE REMODELING AROUND THEM

ABSTRACT

In this study, a hygro-elastic finite element framework, along with a strain-energy-density based bone remodeling framework, were developed and used to simulate the swelling of co-polymeric implants and bone anchors in order to investigate their hygro-mechanical response [1, 2]. Free swelling experiments were conducted on co-polymeric porous bone anchors (composed of cross-linked poly (MMA-AA)) with two ratios of 80/20 and 90/10, to investigate their swelling characteristics in bovine serum, mimicking the in-vivo conditions. The purpose for the use of the two compositions is to have means of comparison and to analyze the optimal swelling ratio. Using the free swelling experimental data (i.e., weight gain and dimensional changes), the hygro-elastic framework was validated. Subsequently, the swelling of bone anchors was simulated embedded in bone regions with different densities. The radial stresses induced in the interface were extracted to ensure the sensible fixation strength of the bone anchor, as well as to look into the mechanical response of the surrounding bone and the associated bone regeneration. According to Wolff's law, such mechanical loads can be regarded by bone mechanotransducers as stimuli for remodeling [3]. Therefore, the bone remodeling framework helped us to evaluate the impact of the radial force induced by the swelling on the surrounding bone. It was discovered that the swelling ratio plays an important role in bone remodeling, and that it must be controlled within a certain threshold.

AN INCOMPRESSIBLE SPH STRATEGY FOR MULTI-PHYSICS' INTERFACIAL PROBLEMS

*Mostafa Safdari Shadloo**[1]

[1]*INSA Rouen Normandy*

ABSTRACT

In this work, we investigate the synergistic impact of electro-hydrodynamic (EHD) and thermo-capillary (TC) forces on the dynamic behaviour of multiphase flow systems. The study employs an incompressible Smoothed Particle Hydrodynamic (ISPH) multiphase model to simulate flows driven by EHD and TC forces. To capture the intricate hydrodynamic interactions, the continuum surface force (CSF) method is employed. This method calculates the gradient of interfacial tension and Marangoni forces, achieving an approximate error of less than 0.02% in Marangoni force calculations compared to analytical solutions. This represents a substantial improvement over previous SPH simulation studies.
EHD phenomena integrated into the system by solving the Maxwell stress tensor. It also influence interface morphology based on the electrical characteristics the surrounding fluids, i.e. electrical permittivities and conductivities. We study diverse test cases and integrates novel benchmarks. These encompass the EHD deformation of a droplet within a fluid, interactions of multiple droplets, and the Rayleigh-Taylor instability in the presence of an external electric field. The findings presented herein demonstrate the remarkable efficacy of the proposed SPH method and its resilience in simulating multiphase flows characterised by intricate interfaces when subjected to a consistent external electric field as well as thermal stresses.

ACCELERATING PHASE FIELD SIMULATIONS THROUGH TIME EXTRAPOLATION USING NEURAL OPERATORS AND GENERATIVE MODELS

Cosmin Safta[*1], Christophe Bonneville[1], Arun Hegde[1], Habib Najm[1] and Laurent Capolungo[2]*

[1]*Sandia National Laboratories*
[2]*Los Alamos National Laboratory*

ABSTRACT

Computational simulation of phase field dynamics can be prohibitively expensive when using standard numerical solvers. For example, high-fidelity simulations often use very small time steps due to stability considerations, which can become a bottleneck when the target quantities of interest require predictions far out in time. To address this challenge, we employ machine learning-based surrogate models to help extrapolate forward in time, enabling predictions at time horizons far beyond what is achievable through traditional methods alone. Specifically, we investigate two deep learning architectures, Fourier Neural Operators (FNOs) and UNets, and train them to predict future states with much coarser time steps – thus encapsulating multiple high-fidelity steps within a single surrogate evaluation. While this approach enables more rapid predictions through autoregressive evaluation of the surrogate, the incurred error is essentially uncontrolled. To alleviate this, we adopt a hybrid prediction strategy which alternates between surrogate evaluations – which leap forward in time – and high fidelity simulation steps – which reduce errors and bring the system state back to the solution manifold. Moreover, we show that including periodic retraining using synthetic data obtained via diffusion models can improve the quality of the surrogate models. We illustrate these methods on two examples, a simpler Cahn-Hilliard system and a more sophisticated liquid metal dealloying simulation.

REPRESENTATIVE VOLUME ELEMENT MODEL FOR PREDICTING THE COBLE CREEP DEFORMATION AND VOID NUCLEATION/GROWTH IN THREE-DIMENSIONAL POLYCRYSTALLINE STRUCTURE

Kota Sagara[*1] and Kazuki Shibanuma*[1]

[1]*The University of Tokyo*

ABSTRACT

A model is proposed to quantitatively predict the Coble creep deformation and void nucleation/growth in a three-dimensional polycrystalline. The model is developed for a three-dimensional representative volume element containing multiple grains to predict the effects of three-dimensional polycrystalline morphology. The proposed model consists of a creep deformation model and a void nucleation/growth model.
The creep deformation model comprises both static grain growth and dynamic grain growth. Static grain growth is driven by the movement of grain boundary in a direction that reduces the total grain boundary energy. Dynamic grain growth is induced by the diffusion flux on grain boundary, and the growth rate is calculated by relative velocity of grain boundary, which is the rate at which the thickness of grain boundary changes.
Distinct models are developed for the process of void nucleation and growth. The void nucleation probability is calculated by the relative velocity of grain boundary, and voids are randomly generated on grain boundary. The size of the nucleated void is determined based on the conditions for the stable existence of void on grain boundary derived from Helmholtz's free energy. Void growth is carried out in two separate stages. First, each void grows in the direction of grain boundary. The volume change during this stage is determined by the summation of the volumetric diffusion flux of atoms flowing from the voids to the grain boundary. Next, by calculating the diffusion flux on the surface of each void, void grows in the direction perpendicular to the grain boundary. Throughout this process, the volume of the void is kept unchanged.
The developed model was validated by comparing with the theoretical formula of Coble creep and tendency of experiments. Also, the model was able to evaluate the effects of factors that could not be taken into account in the conventional theoretical equations. Consequently, this study has established the foundation for a model to quantitatively predict the deformation and void nucleation/growth caused by Coble creep.

DEEP LEARNING BASED ACCELERATED HIGH STRAIN RATE SIMULATIONS FOR DESIGN OF MATERIALS IN EXTREME ENVIRONMENTS

Indrashish Saha[1] and Lori Graham-Brady*[1]

[1]*Johns Hopkins University*

ABSTRACT

Designing materials with the desired mechanical properties using a combinatorial approach often necessitates multiple iterations. The expense of conducting experiments in each iteration to ascertain material properties can be exorbitantly high. An alternative is leveraging computational models. However, executing high-fidelity, physics-based simulations can be time-consuming. A faster method involves employing deep learning (DL) based models as surrogate models to predict desired parameters. Our current research focuses on laser-driven spall experiments conducted on thin foils. These laser-driven spall tests are high-strain rate experiments (approximately 10^6). They are instrumental in determining the spall strength of materials. Our goal is to develop DL-based techniques to predict spall strength and other relevant parameters from given microstructures. To this end, we will use data from crystal plasticity finite element simulations as the baseline for our analysis.

ENGINEERING SOFTWARE 2.0 FOR DIGITAL TWIN: UNIFICATION OF TRAINING, CALIBRATING, AND LEARNING THROUGH KERNEL INTERPRETATION OF NEURAL NETWORKS

Sourav Saha[*1] and Wing Kam Liu*[1]

[1]*Northwestern University*

ABSTRACT

The field of computational mechanics is evolving from software 1.0, with explicit, task-specific programming, to software 2.0, which uses data and optimization. However, a direct transition to software 2.0 is extremely difficult for engineering science because a) data is scarce for many engineering systems, b) modeling complex multiphysics problems requires extensive calibration of parameters, and c) augmenting the experimental data with the computational model is extremely time-consuming. Consequently, we should focus on Engineering Software 2.0 which is an end-to-end software system that unifies solving, calibrating, and training in science, engineering, and manufacturing problems. Engineering Software 2.0 defines all problems in optimization construct and leverages automatic differentiation to solve unknown parameters. A gap exists in the contemporary computational and/or theoretical methods that can engender engineering software 2.0. This talk explores the connection between kernel methods in machine learning and deep neural networks, demonstrating how this perspective bridges the gap between interpolation methods in numerical analysis and the concept of universal approximation in neural networks. The presentation is built upon the mathematical foundations of Deep Learning Discrete Calculus (DLDC) [1] and the scientific and engineering principles of Hierarchical Deep Learning Neural Network (HiDeNN) [2], and will show how to solve three general types of problems encountered in science and engineering with this new approach. The first type of problem occurs when there is no known closed-form physical equation. The second type arises when the knowledge of governing laws is incomplete. Lastly, the third type of problem involves known governing equations where computational speed needs improvement. All these three types of problems are to be solved in unified engineering software 2.0. The talk will present a demonstration of this software system and shed light on how it works.

ABSTRACT

Many natural materials exhibit highly complex, nonlinear, anisotropic, and heterogeneous mechanical properties. Recently, it has been demonstrated that data-driven strain energy functions possess the flexibility to capture the behavior of these complex materials with high accuracy while satisfying physics-based constraints. However, most of these approaches disregard the uncertainty in the estimates and the spatial heterogeneity of these materials. In this work, we leverage recent advances in generative models to address these issues. We use as building block neural ordinary equations (NODE) that -by construction- create polyconvex strain energy functions, a key property of realistic hyperelastic material models. We combine this approach with probabilistic diffusion models to generate new samples of strain energy functions. This technique allows us to sample a vector of Gaussian white noise and translate it to NODE parameters thereby representing plausible strain energy functions. We extend our approach to spatially correlated diffusion resulting in heterogeneous material properties for arbitrary geometries. We extensively test our method with synthetic and experimental data on biological tissues and run finite element simulations with various degrees of spatial heterogeneity. We believe this approach is a major step forward including uncertainty in predictive, data-driven models of hyperelasticity.

ABSTRACT

In this presentation, we will discuss recent accelerator/GPU-enabled tools developed to perform ice-related simulations using the MPAS framework within the DOE's Energy Exascale Earth System Model (E3SM). In particular, we will present GPU-based representation and operations related to unstructured meshes, including non-uniform spherical centroidal Voronoi tessellations, and material points. We will also discuss platform portable abstraction and implementation details (for different accelerators/GPUs) that is achieved using the Kokkos library and the PUMIPic library from the SciDAC FASTMath Institute. We will focus on a C++ library, polyMPO, that we have developed to support all relevant material point/MP-related operations such as initialization of MPs, transfer of fields from mesh-to-MP and MP-to-mesh (on spherical meshes), MP tracking with specialization for a centroidal Voronoi tessellation, addition and deletion of MPs to account for freezing and melting of ice, MP migration for multi-GPU cases, etc. We will also describe our approach to interface with the MPAS code by using a well-defined set of APIs based on iso_c_binding for language interoperability between Fortran-based MPAS code and polyMPO library in C++. We will demonstrate our approach on target problems involving relevant geometries and unstructured/multi-resolution meshes on multi-GPU systems, and present performance and parallel scaling data on supercomputers.

UNBIASED SEGMENT-TO-SEGMENT FRICTIONAL CONTACT ALGORITHM FOR SURFACES WITH VARIOUS DISCRETISATION TOPOLOGIES

Indrajeet Sahu[*1] and Nik Petrinic*[1]

[1]*University of Oxford*

ABSTRACT

For the finite element-based solution of problems involving contact in physical systems, interacting bodies are commonly discretized in hexahedral or tetrahedral meshes. The decision of scheme of discretization and element topology used to do so is dependent upon the geometries of the bodies and the problem in consideration. Multiple strategies have been developed for the enforcement of contact constraints, like Node-to-Node (NTN), Node-to-Segment (NTS), and Segment-to-Segment (STS) [1]. The NTN method has limitation of being restricted in use for conformally discretized surfaces. While the widely popular NTS method [2] overcomes this limitation its use can still be disadvantageous in cases like nodes moving into blind spots, and the change of segment during sliding causing jumps in evaluated traction. While the STS method [3] overcomes these issues, it too suffers biasing with the choice of master-slave surface like NTS method, and the dual pass strategy designed to overcome this biasing can potentially lead to the inequality of the computed contact tractions. By employing a middle surface for contact traction resolution in an unbiased manner, the STS method has been utilized in this work for the solution of problems with both hexahedral and tetrahedral discretization of first and second order elements. Here, the interpenetration between contacting surfaces is penalized in the form of contact tractions which act as nodal forces on the facets of contacting elements in a manner that they maintain the force-moment equivalency and the equilibrium of contact tractions. Using regularized Mohr-Coulomb frictional law, an unbiased tangential traction calculation method is also developed for this STS method. It considers the pairs of contacting segments for any relative tangential movement and calculates the frictional forces based on elasto-plastic analogy. These implementations are tested with several benchmarks for quasi-static and dynamic cases of contact between solids in an explicit time integration framework.

[1]*University of Tsukuba*

ABSTRACT

Civil structures should keep functionality during earthquake events, necessitating detailed seismic evaluations. However, to account for uncertainties in seismic loading, nonlinear time history analyses must be repeated many times, increasing the computational cost. In many studies, machine learning has been used for surrogate models to replace nonlinear time history analysis, and most of them construct surrogate models that predict only peak values. However, predicting only peak values does not capture characteristics such as frequency and energy. Therefore, some studies [1] use deep learning, often RNN, LSTM, or CNN, to predict nonlinear time history waveforms. However, deep learning has some problems, such as the black-box nature of the prediction process and the lack of attention to frequencies, which are essential from a vibration engineering viewpoint. In this study, a surrogate model is constructed from spectrograms using a CNN that incorporates an attention mechanism [2]. The spectrogram is a time-frequency feature calculated from the time history of seismic waveforms using the short-time Fourier transform. It becomes possible to understand which time-frequency features contributed to the output by using the spectrogram as input and a CNN with an attention mechanism. Specifically, an attention map is predicted from the spectrogram using a CNN, and the attention map is multiplied by the spectrogram as weights. Examining this attention map from a vibration engineering perspective improves the validity of the surrogate model. Furthermore, this study verifies the improvement in accuracy by applying convolution in the time and frequency dimensions, considering vibration engineering modeling principles. For example, features occurring later do not contribute to the response of earlier times. The verification involves constructing a surrogate model for the nonlinear response analysis under seismic loads for a lumped-mass model of a concrete pier with a seismic isolation rubber bearing and a frame model of a curved highway bridge with six-span continuous two-box girders. As results, it is confirmed that the attention map predicted from the CNN has large values around the natural frequencies, which are considered valid from a vibration engineering point of view. Vibration engineering CNN modeling is also confirmed to improve the accuracy of surrogate models.

BOUNDARY ELEMENT METHOD USING QUANTUM COMPUTER FOR 2D LAPLACE AND HELMHOLTZ EQUATIONS

Takahiro Saitoh[1]*

[1]*Gunma University*

ABSTRACT

In recent years, there has been increasing attention on the utilization of quantum computers worldwide. However, the development of computational mechanics methods, such as the finite difference method (FDM), finite element method (FEM) and boundary element method (BEM), using quantum computers has seen little progress. Although limited, some reports have emerged on using quantum computers in the FEM [1][2][3], particularly for simple problems. It appears that utilizing quantum computers in the BEM is still rare.

Therefore, in this presentation, my recent research on the BEM using quantum computing is presented. Two types of quantum computers have been proposed: quantum annealing, developed specifically for optimization problems, and the conventional gate-based method. In this discussion, we assume that the use of the quantum gate approach. Generally speaking, it is not yet possible to execute all BEM processes on a quantum computer. Hence, we examine a hybrid computational method involving both classical and quantum computers. Currently, it seems challenging to perform pre-processing and calculate influence functions which involve the numerical integration for fundamental solutions in the BEM using quantum computers. We consider a quantum-classical hybrid computation approach where the influence function calculation is performed on a classical computer, and linear equations are encoded into a quantum computer. Linear equation Methods like the Harrow-Hassidim-Lloyd (HHL) algorithm and the Linear Combination of Unitaries (LCU) algorithm have been proposed for solving linear equations with quantum computers.

In our presentation, we will present the current state of quantum computers, some simple numerical examples using the 2-dimensional Laplace and Helmholtz equations with the HHL and LCU algorithms, and discuss future prospects and related topics.

ADAPTIVE ONLINE LEARNING WITH PHYSICS-INFORMED NEURAL NETWORKS FOR ENHANCED THERMAL PREDICTION IN METAL ADDITIVE MANUFACTURING

Pouyan Sajadi[1], Mostafa Rahmani Dehaghani[1], Yifan Tang[1] and Gary Wang[1]*

[1]*Simon Fraser University*

ABSTRACT

Metal additive manufacturing (AM), a pivotal technology in modern industrial fabrication, is revolutionizing the production of metal parts through its layer-by-layer construction approach. This technique offers exceptional flexibility in design and rapid prototyping. A critical aspect of this process is the understanding and control of its thermal behavior, which significantly influences the mechanical properties and structural integrity of the final product. Accurately predicting temperature fields during the manufacturing process is thus crucial for ensuring optimal outcomes. This becomes particularly challenging with new manufacturing processes, where specific data for model training is often lacking. When we use models trained on data from previous, different processes, the results can be inaccurate. This is because these models might not fully capture the unique characteristics and variations found in the new processes.

This paper introduces a novel solution to this challenge by employing a physics-informed neural network (PINN) in an online learning framework. Our approach involves a two-phase algorithm: an initial pretraining phase and a subsequent phase of online learning. Initially, the PINN is pre-trained with datasets from known manufacturing processes with existing data, enabling the network to develop a fundamental understanding of thermal behaviors. This foundation allows the network to establish robust predictive capabilities.

Following the pretraining, the network adapts to new processes through online learning by incorporating real-time data from these processes. This adaptation is facilitated through optimization, allowing for the fine-tuning of the network's parameters in response to each unique data set. A key feature of our method is the integration of physical principles of thermodynamics into the learning process, ensuring that predictions are both data-driven and rooted in the fundamental laws of heat transfer specific to metal additive manufacturing.

This approach, which combines pretraining with adaptive online learning and a physics-informed foundation, enables our network to effectively adapt to new processes. It significantly enhances accuracy and reliability in thermal prediction, establishing a new benchmark in the application of online learning in the additive manufacturing sector. This study not only addresses the challenges of process variability but also opens doors for future advancements in theoretical adaptive control in manufacturing.

DEVELOPMENT AND INDUSTRIAL APPLICATION OF THE ADVANCED DISCRETE ELEMENT METHOD

*Mikio Sakai**[1]

[1]*The University of Tokyo*

ABSTRACT

The Discrete Element Method (DEM) is an innovative Lagrangian approach extensively utilized in addressing industrial challenges. Our research group has pioneered the creation of original models for the application of DEM to industrial systems. Noteworthy contributions include the introduction of the signed distance function [1] for the wall boundary model, a scaling law model exemplified by the coarse-grained DEM [2], a non-spherical particle model [3] grounded in ellipsoid principles, and the integration of an implicit algorithm to address the drag force term [4]. This presentation will showcase recent applications, such as those involving a fluidized bed [5], a twin-screw kneader [6], a three-phase fluidized bed [7], and an industrial blender [8]. Additionally, we will delve into the pivotal models pivotal for advancing the development of a digital twin for powder processes.

INCOMPRESSIBLE VISCOUS FLUID ANALYSIS AROUND COMPLEX SHAPES USING ISOGEOMETRIC ANALYSIS

Yuto Sakai[*1], Kazuo Kashiyama[1] and Hiroshi Hasebe[2]*

[1]*Chuo University*
[2]*Nihon University*

ABSTRACT

In Finite Element Method(FEM) analysis, low-order interpolation functions are usually used for the shape functions, which leads to shape errors in curved shapes. To address this issue, Isogeometric Analysis(IGA) [1] has recently attracted attention as an analysis method with arbitrary surfaces. IGA is effective for flow around structures with complex shapes and their fluid-structure interaction problems.

In this paper, IGA is applied to an incompressible viscous flow problem as a fundamental study. The IGA method based on multi-patches is employed; the continuity condition by superposition of Matrix Vectors is applied between patches. In order to investigate the validity and effectiveness of the present method, several benchmark problems with curves are carried out. The influence of differences in the order of the Non-Uniform Rational B-Splines(NURBS) function on numerical accuracy is investigated. The present method is also applied to the fluid-structure interaction problem. The effectiveness of IGA for viscous fluid analysis is discussed in comparison with the conventional finite element method.

LARGE-SCALE PHASE-FIELD SIMULATION OF CELL GROWTH IN MOLTEN POOL OF POWDER BED FUSION

Shinji Sakane[1], Lu Wang[2], Wentao Yan[2] and Tomohiro Takaki[1]*

[1]*Kyoto Institute of Technology*
[2]*National University of Singapore*

ABSTRACT

In laser powder bed fusion, the distinctive three-dimensional (3D) temperature profile in the molten pool significantly influences the morphology of dendritic/cellular microstructures. In this study, we have devised a novel model to precisely predict the 3D microstructure in the molten pool. This model bridges the meso-scale multi-physics thermal-fluid flow model [L. Wang, Y. Zhang, H. Y. Chia and W. Yan, npj Computational Materials 8 (2022) 1-11.] to the micro-scale PF model for rapid solidification of binary alloy [T. Pinomaa and N. Provatas, Acta Materialia 168 (2019) 167-177.]. To facilitate large-scale 3D PF simulations, we accelerate PF computations using the parallel computing with multiple graphics processing units (GPUs) and the adaptive mesh refinement (AMR) method (parallel-GPU AMR) [S. Sakane, T. Takaki and T. Aoki, Materials Theory 6 (2022) 1-19.]. Employing this developed model, we simulated the growth of columnar cells in the 3D thin-film cross-section domain around the bottom of the molten pool during the single-track laser scan process of an Inconel 718 plate. The simulation results were validated through comparison with experimental results and demonstrated that a characteristic 3D microstructure at the bottom of a curved molten pool can be obtained by the developed model.

AN ANALYTICAL MODEL FOR THE ANALYSIS OF DENSITY-BASED CELL-SORTING MICROFLUIFIC DEVICES IN COMBINATION WITH TRADITIONAL NUMERICAL APPROACHES

Aniol Sala[*1], Guillermo Casas[1] and Eugenio Oñate[1]*

[1]CIMNE

ABSTRACT

In this work, we present an analytic model for the analysis of density-based cell-sorting microfluidic devices. Devices of this class exploit small density variations among the various particle types to classify them. The sorting mechanism is based on maintaining a stratified flow with several fluid layers of different densities, which causes the particles to drift to their equilibrium position as they move along the circuit. Previous work relied on numerical simulations alone, as an analytical solution was not known. The model presented here predicts the density field for tubes of circular cross-section and an arbitrary number of strata with arbitrary accuracy. We discuss how it can be used to directly predict the sorting efficiency of the device in simple cases, without the need to resort to any numerical simulation. Furthermore, we consider its relevance outside its strict validity range and how it may be combined with a stabilized finite element method to produce a much more efficient hybrid method with a wider applicability range. We evaluate the accuracy of our approach against empirical data from real microfluidic devices.

AN HP-ADAPTIVE PHASE-FIELD MODEL FOR FATIGUE CRACK GROWTH

Jacob Salazar Solano[1] and Leszek Demkowicz*[1]

[1]*The University of Texas at Austin*

ABSTRACT

We present the numerical solution of a non-linear phase-field model for crack propagation with mesh adaptivity, discretized with the Discontinuous Petrov-Galerkin (DPG) FE methodology developed by Demkowicz and Gopalakrishnan [1].

Phase-field models have gained attention as a competitive tool to predict mesoscale morphological and micro-structure evolution in materials. In the context of crack propagation, such models provide the capability to reproduce complex crack growth patterns, such as turning, branching and merging. Unlike more traditional methods, with the phase-field approach the domain does not change as the crack grows. The use of this field parameters introduces a significant challenge: nonlinearities. The sources of nonlinearities in the selected model are two: i) The evolution of the phase-field parameter is governed by the micro-forces balance equations which are inherently nonlinear, and ii) in order to account for the discrimination of compressive and tensile stresses' contributions to the free energy, the latter must be defined by parts [2].

The DPG methodology retains various attractive features: it is a variationally flexible discretization method, that includes automatic discrete stability thanks to its optimal test functions, and has a built-in a-posteriori error estimator that naturally allows for adaptivity [3]. This results to be particularly useful for the purpose of solving phase-field models for crack growth, given the required refinements near the crack tip and near the process zone (the region of the domain where the scalar field changes from intact to damaged material zone).

While the DPG framework has been implemented for solving many models in science and engineering, only a few recent works have tackled nonlinearities. With this work, we tackle a complex problem in terms of the nonlinearities, by taking advantage of the optimal test functions.

INTERACTIVE ACTIVE SURFACES: A MODEL FOR CELL AGGREGATES

Guillaume Salbreux[*1]

[1]*University of Geneva*

ABSTRACT

Biological tissues self-organise thanks to patterning processes coupled to cellular mechanical interactions, which play a fundamental role in driving coordinated cell movements. Here I will discuss how polarity-oriented active mechanical forces drive collective cell motion in three dimensions by modulating cell surface mechanics. I will introduce the framework of « interacting active surfaces », which describe cell aggregates as mechanically coupled flowing active surfaces. The continuum equations of active fluids, describing the flows and shape changes of the cell surfaces, are solved with finite elements. I will discuss application of this method to the three-dimensional rotational motion of cell doublets, which arise from polarised distribution of myosin motors in the cortex of the doublet cells. I will show how the interacting active surface simulation allows to capture the rotational motion of the doublet and its link with cortical flows. I will discuss how the shape of the doublet interface can be understood from an analysis of the group of symmetry of the cell doublet and application of the Curie principle. I will then discuss how principles of polarity dynamics and polarity-based mechanical interactions can act in larger three-dimensional cellular aggregates and lead to active self-assembly.

[1]*University of Leicester*
[2]*Rolls-Royce UK*

ABSTRACT

The Densification Based Finite Element Method (DFEM) is a computational modelling technique in the field of sintering that does not rely on a full constitutive law. It utilizes densification data to predict the temporal evolution of sintering deformation in products. DFEM is advantageous when calibrating all parameters of a constitutive law is impractical for a full finite element analysis. It is not restricted to any specific sintering mechanism, making it versatile across various processes like grain boundary diffusion, vapor evaporation condensation, or liquid phase sintering. The accuracy of DFEM is comparable to that of models using full constitutive laws, making it particularly useful for proof-of-concept analyses when sintering new complex-shaped products. However, it has limitations, including its applicability only to pressureless sintering scenarios.

While DFEM has historically been applied using empirical numerical methods for calculating sintering deformation of ceramic powder compacts without detailed knowledge of viscosities and sintering potential, this research represents the first application of DFEM to an industrial part, full-scale heat shield (FSHS), using the finite element analysis. In tackling the prevalent challenge of limited data during the nascent phases of industrial development, DFEM proves to be an invaluable tool for predicting sintering distortion and shrinkage in such large-scale parts. This expansion of DFEM's application, showcased on a Rolls-Royce demonstrator part, marks a significant advancement in its practical utility. In conjunction with the DFEM digital twin of FSHS, the study proposes sintering boundary conditions to suppress real-time distortion.

HARNESSING ADVANCED CFD AND ML COMPILER TOOLS FOR TOPOLOGY OPTIMIZATION OF LARGE-SCALE FLUID THERMAL PROCESSES

Hesam Salehipour[1], Massimiliano Meneghin[1], Mohammadmehdi Ataei[1], Pradeep Kumar Jayaraman[1], Nigel Morris[1] and Adrian Butscher[1]*

[1]*Autodesk Research*

ABSTRACT

Topology optimization (TO) of real engineering flows requires robust CFD algorithms that are highly optimized for maximum performance and include advanced capabilities to handle high Reynolds number flows, wall models, complex boundary conditions, and coupled physics for fluid-thermal processes. The adjoint computations, which are an essential part of gradient-based topology optimization, must be equally efficient and equipped with the same advanced capabilities to be useful for realistic design optimization purposes.

In many ways, the computational challenges of TO algorithms are similar in principle to those faced by the AI community where large-scale models need to run efficiently in both forward and backward modes to perform gradient descent optimization.

In this talk, we will present how recent compiler technologies developed for ML research (such as JAX and Pallas frameworks) may be leveraged to produce a massively parallelizable adjoint CFD solver based on the Lattice Boltzmann method (LBM). Our proposed solution, namely XLB [1, 2], leverages the solver's differentiability and is highly extensible in Python. We will demonstrate results of level-set-based topology optimization for a wide range of problems that incorporate advanced LBM techniques and capture coupled fluid-thermal physics with arbitrarily complex objectives and constraints. The efficient multi-GPU performance of forward and backward computations, that are key for large-scale TO problems, will also be highlighted.

DIGITAL TWINNING IN COMPUTATIONAL CARDIOLOGY

Matteo Salvador[*1], Fanwei Kong[1], Mathias Peirlinck[2] and Alison Marsden[1]*

[1]*Stanford University*
[2]*Delft University of Technology*

ABSTRACT

In recent years, blending physics-based modeling with data-driven methods has had a major impact on digital healthcare. Several frameworks have been proposed to create certified digital replicas of different areas of the cardiovascular system. These computational pipelines include multiscale and multiphysics mathematical models based on differential equations, machine learning methods to build accurate and efficient surrogate models of cardiovascular function, sensitivity analysis, and parameter inference with uncertainty quantification. Here, we show the potential of Branched Latent Neural Maps (BLNMs), a recently proposed scientific machine learning tool, to learn complex space-time fields coming from physics-based models, and how these simple and compact feedforward partially connected neural networks can be effectively deployed for personalized medicine. BLNMs have different advantages. Indeed, they use additional latent outputs to improve the learned space-time dynamics, they break the curse of dimensionality, and they retain excellent in-distribution generalization over an arbitrary discretization. Several applications of BLNMs for digital twinning in computational cardiology will be shown.

A NONLINEAR REDUCED BASIS APPROXIMATION OF DISCRETE CONTACT PROBLEMS IN CROWD MOTION

Giulia Sambataro[*1] and Virginie Ehrlacher*[1]

[1]*Ecole des Ponts*

ABSTRACT

In this work we develop new model reduction approaches to predict the solutions of time-dependent parametrized problems describing crowd motion in the presence of obstacles.

The problem of interest is described by a discrete contact model (DCM), which is formulated as a constrained least-squares optimization statement: the particles velocity field is seeked as the projection of the spontaneous velocities of each particle into a feasibility set (which prevents the overlap between particles and between particles and obstacles).

The parametric variations in the problem are associated with the geometric configuration of the system and to the initial positions of the particles: they have a dramatic impact in the solution, both in terms of positions and contact forces. We investigate new developments of the reduced-basis method and supervised machine-learning techniques to effectively find, in a decorrelated manner, primal and dual reduced spaces: to do so, we rely on a non-linear reconstruction from the first coordinates of a linear reduced basis approximation.

To assess the validity of the method, the nonlinear compressive strategy is then compared to more standard linear and nonlinear approximations.

A SPACE-TIME FINITE ELEMENT FORMULATION FOR LARGE DISPLACEMENT PROBLEMS WITH COMPUTATIONAL COSTS EQUIVALENT TO TIME-MARCHING METHODS

Rodolfo Sanches[*1]

[1]*University of São Paulo*

ABSTRACT

This study introduces a space-time finite element formulation for solid mechanics, featuring specially designed quadratic shape functions in the time direction. The approach employs the time-slab concept, where trial functions within each slab are determined by nodal parameters of velocity and position at the initial time-slab boundary and position at the final time-slab boundary. Each time-slab is independently solved, taking velocity and position values from the preceding slab final boundary as initial conditions, with the position nodal values at the current time-slab's final boundary as unknowns. As a result, the number of unknowns is the same as in standard time marching methods with identical spatial finite element discretization. Three different options are explored for selecting test functions with the same shape functions of positions, while restraining distinct test function nodal parameters. These choices result in diverse stability and dissipation characteristics. To evaluate the numerical characteristics of the method, we firstly perform testing with linear 1D problems, and following, we apply it to develop a space-time finite element formulation for 2D elasticity with large displacements, using a total Lagrangian description and taking the current nodal positions as main variables. The proposed approach has computational cost similar to the standard time-marching approaches, demonstrating favorable convergence rates and stability. Future applications are anticipated for more intricate nonlinear problems.

SYMPLECTIC HAMILTONIAN HYBRIDIZABLE DISCONTINUOUS GALERKIN METHODS FOR LINEARIZED SHALLOWS-WATER EQUATIONS

*Manuel Sanchez**[1] and Cristhian Nunez*[1]

[1]*Pontificia Universidad Catolica de Chile*

ABSTRACT

We propose a new hybridizable discontinuous Galerkin method for approximating the linearized shallow-water equations. The discretization aims to preserve relevant physical quantities such as mass, vorticity, and energy. Specifically, we reformulate the system of equations in a Hamiltonian form, employing Hybridizable Discontinuous Galerkin Methods (HDG) for spatial discretization and obtaining a semi-discrete scheme written in Hamiltonian form. By leveraging on the inherent Hamiltonian structure of the numerical method and implementing symplectic time-marching schemes, we ensure the conservation properties of the fully discrete system of equations. We discuss the fundamental properties of our analysis and present numerical experiments to validate its performance.

GRAPHICS PROCESSING UNIT ACCELERATED ICE FLOW SOLVER FOR UNSTRUCTURED MESHES USING THE SHALLOW SHELF APPROXIMATION (FASTICEFLO V1.0.1)

Anjali Sandip[1], Ludovic Räss[2] and Mathieu Morlighem[3]*

[1]*University of North Dakota*
[2]*University of Lausanne*
[3]*Dartmouth College*

ABSTRACT

Ice-sheet flow models capable of accurately projecting their future mass balance constitute tools to improve flood risk assessment and assist sea-level rise mitigation associated with enhanced ice discharge. Some processes that need to be captured, such as grounding line migration, require high spatial resolution under the kilometer scale. Conventional ice flow models mainly execute on central processing units (CPUs), which feature limited parallel processing capabilities and peak memory bandwidth. This may hinder model scalability and result in long run times requiring significant computational resources. As an alternative, graphics processing units (GPUs) are ideally suited for high spatial resolution as the calculations can be performed concurrently by thousands of threads, processing most of the computational domain simultaneously. In this study, we combine a GPU-based approach with the pseudo-transient (PT) method, an accelerated iterative and matrix-free solution strategy, and investigate its performance for finite elements and unstructured meshes with application to two-dimensional (2-D) models of real glaciers at a regional scale. For both Jakobshavn and Pine Island glacier models, the number of nonlinear PT iterations required to converge a given number of vertices N scales in the order of N1.2 or better. We further compare the performance of the PT CUDA C implementation with a standard finite-element CPU-based implementation using the price-to-performance metric. The price of a single Tesla V100 GPU is 1.5 times that of two Intel Xeon Gold 6140 CPUs. We expect a minimum speed-up of at least 1.5x to justify the Tesla V100 GPU price to performance. Our developments result in a GPU-based implementation that achieves this goal with a speed-up beyond 1.5x. This study represents a first step toward leveraging GPU processing power, enabling more accurate polar ice discharge predictions. The insights gained will benefit efforts to diminish spatial resolution constraints at higher computing performance. The higher computing performance will allow running ensembles of ice-sheet flow simulations at the continental scale and higher resolution, a previously challenging task. The advances will further enable quantification of model sensitivity to changes in upcoming climate forcings. These findings will significantly benefit process-oriented sea-level-projection studies over the coming decades.

A UNIFYING FRAMEWORK FOR OPERATOR LEARNING VIA NEURAL FIELDS

Jacob Seidman[1], Hanwen Wang[1], Shyam Sankaran[1], Paris Perdikaris[1] and George Pappas[1]*

[1]University of Pennsylvania

ABSTRACT

Operator learning is an emerging area of machine learning which aims to learn mappings between infinite dimensional function spaces and has led to the development of new architectures such as the Fourier Neural Operator, the DeepONet, and their extensions. In this work we uncover a previously unrecognized connection between existing operator learning architectures and conditioned neural fields used in computer vision. This results in a unified framework for explaining differences between popular operator learning architectures, and creates a bridge for adapting well-developed tools from computer vision for operator learning. In particular, we find all existing operator learning architectures are neural fields whose conditioning mechanisms are restricted to use only pointwise and/or global information. This motivates us to design new architectures which make use of a hierarchy of scales for conditioning a base neural field. By making use of multi-scale conditioning, we observe consistent performance gains and obtain state of the art results across a collection of challenging benchmarks in climate modelling and fluid dynamics.

Model order reduction for parametrized continuum mechanics

ON METAHEURISTIC STRUCTURAL OPTIMIZATION WITH PARAMETRIC MODEL ORDER REDUCTION

Varakini Sanmugadas[*1] and Rakesh Kapania*[1]

[1]*Virginia Tech*

ABSTRACT

Design optimization involving complex structures can be a very resource intensive task. The present work focuses on the non-convex optimization problem involving eigenvalues that arises in structural design optimization. Parametric Model Order Reduction (PMOR) was identified as a potential tool for improving the efficiency of the optimization process. For the buckling eigenvalue problem, we turned to meta-heuristic approaches due to the non-linear dependence of the geometric stiffness matrix on the design variables. A two-step optimization procedure was developed. In the first, a set of projection vectors that can be used to project the solutions of the governing higher order partial differential equations to a lower manifold is assembled. Invariant components of the system matrices that do not depend on the design variables were identified and reduced using the projection vectors. In the second (online) step, particle swarm optimization (PSO) was carried out. Here, the buckling analysis problem for each design is assembled and solved directly in the reduced form. Applicability of this approach to the design of variable angle tow fiber composite structures was investigated and an efficient matrix decomposition for the linear stiffness matrices was derived to aid in this process. PMOR-based optimization exhibited a 0.55% relative error compared to full order model-based studies and similar convergence history. The optimization efficiency was improved by 64.41% with a reduction of 86.57% in eigenvalue analysis time and 99.8% in memory requirements, affirming PMOR's suitability for global optimization of VAT fiber composite structures. Further improvement in computational time is expected with current work on deriving an affine decomposition for geometric stiffness matrix. Investigations are also being carried out on the impact of PMOR on the convergence properties of PSO.

A MULTIDIMENSIONAL MODELING FRAMEWORK FOR ASSESSING COMPOUND INUNDATION THROUGH A REDUCED-PHYSICS APPROACH IN COASTAL WATERSHEDS

Felix Santiago-Collazo[*1], Logan Bayer[1] and Matthew Bilskie[1]*

[1]*University of Georgia*

ABSTRACT

Water is vital for any civilization to prosper; thus, settlements have been established within the coastal or fluvial floodplain throughout history. These communities, especially low-gradient ones, are prone to flood hazards such as nuisance flooding, storm surges, extreme rainfall, and high river discharge. However, compound inundation occurs when two or more flood drivers (e.g., coastal and hydrological) coincide or are in close succession. Consequently, the flood impacts during these events can be exacerbated due to the nonlinear interaction of the coastal and hydrologic processes. However, current numerical modeling approaches are not suited to capture this intricate relationship accurately by coupling different models for each process.

This research presents a unified approach for compound flood assessments based on a reduced-physics numerical scheme. This unstructured finite element model simulates coastal, fluvial, and pluvial processes that employ the full or a reduced form of shallow water equations. As a first step, a one-dimensional (1-D) approach was employed in idealized coastal watersheds to understand better the physical processes and their interaction during a compound flood event. This reduced-physics modeling approach employs the kinematic wave equations (KWE) to simulate overland runoff in the watershed and riverine flow in non-estuarine locations. In contrast, the diffusive wave equations (DWE) are applied to simulate riverine flow in estuarine regions to account for backwater processes. Lastly, the complete shallow water equations are applied in the coastal areas for simulating astronomical tides and storm surges. Next, the lessons learned from the 1-D approach were extended to a two-dimensional (2-D) approach by developing a hydrologic model based on the reduced-physics approach. This model uses a finite element spatial discretization (e.g., symmetrical weak weighted residual) and a Crank-Nicolson scheme for time discretization.

Initial results highlight the nonlinearity of the flood processes within a compound flood event. This nonlinearity may be attributed mainly to the peak levels occurring at different times for each flood driver. However, the time-to-peak water levels of all the individual flood scenarios arrive within an hour at the exact location, but the linear superposition overestimates the total inundation. Therefore, the non-linearity depends not only on the time-to-peak water levels but also on the momentum exchange. By improving this relationship between flood drivers in a compounding flood event, holistic modeling frameworks can be developed and serve as a critical planning tool for decision-makers, stakeholders, and authorities.

CALIBRATION OF A RATE-DEPENDENT CONCRETE MATERIAL MODEL USING HIGH-VELOCITY IMPACT EXPERIMENTS AND SURROGATE-BASED OPTIMIZATION

Jean Santiago-Padilla[*1], William Lawrimore*[1], Jesse Sherburn*[1] *and Andreas Frank*[1]

[1]*U.S. Army Engineer Research and Development Center*

ABSTRACT

The U.S. Army's ERDC has developed an advanced concrete material model adept at capturing multiple rate-dependency effects, as well as complex damage mechanisms encompassing macro- and micro-cracking. This allows for better prediction of concrete behavior under extreme loadings such as blast and projectile impact, which is of great interest to the U.S. Army in the design of their protective structures. However, one of the challenges with this new material model is the inability to constrain certain strain-rate parameters through standard lab tests. A solution is to leverage carefully designed high-velocity impact experiments to calibrate these unconstrained material model parameters. In this work, an inverse method using surrogate-based optimization is proposed to calibrate ERDC’s concrete model to a series of terminal ballistic experiments with rigid ogive penetrators. To do this, numerical simulations using the EPIC hydrocode are run through an optimization workflow in the Dakota framework. The design parameters are the material model coefficients, while the objective is to minimize error between simulated acceleration-time histories and experiments. Computational analysis includes a factor screening to determine each parameter’s effect on the response metric, a parametric study testing different surrogate models and optimization algorithms, and an assessment of design feasibility when adding physical constraints on the concrete’s strain energy. To check robustness, the resulting calibrated model is then validated against an additional set of experiments with impact conditions not considered in the optimization process.

MINIMIZATION OF VIBRATIONS IN AERONAUTICAL WING SPARS UNDER FLUTTER SITUATION

Larissa Santos[1], Marcelo Araujo Silva[1] and Reyolando Brasil[1]*

[1]*Federal University of ABC*

ABSTRACT

The present work aims to study the mitigation of vibrations of aeronautical wing spars in cases of flutter. For these cases will be studied aero elasticity, which is defined as the science that is interested in the mutual interaction between elastic, aerodynamic and inertial forces in a body on aerodynamic flow. Among aeroelastic phenomena, flutter can be defined as the self-excited interaction between two or more modes of vibration of a properly altered system. This is fed back by the flow of a fluid, which can, at certain speeds (flutter speed), result in a tragic failure. This occurs due to the development of oscillations of increasing amplitudes, impairing the performance and safety of the aircraft, which can lead to a failure of the structure. This is a critical problem faced by aircraft designers, especially in the design of those structures where high performance is required. In this case, it is necessary to reduce the weight and control the aerodynamic loads. Thus, an analytical method was developed through the equation of motion for a typical section with two degrees of freedom: torsion and flexion. The flutter velocity for the studied aircraft problem was obtained through the analysis of the stiffness and mass matrices, obtaining a V-f diagram in addition to the damping values as a function of the velocity V. Finally, a degree of freedom was added to the system, corresponding to a TMD (Tunned Mass Damper), which aimed to increase the flutter speed using optimization techniques. With this, the aircraft could have a greater range of speeds for Operation. Suggestions for future work were also proposed.

Advanced analysis of steel and steel-concrete composite structures

HUMAN COMFORT ASSESSMENT OF PEDESTRIAN FOOTBRIDGES BASED ON THE USE OF DESIGN RESPONSE SPECTRA

Paula Oliveira Bezerra Diniz[1], Jorge Maurício Souza[1], Amanda Borges Oliveira[1], Gilvan Lunz Debona[2] and José Guilherme Santos da Silva[1]*

[1]State University of Rio de Janeiro (UERJ)
[2]Rural Federal University of Rio de Janeiro (UFRRJ)

ABSTRACT

The pedestrian footbridges are more and more becoming the modern landmarks of urban areas. The designers seem to continuously move the safety border, aiming to increase the pedestrian footbridges slenderness and lightness. However, more and more footbridges are carried out as light weight structures with low frequencies and low damping. These facts have generated very slender footbridges, sensitive to dynamic excitations, and consequently changed the serviceability limit states associated to the design. In general, the current design codes and guides recommend the use of deterministic models to assess the dynamic behaviour of footbridges. On the other hand, the effect of the uncertainties in mass, stiffness and damping of the investigated structure are relevant and lead to uncertainties on the values of the footbridges natural frequencies. Nevertheless, the human walking is a stochastic phenomenon and the dynamic force generated at each step depends of the weight, the step frequency and the step length of each pedestrian. This way, this research work aims to contribute with the structural designers based on the development of a probabilistic approach to assess the dynamic behaviour of footbridges considering the stochastic nature of the pedestrian's walking, in order to evaluating the structural response with regard to excessive vibrations that may cause human discomfort. Based on the use of probabilistic methods, it becomes possible to determine the probability of the footbridge's peak acceleration values exceeding or not the human comfort criteria. The results obtained in this investigation reveal that the values of maximum accelerations calculated based on the deterministic methods may be overestimated in design situations.

3D STRUCTURAL FOUNDATION DESIGN FOR ONSHORE WIND TURBINES VIA TOPOLOGY OPTIMIZATION

Kamilla Emily Santos Silva[*1], Gabriel Vicentin Pereira Lapa[1], Josue Labaki[2], Alfredo Gay Neto[1], Emilio Carlos Nelli Silva[1] and Renato Picelli[1]*

[1]*Universidade de São Paulo*
[2]*The State University of Campinas*

ABSTRACT

Structural foundations for onshore wind turbines face the dual challenge of balancing structural integrity with cost efficiency. While opting for a robust foundation with substantial mass to ensure a stiffer structure may be tempting, this approach often translates to higher costs. In this context, this work proposes a topology optimization methodology for 3D designs of onshore wind turbine foundations. The primary objective is to design optimized structural foundations considering a maximum concrete volume constraint. The analysis encompasses considerations for both static and dynamic loads. The structural foundation is designed over a large portion of soil beneath the wind turbine, designated as the design domain. Material properties within the design domain are defined based on binary decision variables, denoted as {1} for concrete or {0} for soil. The soil-structure problem is solved through the Finite Element Method, employing the Perfectly Matched Layer (PML) approach to absorb dynamic waves and simulate an infinite domain. Different volume fractions of concrete are explored. The sensitivities of the problem are calculated using semi-automatic differentiation, and the Topology Optimization of Binary Structures with Geometry Trimming (TOBS-GT) method is employed to solve the {0,1} optimization problem via Integer Linear Programming. The numerical results show the effectiveness of the proposed methodology in designing cost-effective 3D structural foundations and its potential to provide useful insights into onshore wind turbine foundations.

PHASE-FIELD MODELING OF FATIGUE BASED ON MICROMECHANICS APPROACH

Mina Sarem[1], Nuhamin E. Deresse[1], Jacinto Ulloa[2], Els Verstrynge[1] and Stijn Francois[1]*

[1]*KU Leuven*
[2]*California Institute of Technology*

ABSTRACT

This presentation addresses the development of a micromechanics-base phase-field model for characterizing fatigue failure in (quasi-)brittle materials, as fatigue stands as an important cause of fracture in engineering structures. The phase-field variational method is utilized to simulate and regularize the complex, discontinuous functions governing the physics of cracks. Despite its computational benefits, the phase-field approach has limitations, such as the inability to distinguish between tensile and compressive failure, potentially leading to the development of unrealistic crack patterns in compression. In this study, we employ a framework that enhances the phase-field model by integrating a micromechanics-based approach [1, 2]. This combination helps to differentiate between failure modes without adopting heuristic modifications, by distinguishing between open and closed microcracks. This framework links macroscale field variables, such as plastic strain and damage variable, to micromechanical mechanisms like frictional sliding and opening of microcracks.
Our primary focus is to incorporate accumulation of fatigue damage and deterioration caused by cyclic loading into the micromechanics-based phase-field model. To achieve this, we first improve the algorithm's stability for loading-unloading in the tensile regime by modifying the plasticity evolution equations. Additionally, we introduce a fatigue degradation function to the model, which degrades the fracture energy upon reaching a specified threshold during cyclic loading [3]. Various cyclic loads are applied to benchmark tests to capture diverse failure modes. Our results demonstrate the model's capability to accurately simulate the main features of fatigue behavior, including crack nucleation, growth, and coalescence.

REVISITING THE ISSUE OF ENERGY CONSERVATION IN PHASE-FIELD MODELS FOR FRACTURE

Juan Michael Sargado[*1] and Joachim Mathiesen*[1]

[1]*University of Copenhagen*

ABSTRACT

Phase-field models for fracture have become very popular in recent years due to their innate ability to predict the path of crack propagation and their robustness with regard to topological challenges associated with crack nucleation, branching and coalescence. However, enforcing energy conservation in the event of brutal cracking remains an open problem. Even in problems involving purely quasi-static loading, it is well known that the resulting fracture evolution may nevertheless include both stable and unstable crack growth. In the latter case, a naive solution of the governing equations in the corresponding simulations leads to a loss in the total potential energy: an apparent violation of the energy conservation law. This energetic signature is not limited to crack nucleation events, but can also be observed in connection with the finite (as opposed to infinitesimal) extension of an existing crack. Previous attempts at recovering energy conservation involved the use of backtracking schemes based on a global energy minimization principle, however such schemes can lead to unphysical results including violation of Griffith's criterion.

In this talk, we present an alternative paradigm aimed at recovering energy conservation without resorting to global minimization. Instead, we take into account the fact that unstable crack growth is an inherently dynamic phenomenon, and adopt a heuristic approach to include such dynamic effects within an otherwise quasi-static framework. This enables us to avoid having to solve the full dynamic linear momentum equation, and additionally also allows us to simulate crack evolution anywhere within the spectrum defined by full energy conservation at one end, and maximal energy loss at the other. We compare numerical results obtained using the proposed framework to recently published experiments, as well as results obtained with classical phase-field approaches.

A STATE-OF-THE-ART REVIEW ON THE RECENT ADVANCES OF AN EFFECTIVE FINITE ELEMENT TOOL FOR FRACTURE ANALYSIS

*Murat Saribay**[1]

[1]*Istanbul Bilgi University*

ABSTRACT

The computation of fracture mechanics parameters has always been challenging for the people working in this field. Besides the ongoing improvements demonstrated by commercial software, many research groups have dedicated themselves to developing their in-house codes. A particular example of such codes was given in the past by introducing FRAC3D program to the fracture community [1]. As a specialized finite element software, FRAC3D benefits from enriched elements to determine fracture parameters. The advantage of this program over other similar software is the accuracy levels obtained by using much less elements around the crack region. Hence, the main objective for the users of this program has been to increase its capabilities for covering a wide range of fracture-related problems. Recently, several developments for this program were demonstrated by using various fracture examples. The dynamic version of the program was used to simulate the stress wave propagation phenomenon and compute time-dependent fracture parameters for straight and curved crack fronts. On the other hand, a parallel version of the same code was created by using multiprocessing (MPI) tools and this was shown with the aid of the fracture analysis of an electronic packaging structure [2]. Another interesting problem involves the computation of welding residual stresses on a specific component with external welding software, and then the determination of residual stress effects on fracture parameters for the same geometry with a stationary crack that is subjected to a subsequent load [3]. The latter part of that study was realized by using FRAC3D with necessary implementations. Current investigations concentrate on the details for the incorporation of residual stress effects and crack growth simulations. Having an efficient tool for this purpose seems very significant considering the complexities associated with this type of analysis.

[5]Royal Military Academy of Canada

ABSTRACT

The nonlinear sparse Bayesian learning (NSBL) algorithm permits the automatic discovery of optimal nested models [1]. Inspired by applications in engineering for nonlinear-in-parameter models, NSBL generalizes the concept of relevance vector machines permitting the inclusion of informative priors for a priori relevant parameters while leveraging the use of Gaussian automatic relevance determination (ARD) priors for parameters of questionable relevance. The optimal model is thus revealed by pruning irrelevant parameters. This is achieved by optimizing the parameters of the ARD priors (the hyperparameters). The efficiency of the algorithm relied on the use of a Gaussian mixture model (GMM) approximation for the product of the likelihood and informative priors which permits the derivation of semi-analytical expressions for several Bayesian entities for nonlinear models, with non-Gaussian priors or likelihood functions. Expressions for the parameter posterior pdf, the model evidence, and the NSBL objective function can be derived in terms of the GMM kernel parameters and the hyperparameters.

The success of the NSBL algorithm critically depends on the construction of the GMM approximation. Kernel density estimation or clustering methods can be used to construct a GMM using Markov Chain Monte Carlo samples. While this can accurately capture non-Gaussian attributes and correlation between parameters, these methods are computationally expensive and do not scale well. Conversely, variational methods adopting mean-field approximations scale well, but generally discards critical information on the correlation structure of the posterior which is critical for sparse learning. Towards developing scalable implementations of NSBL, we consider the use of the global optimization and Laplace approximation (GOLA) algorithm [2] for the construction of the GMM. This methodology was recently proposed as a warm-start for variational inference. Here we investigate the suitability of this approach for the purpose of constructing the NSBL objective function as necessary component of the optimal model discovery.

NUMERICAL MODELLING OF STEAM GENERATOR ROLLED PLUG USING PHASE FIELD APPROACH

Luka Sarlija[1] and Tomislav Lesicar*[2]

[1]*Institute for Nuclear Technology*
[2]*University of Zagreb*

ABSTRACT

Rolled plugs are elements used for defected steam generator tubes plugging to prevent leakage of radioactive water from the primary circuit into the environment by forming leak tight seal with the tube. They are installed inside the tube using rolling process which causes plastic deformation of the plug shell made out of Inconel 690 TT. Hot temperature, high pressure, flow-induced vibrations, primary water stress corrosion cracking and transient conditions during startup and shutdown of nuclear power plant affect rolled plug structural integrity and can have impact on the plug performance. Additionally, the impact of the irradiation-hardening must be taken into consideration. 60-year lifespan of the rolled plug which must meet requirements of the new generation of nuclear power plants adds to the significance of the material fatigue and degradation mechanisms which affect component lifespan. The critical area of the plug represents deformed rolling area in contact with the tube where material fatigue is expected to exhibit.

Common approaches for material fatigue are based on stress-life, strain-life and linear elastic fracture mechanics principles. Recently, phase field method has become immensely popular for modelling of material fatigue and fatigue crack growth prediction, based on the energy release rate [1]. At the same time, it can accurately capture material fatigue while taking into consideration thermo-mechanical material properties [2].

The conducted research will provide more information about the impact of the rolling process on the plug fatigue, which can also be used for steam generator tube rolling process simulations and research. Phase field method will provide more detailed insight into harsh nuclear power plant primary circuit conditions which act on the rolled plug performance during whole 60-year lifespan and the safety of the components inside the primary circuit of the nuclear power plant.

MODELING HURRICANE STORM SURGES USING RADIAL BASIS FUNCTIONS: A MESHLESS APPROACH

Vilas Sarsani[*1] and Ethan Kubatko*[1]

[1]*The Ohio State University*

ABSTRACT

Accurately predicting storm surges holds paramount importance for coastal communities grappling with rising sea levels and more frequent extreme weather events. Traditional numerical methods such as Finite Difference, Finite Element, and Finite Volume methods are widely employed for these simulations but face challenges in generating meshes, particularly when handling complex coastlines with rapidly changing bathymetry. In contrast, meshless methods have emerged as a viable alternative, gaining traction in recent years due to their ability to bypass the intricate and laborious steps of mesh generation.

This abstract presents a meshless approach utilizing the radial basis function (RBF) method to solve the shallow water equations (SWEs) and simulate storm surges. The method offers flexibility in node placement and eliminates numerical issues related to element/cell quality. Our method employs a method-of-lines formulation, wherein surface derivatives inherent to the SWEs are locally approximated using RBF interpolation. Additionally, we utilize polyharmonic splines as a radial basis function to circumvent the requirement of specifying an arbitrary shape parameter. This presentation will delve into the intricacies of the RBF method, highlighting its unique capabilities. We will discuss several test cases to showcase the effectiveness and efficiency of our proposed approach in accurately predicting storm surges.

ON REMESHING AND DATA TRANSFER IN THE FINITE CELL METHOD

Roman Sartorti[1] and Alexander Düster*[1]

[1]*Hamburg University of Technology*

ABSTRACT

The numerical analysis of complex geometries in finite element analysis can be challenging because the generation of boundary-conforming meshes of good quality is important to obtain reliable results. This meshing process can be simplified by using immersed-boundary methods such as the finite cell method (FCM). In the FCM the domain is discretised with a Cartesian mesh using high order shape functions. The discontinuity introduced by the immersed boundary requires special treatment during numerical integration. In addition, cells with a low volume fraction tend to distort severely during the numerical analysis. This can be particularly problematic for finite strain analysis, where the tangent stiffness matrix is computed in the deformed state. The large distortions can then cause convergence problems for the incremental/iterative solver.

One way to heal the distorted cells is to apply remeshing. This will be discussed in this presentation, including an analysis of different methods for data transfer during the remeshing process.

QUANTUM ALGORITHM FOR TIME-EVOLVING PARTIAL DIFFERENTIAL EQUATION VIA HAMILTONIAN SIMULATION

Yuki Sato[1,2], Ruho Kondo*[1,2], Tamiya Onodera[3,2] and Naoki Yamamoto[2]*

[1]*Toyota Central R&D Labs., Inc.*
[2]*Keio University*
[3]*IBM Japan*

ABSTRACT

Partial Differential Equations (PDEs) serve in modeling the dynamic behavior of various physical phenomena such as solid mechanics, heat conduction, and fluid dynamics. In contemporary engineering, solving these equations as fast as possible for extremely large-scale systems is crucial for advancing industrial developments. Despite the evolution of supercomputers, solving PDEs for extensive systems within a reasonable timeframe remains a formidable challenge.

Quantum computing, an area garnering significant interest over recent decades, is recognized for its potential to execute computations much faster than classical computers. Although current quantum computers face limitations in hardware scalability and noise resistance, significant advancements in hardware performance have been observed. Notably, quantum computing shows great promise as an efficient solver for PDEs.

In steady-state, PDEs reduce to systems of linear or non-linear equations solvable by linear system solvers. Among the quantum algorithms applicable to these problems, two types are predominantly considered: variational quantum algorithms and the so-called Harrow-Hassidim-Lloyd (HHL) algorithm [1]. Variational quantum algorithms are tailored for near-term quantum devices and have undergone extensive research for PDE applications. Conversely, HHL-based algorithms require fault-tolerant quantum computers, offering theoretical advantages over classical algorithms under specific conditions. For time evolution problems, near-term and long term-quantum algorithms have also been proposed. Variational quantum simulation is a representative method for near-term devices while Hamiltonian simulation is a counterpart for long-term ones [2].

Given the recent progress of hardware toward the era of early fault-tolerant quantum computers, we focus on Hamiltonian simulation for partial differential equations. Specifically, we propose an algorithm for explicitly constructing quantum circuits of time evolution operators for Hamiltonian described by spatial difference operators. The key concept of our method is to quantize PDEs into the qubit system and perform time evolution on the Bell basis. In our presentation, we will showcase several numerical experiments to demonstrate the validity and effectiveness of our proposed method. These experiments suggest the capability of quantum algorithms to handle large-scale PDEs efficiently, which we believe not only advances the field of quantum computing but also opens new avenues in computational mechanics.

NETWORK DYNAMICS OF CARDIAC INFLAMMATION-FIBROSIS COUPLING

*Jeff Saucerman**[1]

[1]*University of Virginia*

ABSTRACT

Inflammation and fibrosis are conserved phases of wound healing in the heart, skin, and other organs. Yet therapeutic attempts at manipulating inflammation and fibrosis have had limited success, indicating a need for greater understanding of how inflammation and fibrosis are controlled by intracellular and intercellular molecular networks. In this talk, I will present our computational and experimental systems biology research on cardiac inflammation and fibrosis. These studies include large-scale computational models of the intracellular signaling networks in fibroblasts, macrophages, and most recently neutrophils, as well as simulations of their intercellular interactions that predict how cardiac cells coordinate inflammation-fibrosis coupling. These computational models highlight a critical role of fibroblast proliferation and its regulation by the scavenger receptor LRP1 via Src and JNK signaling. Our computational models are validated with experimental data from the literature as well as new experiments with fibroblast proliferation and a new fibroblast-specific LRP1 deletion mouse model after myocardial infarction.

A CURVILINEAR SURFACE ALE FORMULATION FOR NAVIER-STOKES FLOW ON DEFORMING SURFACES

Roger Sauer[1,2,3]*

[1]*Gdansk University of Technology*
[2]*Ruhr University Bochum*
[3]*Indian Institute of Technology Guwahati*

ABSTRACT

A new arbitrary Lagrangian-Eulerian (ALE) framework for fluid membranes, such as soap films, bubbles and lipid bilayers, is presented. These membranes are characterized by in-plane fluid flow and out-of-plane elasticity. This leads to the challenging task of describing fluid flow, such as incompressible Navier-Stokes flow, on evolving surfaces. The new formulation extends the surface ALE formulation of [1] to more general surface motions. It is based on a new curvilinear surface parameterization that describes the motion of the ALE frame. Its in-plane part becomes fully arbitrary, while its out-of-plane part follows the material motion of the surface. This allows for the description of flows on deforming surfaces using only surface meshes. The unknown fields are the fluid pressure, fluid velocity and surface motion, where the latter two share the same normal velocity. The new theory is implemented in the nonlinear finite element framework of [2] using the stabilization scheme of [3] for the incompressibility constraint. The implementation is verified through several manufactured steady and transient solutions, obtaining optimal convergence rates in all cases.

CHEMO-MECHANICAL MODEL FOR STRESS CORROSION CRACKING ACCOUNTING MICROSTRUCTURAL HETEROGENEITY

Kumar Saurav[*1] and Siladitya Pal*[1]

[1]*Indian Institute of Technology Roorkee*

ABSTRACT

Stress corrosion cracking (SCC) is one of the most unforeseen phenomena that can result in the catastrophic breakdown of load bearing components in harsh environments across multiple engineering sectors. This occurs primarily because of arbitrary progression of corrosion pits leading to fracture and thus, the ultimate load carrying capacity of structural members for its service life is significantly compromised. Therefore, enlargement of the pits and associated SCC is a strongly coupled chemo-mechanical phenomena. Notably, the development of the complex SCC profile is observed to be substantially influenced by intrinsic microstructural characteristics, such as grain boundary character, grain size and crystallographic texture. Although numerous experimental and numerical studies have been performed to investigate the intertwined SCC phenomena, the influence of microstructural features on the corrosion evolution and subsequent formation of fracture is not addressed rigorously. Therefore, it is utmost necessary to unlock SCC with respect to material heterogeneity and external environmental and mechanical loading conditions towards the service life assessment of the mechanical component.

In the present work, a thermodynamically consistent chemo-mechanical model is developed to account for the evolution of corrosion, deformation and crack formation in heterogeneous materials. The classical Allen-Cahn equation is considered adopting a phase field descriptor for the corrosion field while the phase field fracture method is applied for crack propagation. In the phase field method, the sharp interface is modeled through a continuous field variable. The non-equilibrium thermodynamics will be employed to extract the constitutive relationships and driving forces for evolution laws of order parameters describing corrosion and fracture of material. Using variational principle, the weak forms of the coupled governing equations are extracted. Employing finite element procedure, the discretized equations are obtained for displacement, phase field order parameter for corrosion and phase field variable for fracture. Utilizing Newton-Raphson based staggered iterative procedure, the linearized set of coupled equations will be developed and solved efficiently through an in-house developed parallel computing simulation platform. Upon generating various polycrystalline microstructures, the corrosion pit growth and its transition into crack will be simulated. The effect of crystal orientation will be accounted for in corrosion kinetic parameters as well as elastic moduli. A systematic parametric study will be performed to investigate spatial evolution of the stress corrosion cracking for various grain sizes in different electrochemical conditions under applied external deformation. Finally, predictive estimation of remaining service life will be accomplished for load bearing elements with various chemical and mechanical conditions.

Modeling and simulation for additive manufacturing

ABSTRACT

The emergence of Additively manufactured, commonly referred as 3D printed, bone scaffolds provides a novel treatment avenue for the patients experiencing severe bone infections or injuries from accidents in absence of autografts or allografts as viable options. The effectiveness of these scaffolds hinges on their ability to mimic the natural bone extracellular matrix environment and promote bone regeneration. Kalsi, Singh & Kumar Sehgal emphasize the importance of achieving structural, physiological, chemical, and mechanical similarity to genuine bone for an optimal scaffold [1]. This study is dedicated to assessing the mechanical strength of four alternative scaffold structures and their compatibility with the additive manufacturing (AM) process.

In this study, 20 × 20 × 20 mm3 scaffolds, with diverse structural designs and a porosity of 65%^±0.5, are designed using Dassault Systèmes SolidWorks software. Hexagon Simufact Additive software will be employed to simulate the AM process, capturing deformation and residual stresses in the scaffold structures for both 17-4PH and ceramic materials. Subsequently, numerical models from Simufact will be transferred to Simulia ABAQUS for mechanical testing to assess the mechanical strength of the scaffold structures. The results for each structure and material will be compared to discern their behaviour under loading conditions and their compatibility with AM.
The study aims to evaluate the impact of the AM process on mechanical strength compared to conventional manufacturing techniques and investigate the influence of scaffold structure and material on overall mechanical strength.

MICROSTRUCTURE-INFORMED DATA-DRIVEN MODELING OF MECHANICAL BEHAVIOR OF COLD-SPRAYED ADDITIVELY MANUFACTURED METAL-CERAMIC COMPOSITES

Saman Sayahlatifi[*1], Zahra Zaiemyekeh[1], André McDonald[1] and James Hogan[1]*

[1]*University of Alberta*

ABSTRACT

This study aims to develop a microstructure-based data-driven model to predict the stress-state and- strain-rate-dependent mechanical response of Al-Al2O3 composites fabricated by cold spray additive manufacturing (CSAM). Multiscale finite element modeling is leveraged to generate rich datasets for the training/validation process of the data-driven model. Accordingly, representative volume elements (RVEs) informed by the microstructural characteristics (e.g., Al2O3 particle weight fraction, Al2O3 particle size distribution, and porosity in the Al matrix) of the CSAM composite are randomly generated. For the Al matrix and Al2O3 particle, constitutive material models were implemented by a VUMAT subroutine in Abaqus/Explicit finite element (FE) solver that accounts for the effect of stress state and strain rates on the material failure behavior. The micromechanical FE model was validated with experimental data regarding stress-strain curves and observed failure mechanisms under quasi-static and dynamic loading. Once validated, the multiscale framework was exercised across the space of design variables (i.e., microstructural features) and loading conditions (i.e., stress states and strain rates) for generating datasets for the training and validation of an artificial neural network (ANN); this ANN model correspondingly correlates the macroscale mechanical response of the composite material to its microstructural characteristics. The outcomes indicated that the developed multiscale data-driven model successfully reconstructs the stress-state- and strain-rate-dependent stress-strain response of the material as a function of microstructure. Overall, the current microstructure-based data-driven model has profound implications for the computationally efficient design and optimization of CSAM metal-ceramic composites for clean technology and aerospace applications through (1) Bridging the scales by paving the way for the establishment of a micromechanism-based ML-enabled constitutive model that is implementable in commercial FE packages as a user-subroutine applicable to structural scale modeling, and (2) Being leveraged as a surrogate model in conjunction with multi-objective genetic optimization algorithms for the computationally-assisted design of the material with tailored mechanical properties.

EVALUATION OF CARDIAC FIBROSIS AND INTERVENTION USING COMPUTATIONAL BIOMECHANICS

John Sayut[1], Javiera Jilberto[1], Mia Bonini[1], Will Zhang[1] and David Nordsletten[1]*

[1]*University of Michigan*

ABSTRACT

Chronic heart failure is often caused by irreparable damage to the myocardium, leading to a progressive decline in cardiac function and patient outcomes. Given the global shortage of donor hearts, researchers look to engineered solutions including fabricated tissue patches, stem cell seeding, and devices [1]. The fabrication of heart muscle remains a challenge - with cardiomyocyte maturation and formation of tissue structure loosely approximating adult heart muscle [2]. However, it remains unclear how much benefit could be derived from current engineered muscles in vivo and how to prioritize optimization of structure and function.

Bridging between engineering and application, computational biomechanics enables quantification of the relative influence of maturation and structure on whole organ function. To understand this relative influence, we developed a model by coupling a biventricular solid mechanical model to a zero-dimensional Windkessel systemic flow model [2]. The material law selected represents cardiac tissue properties of viscoelasticity, compressibility, and muscle contraction. To model fibrosis and intervention, a simulated transmural fibrotic patch is defined in the basolateral region of the left ventricle with a linearized border zone. Finite element simulations investigate the driving factors behind functional improvement with alterations to contractility, patch material parameters, and patch fiber orientation.

Each model is studied throughout the cardiac cycle, including an analysis of cardiac functional indicators such as ejection fraction and stroke work. Results show that contractility is a principal contributor to cardiac function - improved myocyte response to activation signals can impressively recover over half of ejection fraction with a purely circumferential myofiber orientation. In addition, the data does also indicate that native fiber alignment improves cardiac function. The native transmural variation better matches the native biomechanics, driving the twisting behavior characteristic of cardiac contraction. Additionally, native hyperelastic stiffness improves cardiac function, especially in the diastolic filling phase. This information illustrates the key engineering decisions facing the current state of cardiac tissue engineering and fibrosis treatment.

COMPLETE VARIABLE KINEMATIC CUF-BASED MULTILAYERED SHELL ELEMENTS

Erasmo Carrera[1] and Daniele Scano[1]*

[1]Politecnico di Torino

ABSTRACT

Shells structures play a crucial role in various engineering applications owing to their efficient load-bearing capacities. However, the evolution of structural materials, such as composite materials, has led to more intricate designs, necessitating rigorous analyses, which lead to a considerable rise in computational costs.

The complexity of analysing these structures primarily arises from anisotropic nature, leading to intricate mechanical phenomena. These problems include challenges such as ensuring continuity between layers for shear components and meeting zig-zag distribution requirements for displacements, commonly known as C0z requirements [1]. The combination of out-of-plane and in-plane strain components increases the intricacy. Thus, the classical theories cannot accurately study such structures. Scholars proposed several refined theories for composite structures, employing two primary modelling techniques: the Equivalent-Single Layer (ESL) and the Layer Wise (LW) approaches. In the ESL approach, mathematical assumptions regarding the displacement field remain consistent across all layers. Consequently, the resulting model encompasses variables for the entire composite structure. Conversely, the LW approach involves distinct variables described in each layer, while ensuring mechanical characteristics' continuity at the interlaminar level.

The primary objective of this study is to approach shell analysis from a new perspective, wherein each displacement field can be approximated using an appropriate structural theory. For instance, employing advanced LW theories for in-plane displacements and ESL models for transverse displacements. The Carrera Unified Formulation (CUF) [2] serves as the tool enabling the implementation of each theory in a simple and hierarchical manner within a Finite Element (FE) framework The novel CUF uses nine scalar Fundamental Nuclei, whose formulation does not change with the chosen kinematic theory.

The study comprehensively analyses shells, ranging from thick to thin structures. To counteract the shear and membrane locking of the FE methods, the Mixed Interpolation of Tensorial Components is implemented in the formulation [2]. The analysis employs nine-node Lagrangian elements as shape functions and considers diverse boundary conditions and loading types. Both displacement and stresses can be accurately described. The results lead to interesting conclusions: (a) it is possible to reduce computational costs using only the significant terms; (b) the number of effective variables depends on the specific problem; (c) implementing the Mixed ESL/LW approach proves to be efficient.

STORM SURGE MODELING ON THE FJORDS OF NORWAY WITH ADCIRC

Matthew Scarborough[*1] and Eirik Valseth*[1]

[1]*Norwegian University of Life Sciences*

ABSTRACT

Storm surge and coastal hazards can have devastating consequences for a coastal nation like Norway, especially considering sea level rise due to climate change. Since 2011, the Norwegian Directorate of Civil Protection (DSB) has been publishing guidelines on dealing with these issues in local planning.[1] We present a finite element model, which is necessary to better understand and predict the impacts of storm-induced flooding in Norway.

The Norwegian Meteorological Institute (MET) has been modeling the coast for a variety of applications; however, both of these models are difficult to scale to higher resolutions. The finest one, NorKyst-800, has a resolution of 800 meters, and while they both model the shallow-water equations, they use a uniform grid with finite difference methods.[2] The global finite element model, STOFS-2D, is still relatively coarse in Norway.[3]

In order to better model the complexity of Norway's fjords, a much finer coastal resolution is required. We can then see the effects of flooding further into the fjords, and eventually allow for more complex models, such as compound flooding. To this aim, present a new grid of Norway's coast at a variety of resolutions, down to about 30 meters, including limited topography information to assist with flood modeling.

We use the Advanced CIRCulation model (ADCIRC) with these new meshes to simulate the effects of tides and winds along the shoreline, beginning with a smaller-scale mesh of the Oslo fjord, and continuing with the full coastal mesh. The results from these are compared to the results from NorKyst-800, as well as MET water level gauges in various locations.

[3]*Gran Sasso Science Institute*

ABSTRACT

The development of digital twins of the cardiovascular (CV) system presents several challenges, for example, in achieving custimization to induvidual patients. While Fluid-structure interaction (FSI) models represent one of the best high-fidelity tools for this purpose, their practical application is often constrained by the necessity of multiple patient-specific parameters that remain unknown. Although medical imaging provides large amounts of in-vivo data, its full integration into in-silico models still faces several problems.

This study employs data assimilation techniques to merge dynamic CT scan data with an FSI simulation to create a high-fidelity digital twin of a patient's left ventricle (LV) and aorta. An ECG-gated CT scan of a patient is used to obtain segmentations of the aorta and LV lumen boundaries at each of the 20 cardiac phases acquired. Lagrangian markers are defined on these surfaces and tracked over time employing a gradient-based registration method [1]. Data-driven FSI simulations are performed using an in-house code based on the Immersed Boundary method [2]. Data assimilation is applied to the dynamics of the CV structures to conform to in-vivo kinematics. A variation of the Nudging technique [3] is developed to simultaneously integrate local and integral measurements. For anatomical regions where in vivo data is accurate, local measurements guide each Lagrangian marker. Conversely, in areas with less reliable data, nudging is applied to follow integral measurements, such as tracking the LV volume over time.

The methods used in this study allow for the accurate reproduction of the kinematics of the cardiovascular structures, which is crucial in capturing hemodynamics as well. The method effectively transitions from a purely FSI-based simulation to one driven by kinematics, offering enhanced adaptability in the simulation process. This flexibility allows for testing various scenarios to derive the most precise outcomes.

NOVEL QUADRATURES IN CONTINUUM-KINEMATICS-INSPIRED PERIDYNAMICS

Emely Schaller[*1], Ali Javili[2] and Paul Steinmann[1]*

[1]*Friedrich-Alexander-Universität Erlangen-Nürnberg*
[2]*Bilkent University*

ABSTRACT

Continuum-kinematics-inspired peridynamics (CPD) [1] is an extension to peridynamics (PD) [2] that can capture the Poisson effect correctly and in addition does not suffer from zero energy modes. (C)PD is a nonlocal continuum mechanics formulation, where every continuum point interacts with continuum points in its finite-sized neighbourhood, the so-called horizon. CPD, in contrast to PD, classifies the interactions in one-, two- and three-neighbour interactions dependent on the number of contributing neighbours. Considering the change in pair-length, triplet-area and tetrad-volume allows CPD to be a geometrically exact formulation and to reflect the Poisson effect in 2D and 3D problems.

The nonlocal interactions between continuum points result in integro-differential governing equations that depend consequently on the integration over the horizon. It is difficult to solve the integro-differential equations analytically, which is why numerical methods need to be exploited. In (C)PD models, the continuum is typically discretized by a finite number of so-called collocation points, at which the governing equations are evaluated. The collocation points can additionally serve as integration points for the quadrature of the horizon. This method is commonly used for (C)PD models despite its dependence of the integration accuracy and computational cost on the discretization. To address this problem, we established a novel quadrature for (C)PD, where the integration and collocation points no longer necessarily coincide. To do so, we align the integration points in a hexagonal pattern for 2D problems and evaluate the governing quantities at the integration points by interpolating the governing quantities of the collocation points with either linear or quadratic interpolation schemes. Thus, our novel quadrature of the horizon in 2D has a fixed number of six integration points and is independent of the discretization of the continuum with respect to the computational cost.

We validate the accuracy of our novel quadrature by various numerical examples. The results of the novel quadrature show a good accuracy and are in good accordance with the results obtained with the quadrature dependent on the discretization, while the computational cost is reduced tremendously. In future work, we want to extend our approach to 3D problems.

3D-ACA FOR THE TIME DOMAIN BOUNDARY ELEMENT METHOD: COMPARISON OF FMM AND H-MATRIX BASED APPROACHES

Martin Schanz[1]*

[1]*Graz University of Technology*

ABSTRACT

The time domain boundary element method (BEM) for the homogeneous wave equation with vanishing initial conditions is considered. The generalized convolution quadrature method (gCQ) developed by Lopez-Fernandez and Sauter [2] is used for the temporal discretisation. The spatial discretisation is done classically using low order shape functions. A collocation approach is applied for the Dirichlet problem and a Galerkin approach for the Neumann problem.

Essentially, the gCQ requires to establish boundary element matrices of the corresponding elliptic problem in Laplace domain at several complex frequencies. Consequently, an array of system matrices is obtained. This array of system matrices can be interpreted as a three-dimensional array of data which should be approximated by a data-sparse representation. The multivariate Adaptive Cross Approximation (3D-ACA) [1] can be applied to get a data sparse representation of these three-dimensional data arrays. Adaptively, the rank of the three-dimensional data array is increased until a prescribed accuracy is obtained. On a pure algebraic level it is decided whether a low-rank approximation of the three-dimensional data array is close enough to the original matrix. Within the data slices corresponding to the BEM calculations at each frequency either the standard H-matrices approach with ACA or a fast multipole (FMM) approach can be used. The third dimension of the data array represents the complex frequencies. Hence, the algorithm makes not only a data sparse approximation in the two spatial dimensions but detects adaptively how much frequencies are necessary for which matrix block.

In the presentation, this methodology is recalled and both versions either using H-matrices in the slices or FMM will be compared. The study is numerically performed at selected examples as the mathematical analysis gives the same complexity. Nevertheless, the performance of the algorithm differs.

ADVANCING DATA-INTEGRATED TIME STEP ESTIMATION TO IMPROVE SIMULATION PERFORMANCE

Maximilian Schilling[*1], Tobias Willmann[1] and Manfred Bischoff[1]*

[1]*University of Stuttgart*

ABSTRACT

In explicit finite element simulations for structural dynamics, a stable computation is only possible when the chosen time step is smaller than the critical time step of the discretized system. However, computing the critical time step exactly by solving the corresponding eigenvalue problem is numerically too expensive. To circumvent this, there are several approaches to estimate the critical time step of a system, many of them through an estimation on the element level.

One widely used inexpensive approach is the estimation of the critical time step of a finite element via heuristic formulas based on geometric quantities. By means of these a characteristic length is calculated for an element. An estimate for the critical time step is then obtained by dividing this characteristic length by the wave speed.

For instance, the characteristic length of a 2D solid element can be calculated by the element area divided by its longest side or its longest diagonal. However, the resulting time step estimate is not necessarily conservative, which necessitates the introduction of a safety factor to prevent simulation instabilities. For more complex elements the estimate can be even less accurate, as many influencing factors may be neglected when heuristic formulas are used.

On the contrary, data-integrated time step estimation [1, 2] utilizes representative data sets of all relevant element shapes to develop new, accurate time step estimators. Building upon the concept of data-integrated time step estimation, this contribution extends the methodology to a broader range of finite elements and situations, showcasing the adaptability and reliability of the method. Our goal is to demonstrate the effectiveness of data-integrated time step estimation to find accurate time step estimators for complex finite elements. Through our work, we show how this approach can enhance simulation speed and simulation robustness in real-world engineering scenarios.

This research was funded partly by the project DigiTain 19S22006K and partly by the IGF project no. 21466 N by the Federal Ministry of Economic Affairs and Climate Action based on a resolution of the German Bundestag. This support is gratefully acknowledged.

A COUPLED LAGRANGIAN/SEMI-LAGRANGIAN QUASI-CONFORMING EMBEDDED RKPM WITH SMOOTH CONTACT ALGORITHM FOR MODELLING PENETRATION PROBLEMS

Ryan Schlinkman[*1], Jonghyuk Baek*[21] *and Jiun-Shyan Chen*[1]

[1]*University of California, San Diego*
[2]*Coreform, LLC*

ABSTRACT

Key Words: Reproducing Kernel Particle Method, Meshfree Methods, Lagrangian Embedded Methods, Immersed Methods, Quasi-Conforming, Smooth Contact, Energy-Based Contact Algorithm, Multi-Body Contact

We present a coupled Lagrangian/semi-Lagrangian (L-SL) [1], quasi-conforming embedded reproducing kernel particle method (QCE-RKPM) [2] with an enhanced RK smooth contact algorithm [3] for modelling penetration problems. Due to the extreme deformation caused by the penetration process in the form of fracture, fragmentation, and localized shear, the semi-Lagrangian RKPM is utilized only in the areas of extreme deformation, while a Lagrangian RKPM description is used elsewhere. This coupling maintains accuracy in the approximation while improving computational efficiency. Furthermore, the quasi-conforming embedded technique is employed which combines adaptive refinement in the penetrated material ahead of the projectile's path with a variational consistency correction that allows two non-conforming discretizations in contact to pass the contact patch-test thus improving the accuracy and convergence of the contact algorithm. Lastly, RK smooth contact, a node-to-surface contact algorithm which constructs a smooth master surface using the RK approximation for greater accuracy and stability in the contact force and master surface approximation, is enhanced by utilizing spherical representations of the slave nodes and employing an energy-based contact formulation for enforcing the impenetration constraints. This enhancement improves contact detection for coarse slave discretizations while reducing the effect of mesh-dependency. These coupled techniques offer a robust and efficient computational framework for modelling penetration problems.

ERROR-CONTROLLED MULTI-LEVEL HP FINITE CELLS IN THE REALM OF ELASTOPLASTIC ANALYSIS

Jan Niklas Schmäke[*1], Oliver Wege[1] and Martin Ruess[1]*

[1]*Hochschule Düsseldorf*

ABSTRACT

The idea of hp-refinements has established as the method of choice for the analysis of non-smooth solution fields in the finite cell method [1] to ensure a stable and reliable convergence behavior in both, linear and non-linear analysis. In the context of higher order approximation, an adapting hp-refinement over multiple overlay meshes has proven to be an extremely valuable extension, overcoming many of the issues from the established refinement techniques [3, 2].

In this talk, we present an extension of the adaptive multi-level hp-refinement to plasticity problems. Moreover, we show an efficient error-control method to decide about the cell-wise need for refinement [2]. The presented approach allows for an independent local h- and p-refinement to improve the solution in smooth and non-smooth regions of the problem domain. The local refinements are performed automatically through different error- estimators based cell-specific measures. We assess the performance of the proposed method with benchmark problems and compare our results to other established refinement approaches. Finally, we demonstrate the applicability of our extensions with problems from the engineering routine.

SIMULTANEOUS EQUATION OF STATE PARAMETER CALIBRATION AND ESTIMATION OF EPISTEMIC UNCERTAINTIES IN EXPERIMENTAL DATA

Abigail Schmid[1] and Stephen Andrews*[1]

[1]*Los Alamos National Laboratory*

ABSTRACT

This study aims to simultaneously calibrate the parameter values, with uncertainty, in the Davis Reactants Equation of State (EOS) and estimate epistemic uncertainties in experimental data for the high explosive (HE) PBX 9501.

Bayesian methods are often used to calibrate EOS parameters with uncertainty given experimental data [1-2]. However, it is not uncommon for those experimental data to have poorly characterized uncertainties or be provided without uncertainty information altogether. A common solution is to assume 10% error on the experimental measurements, but this is just a guideline and might not be applicable for any given dataset. Thus, we seek to estimate the experimental errors from the data within the calibration problem.

In this study we formulate the Bayesian parameter calibration as a constrained optimization problem where we seek the EOS parameter values and experimental errors which maximize the log-posterior probability. The types of experimental data used to form the likelihood for the calibration include Hugoniot, specific heat capacity, and thermal expansion tests on the HE and its components. The constrained optimization problem was solved with Sequential Least Squares Programming.

We found optimal posterior EOS parameter values that are consistent with previously calibrated values for the same material [3] and improve the fit of the EOS to the experimental data compared to the prior. We also estimated that the experimental errors range between 5% - 30% depending on the dataset, so the 10% error assumption is not appropriate for all the considered datasets. This study provides a framework for simultaneously calibrating model parameters and estimating epistemic uncertainty in the form of unknown experimental errors.

MULTI-MATERIAL TOPOLOGY OPTIMIZATION WITH CONFORMAL ANALYSIS MESHES

Mathias Schmidt[1], Jorge-Luis Barrera[1], Kenneth Swartz[1], Ketan Mittal[1] and Daniel Tortorelli[1]*

[1]*Lawrence Livermore National Laboratory*

ABSTRACT

The promise of Topology Optimization (TO) is to provide engineers with a systematic computational tool to support the development of optimal designs. Multi-material topology optimization further allows for a larger design space and as such may result in better performing designs. Moreover, multi-material optimization enables the efficient design of active structures. A shortcoming of classic density based multi-material TO designs is the nebulous interphase region between materials, which leads to inaccurate response predictions in these very regions. In contrast, designs based on boundary and interface regions, rather than interphase regions, yield accurate response predictions.

In this study, we develop a multi-material Level-set (LS) topology optimization approach in which geometries are described through the iso-contour of one or multiple LS fields which are discretized over a mesh. The nodal heights, serve as the design parameters. The governing field equations are discretized by a conformal discretization over a separate “analysis” mesh. In the optimization, the “analysis” mesh is morphed such that its boundary and interfaces conform with the isocontours of the LS fields. The mesh morphing is performed using the Target-Matrix Optimization Paradigm (TMOP) approach. Our TMOP formulation is a PDE based mesh morphing operation which aims to improve the interface conformity while preserving mesh quality. Design sensitivities of the optimization cost and constraint functions with respect to all design LS fields are computed through an adjoint approach which accounts for the mesh morphing process. Higher-order basis functions are used for discretizing both the governing equations and the LS fields. The proposed analysis and optimization framework is based on MFEM, a free, lightweight, scalable C++ library for finite element methods which supports the optimization of large-scale optimization problems.

We investigate the robustness of the proposed optimization methodology by solving two- and three-dimensional multi-material optimization problems involving linear diffusion and elasticity. We discuss the advantages and challenges of our approach with regards to the mesh morphing process. Finally, select aspects and challenges of our approach with respect to parallel computing and processor decomposition are discussed.

CONFIGURATIONAL FORCES FOR EFFICIENT CRACK GROWTH SIMULATIONS WITH THE VIRTUAL ELEMENT METHOD

Kevin Schmitz[*1] and Andreas Ricoeur*[1]

[1]*University of Kassel*

ABSTRACT

The virtual element method (VEM) [1] is an efficient discretization scheme for the numerical solution of boundary value problems on polytopal grids, which is most prominently known for offering considerable flexibility in the discretization process. In the context of numerical applications of fracture mechanics, one of its most attractive features results from the possibility to employ elements of complex shape with an arbitrary number of nodes, which may be convex as well as non-convex and may even contain crack tips. Consequently, crack growth simulations with the VEM benefit from the fact that incremental changes in the geometry of a crack do not require any remeshing of the structure, but rather crack paths can run through already existing elements, enabling the realization of very efficient simulations in terms of computational cost.
Although the method provides a valuable tool for modelling crack propagation, there is still research required regarding the implementation of efficient and precise methods to evaluate crack tip loading quantities and crack deflection criteria. Therefore, the concept of configurational forces in material space is employed, which already proved to be very efficient for the calculation of these quantities in the context of the FEM. However, the calculations yield certain numerical difficulties that need to be dealt with, e.g., due to discontinuous stresses and strains at element edges in the vicinity of the crack tip, and require additional effort in connection with curved crack faces [2].
This work aims to discuss theoretical and computational aspects of employing configurational forces for mixed-mode crack growth simulations in the VEM. A framework for calculating nodal configurational forces is presented and comparative studies are conducted, carefully investigating challenges and opportunities emerging from the discretization method for assessing crack tip loading and crack path prediction. Furthermore, virtual elements are modified to align their approximation power with the singular behaviour at crack tips in linear elastic fracture mechanics. Crack growth simulations are presented, and results are compared to reference solutions as well as solutions obtained with the FEM.

ABSTRACT

A number of challenges and issues arises when modeling multicomponent and multiphase solid alloy systems. Multiphase-field methods provide a numerically efficient framework for the prediction of microstructure evolution without the need for grain boundary tracking. Due to their usage in a wide range of fields and their constant development it is crucial to establish standardized benchmarks. Within this work, a series of chemo-elastic equilibrium stages for Fe-C binary alloys is discussed. These simulations contribute to the development of standard benchmarks that validate separately as well as the combination of chemical, capillary, and mechanical driving forces. To this end, a multiphase-field model with chemo-elastic coupling is employed [3]. Sharp interface solutions are recovered by mechanical driving forces employing the jump condition approach [2] and chemical driving forces based on the grand potential density [1]. The Gibbs free energy is approximated using parabolic functions that incorporate parameters from a Calphad database. Thermodynamic and mechanical equilibrium conditions are provided by the sharp interface formulation. The Gibbs-Thomson equation provides an interfacial equilibrium condition. Analytical solutions are derived from these conditions and compared with phase-field simulations.

ABSTRACT

We present a comprehensive investigation into the phase-field simulation of fracture accounting for inhomogeneous material properties. Fracture mechanics plays a pivotal role in understanding the structural integrity of materials, and the phase-field approach provides a powerful framework for capturing crack propagation in a continuous and numerically efficient manner. However, incorporating realistic variations in material properties poses a significant challenge for accurately predicting fracture behavior in heterogeneous structures.

Our study addresses this challenge by integrating a phase-field fracture model with a detailed representation of inhomogeneous material properties. Therefore, we consider the example of Tooth Flank Fracture in case hardened spur gears (TFF) [1]. We adopt a phase-field model that combines classical fatigue damage calculation with the phase-field method [2,3], allowing for the simulation of fatigue crack initiation and propagation in materials with spatially varying mechanical properties. The proposed methodology accounts for the impact of material heterogeneity on crack initiation location, fracture patterns, critical load cycle numbers, and crack paths. The numerical framework is validated against experimental data, demonstrating its capability to capture complex fracture phenomena in the strongly inhomogeneous example of TFF. A more detailed investigation requires the consideration of the actual microstructure to understand crack initiation and early crack growth more. We therefore showcase the versatility of our approach by a general study on the incorporation of resolved microstructures. In a first step the choice of numerical solvers, modelling strategy and general challenges of the extension of phase-field fracture simulations to lower material scales are discussed. Relevant numerical examples are shown and underline the necessarily statistical evaluation of such simulations.

MATERIAL REMOVAL OF A CONVEX PATTERN SURFACE INTERACTING WITH NON-SPHERICAL PARTICLES: A NUMERICAL STUDY

Yunpeng Yan[12], Skirmantas Pargalgauskas[1], Rudy Helmons[1] and Dingena Schott[1]*

[1]TU Delft
[2]Jilin University

ABSTRACT

A convex pattern surface is proposed and optimized to mitigate the sliding wear of bulk handling equipment caused by interaction with bulk solids. This work investigates the effectiveness of the convex pattern surface on wear reduction during interactions with non-spherical particles. Multiple representative particles, obtained through a sampling method, are reconstructed using a photogrammetry technique. Two contact parameters between particles are calibrated through shear box and drawdown tests to ensure flow behavior similar to the real material. The numerical results indicate that the convex pattern surface can effectively reduce wear compared to a plain sample when involving both spherical and non-spherical particles. For a plain sample, the wear volume remains independent of particle shapes and increases linearly with numerical revolutions. For the convex pattern surface, the wear volume demonstrates a quadratic relationship with the test revolutions as the deformation of convex elements weakens the effectiveness of the sample on wear reduction. The particle flow behavior analysis reveals that the convex pattern surface experiences the lowest wear volume when in contact with non-spherical particles. This can be attributed to the non-spherical particles sliding shorter distances and rotating with higher angular velocities on the convex pattern surface.

MODELING OF DAMAGE IN FIBER-REINFORCED HIGH-PERFORMANCE CONCRETE AT LOW CYCLE FATIGUE USING A PHASE-FIELD REGULARIZATION

Jörg Schröder[*1], Mangesh Pise[1] and Dominik Brands[1]*

[1]*University Duisburg-Essen*

ABSTRACT

Fiber-reinforced high-performance concrete (HPC) shows a pseudo-ductile material be- havior during failure, mainly characterized by complex fiber-matrix interactions. We propose a phenomenological material model to discuss the influence of reinforced fibers, represented by orientation distribution functions (ODF), on the failure process of HPC. Therein, an additive type macroscopic energy function is formulated, superimposing the models of one-dimensional elastoplasticity for the steel fibers and an elastoplastic phase- field fracture model, cf. [1], which can predict the nonlinear behavior of high-performance concrete (HPC) during low-cycle fatigue. We apply the pressure-sensitive Drucker-Prager yield criterion as a basis for pure concrete behavior. A phase field model is used to reg- ularize the softening behavior of the material; otherwise, we can expect a pathological response in the finite element method. Two different data-driven degradation functions are calibrated to model the asymmetric tension-compression behavior of HPC, see [2]. Three-point bending experimental tests at low-cycle using notched beams are performed, and the experimental load-CMOD (crack mouth opening displacement) curves are used to calibrate the proposed numerical model. ODFs approximate different distributions and orientations of reinforced fibers, see [3]. The accuracy of the proposed numerical model is verified by comparing the degradation of stiffness in numerical and experimental results.

MATRIX-FREE HIGHER-ORDER FINITE ELEMENT SOLVERS IN TISSUE MECHANICS

Richard Schussnig[*1] and Martin Kronbichler*[1]

[1]*Ruhr University Bochum*

ABSTRACT

Finite element methods play a fundamental role in science and engineering, where low-order approximations are particularly prominent for practical applications. Classical algorithms rely on matrix-based iterative solvers and related preconditioners for implicit solution. However, the time-to-solution of such implementations is mainly determined by memory bandwidth, which determines the speed at which the precomputed and stored matrix entries can be loaded from main memory to evaluate sparse matrix-vector products within iterative solvers. Since modern computer architectures can execute more than 100 arithmetic operations for each variable transferred from memory, so-called matrix-free approaches are getting increasingly attractive. These methods redundantly evaluate the action of the linear operator from the underlying finite element integrals on a vector (see, e.g., [1, 2] for general nonlinear solvers for nodal high-order finite elements). First, such schemes were developed for fluid-mechanics problems building on results of the spectral element community, but recent advances [3, 4] have shown that they can also be fruitfully applied to solid mechanics problems.

Within this work, we focus on static nearly-incompressible hyperelasticity considering anisotropic effects stemming from dispersed fibers as often applied in the context of tissue mechanics. Starting from [3], which focused on isotropic compressible hyperelasticity, we extend the concept towards the nearly-incompressible anisotropic case. A matrix-free approach is presented, combining sum-factorization and tensor-product continuous, higher-order finite elements with hp-multigrid preconditioned Krylov methods. A purely displacement-based approach is chosen, weakly enforcing incompressibility via a penalty term.

The classical total Lagrangian form and an alternative reformulation based on integration in the spatial configuration are investigated in terms of their computational efficiency. These alternative formulations constituting the linearized operator are carefully evaluated in terms of relevant performance metrics, comparing to a matrix-based implementation with an algebraic multigrid preconditioner. We show that matrix-free methods for finite-strain hyperelasticity are indeed promising in both benchmark problems from biomechanics and patient-specific models of vascular tissue, while user adaptations of the constitutive law can be accomplished being largely agnostic toward the remaining implementation.

A HIGH-ORDER EULER-LAGRANGE APPROACH FOR PARTICLE-LADEN FLOW IN MOVING DOMAINS

Anna Schwarz[*1], Patrick Kopper[1] and Andrea Beck[1]*

[1]*University of Stuttgart*

ABSTRACT

Compressible flows with suspended particles occur in a wide variety of applications, e.g., spray injections or aeronautical engineering. Many of these applications can include rotating geometries and/or the altering of component's surfaces through, e.g., icing or erosion, resulting in complex, highly transient multiscale and multiphysics problems. One of the challenges of such problems is to adequately describe the time-resolved coupling between the chosen moving mesh approach and the particle method, while maintaining the efficiency of the resulting numerical scheme.
In this talk, we present the extension of our high-order accurate massively parallel discontinuous Galerkin spectral element framework FLEXI [1,2] towards particle-laden flows in moving domains. The framework is based on the Euler--Lagrange approach and has been previously applied to wall-resolved large-eddy simulation of high-Reynolds number flows with a one- and two-way coupled dispersed particulate phase, delivering accurate results while maintaining excellent scaling up to tens of thousands cores. Rotating geometries will be represented by a sliding mesh method, while for the altering of component's surfaces, a mesh movement based on the arbitrary Lagrangian-Eulerian approach is chosen. Special care is taken to retain the optimal scaling properties of FLEXI. This work concludes by presenting examples of large scale computations for particle-laden flows in complex, possibly moving systems and giving an outlook on the next research challenges.

[2]Linnaeus University
[3]XAIS Asset Management Ltd.

ABSTRACT

For the design of robust timber buildings, it is essential to develop reliable methods to assess possible brittle failure of connections. Therefore, in this contribution a three-step modeling approach was implemented in the ABAQUS finite element software to predict (i) the single fastener behavior, (ii) the stress distribution between fasteners and (iii) brittle failure of the timber in laterally loaded connections with steel dowels and slotted-in steel plates. The local nonlinear behavior of single-dowel connections was determined utilizing a beam-on-foundation (BoF) approach [1]. In the subsequent step, the timber member and the steel plate were modeled using 3D shell elements with linear-elastic orthotropic and isotropic material properties, respectively. In this step, the load-displacement behavior of the single-dowels from the BoF model was represented by nonlinear springs located at the connection shear planes. The interaction between rigid cylinders, representing the dowel, and the 3D shell elements, representing the timber and steel members, was characterized by defining hard contact in the normal direction and friction in the tangential direction. To evaluate potential brittle failure of the timber, a post-processing module was integrated into a Python script based on the mean stress method utilizing linear fracture mechanics as proposed by Gustafsson [2]. The stress distribution was obtained for each load increment during the numerical analysis. Subsequently, the mean stress length was calculated for various potential failure paths along the grain direction. The failure criteria were assessed for each pre-defined path and load increment to identify the critical path and estimate the connection's load-bearing capacity. The numerical model accurately fitted previous experimental tests regarding load-carrying capacity and connection slip. The novel combination of modeling the nonlinear connection behavior with the finite element method and assessment of potential brittle failure with linear fracture mechanics, gives access to a realistic load distribution among the fasteners in a multiple-fastener connection, for a reliable prediction of crack initiation in the timber matrix, while taking advantage of high computational efficiency.

NEURAL GALERKIN SCHEMES THAT CAN PRESERVE HAMILTONIANS AND OTHER QUANTITIES

Paul Schwerdtner[*1], Philipp Schulze[2], Jules Berman[1] and Benjamin Peherstorfer[1]*

[1]*New York University*
[2]*Technische Universität Berlin*

ABSTRACT

Neural Galerkin schemes, based on the Dirac-Frenkel variational principle, train nonlinear parametrizations sequentially in time to approximate solution fields of time-dependent partial differential equations. Due to the nonlinearity of the parametrizations, few parameters efficiently capture even complex dynamics in first-principles-based physical models. Such models are often constructed based on the observation that quantities like energy, mass, and momentum remain constant over time, representing conserved quantities of the physical system. In this talk, we demonstrate how we can modify Neural Galerkin schemes such that these quantities are also conserved quantities in the approximate solutions produced by Neural Galerkin schemes.

We first show that only adding constraints that aim to conserve quantities in continuous time can be insufficient because the nonlinear dependence on the parameters implies that even quantities that are linear in the solution fields become nonlinear in the parameters and are thus not conserved by standard Runge-Kutta time integration schemes. Instead, we propose Neural Galerkin schemes that compute an embedding onto the manifold of nonlinearly parametrized solution fields that conserve given quantities at each time step. We present numerical experiments that show the effectiveness of our proposed method to preserve given quantities up to machine precision. The talk is based on our preprint [1].

NONLOCAL BOUNDARY VALUE PROBLEMS WITH LOCAL BOUNDARY CONDITIONS

James Scott[*1] and Qiang Du*[1]

[1]*Columbia University*

ABSTRACT

We state and analyze nonlocal problems with classically-defined, local boundary conditions. The model takes its horizon parameter to be spatially dependent, vanishing near the boundary of the domain. We establish a Green's identity for the nonlocal operator that recovers the classical boundary integral, which permits the use of variational techniques. We show the existence of solutions, as well as their variational convergence to classical counterparts as the horizon uniformly converges to zero. In certain circumstances, global regularity of solutions can be established, resulting in improved modes and rates of variational convergence. We also show that Galerkin discretization schemes for the nonlocal problems converge unconditionally with respect to the nonlocal parameter, i.e. that the schemes are asymptotically compatible.

[2]*CIMNE*
[3]*CIMNE - University of Catalonia*
[4]*TU Braunschweig*

ABSTRACT

Isogeometric Analysis (IGA) has established itself as a very successful framework for computational mechanics, with broad applications to fundamental and industrial problems. In recent years, great focus has been dedicated to the application of IGA to CAD models which include trimmed surfaces. One of the challenges that trimmed surfaces pose is that they make the geometric description with NURBS more complex. It is for this reason that immersogeometric techniques have been pursued, which however require the integration of the IGA variational forms on cut NURBS supports. We present an alternative approach based on the recently developed Shifted Boundary Method. Complex data structures and integration on cut elements are avoided by means of an approximate boundary representation and a modification (shifting) of the boundary conditions via Taylor expansions. This approach maintains optimal accuracy while greatly simplifying the practical implementation. We show a prototypical example in the context of the Poisson equation.

BEYOND LUBRICATION FLOW FOR THIN-FILM MANUFACTURING

Robert Secor[1], Rekha Rao[2] and Weston Ortiz[1]*

[1]*University of New Mexico*
[2]*Sandia National Laboratories*

ABSTRACT

Reynolds' hydrodynamic lubrication theory has been used extensively to analyze and quantify thin-film manufacturing (Roberts et al. 2013). Applications span liquid flows in bearings, coatings, and molds, and gas flows between rigid or elastic surfaces. To enable further applications of efficient, reduced-order modelling, we pursue streamlined algorithms for non-Newtonian liquids in marginally "thin" geometries with multiple phases and capillarity. The goal is expanded use of "modified", non-traditional lubrication methods to bring physics-based knowledge to bear in process design, optimization, and control methods.

Reynolds' lubrication applies to Newtonian fluids through thin flow channels. Accommodation for non-Newtonian flow behavior via generalized Newtonian constitutive relations can be achieved with the aid of variable transformations. The known stress-rate relation for a particular non-Newtonian rheological model can be transposed to yield pressure-drop/flowrate relationships of non-Newtonian lubrication flow. For non-moving boundaries, non-Newtonian lubrication can be formulated as one mass conservation and one momentum balance equation. When one or more channel boundaries are moving, the momentum balance expands to three equations to fully capture the shear-rate coupling between different momentum transport mechanisms.

For marginally high aspect-ratio flow channels, side walls exert significant drag on the flow that is not present in Reynolds' theory. An effectively lower liquid permeability instituted through a wall distance function suitably captures sidewall drag. Liquid-gas interfaces in filling applications are captured using level set tracking. Surface tension forces for high and medium Capillary Number flows are an additional lubrication modification. By combining an analytical thickness direction curvature with an in-plane level-set curvature field, wetting and de-wetting behavior are added to reduced-order lubrication modeling.

Non-Newtonian rheology, sidewall drag, and capillary forces are added to make a "modified" lubrication model. The resulting reduced dimensionality (3D flow problems are reduced to 2.5D) promises a "step change" in model efficiency leading to increased capability for model size and complexity. We demonstrate this reduced order method on the flow of Newtonian and power-law liquids through a patterned channel and find good agreement compared to a fully three-dimensional approach.

REALISTIC RVES BY MICROSTRUCTURE RECONSTRUCTION: HARNESSING DESCRIPTOR DIFFERENTIABILITY

Paul Seibert[*1], Alexander Raßloff[1], Karl Kalina[1] and Markus Kästner[1]*

[1]TU Dresden

ABSTRACT

One of the most important pillars supporting the digitization and acceleration of materials engineering is microstructure reconstruction and characterization (MCR). Specifically, MCR is needed for the following tasks: (i) creating a 3D computational domain that makes sense from 2D data, such as a microscopy image; (ii) reconstructing a small, periodic domain from a large, aperiodic CT scan; (iii) creating a set of statistical volume elements from a single reference; and (iv) enhancing microstructure datasets by sampling and interpolating in the descriptor space and then reconstructing the corresponding microstructures. The specific focus of this contribution is on descriptor-based MCR, in which the statistical microstructure description is given directly. Descriptor-based MCR has an advantage over machine learning-based MCR in that it does not need a data set. Instead, it can be used to create it, making data-driven modeling and simulation possible on otherwise insufficient amounts of data.

After a brief introduction to the underlying concepts, the potential of differentiable descriptors is analyzed in depth. As a first example, it makes the use of gradient-based optimization algorithms possible, reducing the number of iterations by orders of magnitude when compared to the Yeong-Torquato algorithm [1,2]. This is discussed alongside with a validation [3] and an implementation [4]. Secondly, this also applies to non-voxel-based structures, as is demonstrated by analytical solutions for ellipsoidal inclusions [5]. Thirdly, instead of solving a new optimization problem for each realization of a medium, a neural cellular automaton can be trained to identify a PDE system that generates structures very efficiently. Therein, the descriptors define the loss function and not data set us required. Finally, (approximate) gradient projection operators can be defined for individual descriptors, increasing the computational and memory efficiency even further.

CALIBRATION OF HYBRID CONSTITUTIVE MODELS FROM FULL-FIELD DATA

Daniel Seidl[*1], Brian Granzow[1], Reese Jones[1] and Ravi Patel[1]*

[1]*Sandia National Laboratories*

ABSTRACT

Constitutive models play a vital role in computational simulations, where they serve as closure relations for the general conservation laws of physics. Calibration is the process of estimating the parameters in a constitutive model from experimental characterization data. Generally, experiments provide indirect measurements of a material's response (e.g. applied force vs extension), which can only be directly related to constitutive model outputs in special circumstances (e.g. uniaxial stress in a tensile test prior to necking). In recent years there have been efforts to combine conventional constitutive models with machine learning (ML) components to produce hybrid constitutive models with the promise of increasing predictive accuracy and/or providing flexibility in the calibration process.

However, the scientific ML research community overwhelmingly favors training data in the form of direct constitutive model responses (e.g. stress-strain data from another model). This focus on direct measurements is stifling progress by divorcing ML models from their ultimate application within large-scale physics simulations and preventing the use of sources of experimental data that provide indirect measurements. These include infrared thermography and digital image correlation, information-rich metrology techniques for obtaining full-field temperature and deformation (i.e. displacement and strain) measurements, respectively, on the surface of a test specimen.

Furthermore, conventional constitutive models extrapolate in a manner that is well-understood and inherently stable. On the other hand, off-the-self ML models can extrapolate in undesirable, sometimes catastrophic ways. Robust extrapolation is crucial for constitutive models because characterization tests are limited by the design of laboratory equipment — they cannot impose arbitrary states of mechanical and/or thermal loading onto a material. Hence, in an application simulation, a constitutive model will surely extrapolate from the available data.

In this talk, we will discuss the structure of our hybrid models, training methods, and results obtained using synthetic and experimental full-field datasets.

TOPOLOGY OPTIMIZED-THERMAL CLOAKS FOR TRANSIENT HEAT CONDUCTION

Ryosuke Seki[*1], Yuma Dazai[1] and Garuda Fujii[1]*

[1]*Shinshu University*

ABSTRACT

Thermal cloak is a metadevice that can realize thermal undetectability which is an analogy of optical invisibility and a thermal cloak, usually surrounding an insulating obstacle, reproduces temperature field without disturbance around the cloak as if no insulating obstacle is present. Thermal cloaks are usually composed of thermal metamaterials arranged based on transformation thermotics. Thermal metamaterials realize required thermal properties such as anisotropic thermal conductivity by tuning the artificial microstructures. Some different schemes have been also proposed based on isotropic bulk materials for thermal cloaking without using thermal metamaterials. A bilayer thermal cloak is composed of insulating and higher conductive layers whose widths are rigorously derived from the governing equation, thus it realize high performance in thermal undetectability despite its very simple structure.
Also, an ultrathin thermal cloak, that is the extension of the above bilayer scheme to three dimension, was proposed and was experimentally demonstrated. Topology optimization is one of the promising approach to design the thermal cloaks, level set and density-based optimum designs are numerically demonstrated. However, the above thermal cloaks are usually designed for steady state heat conduction.
In this study, an attempt is made to design a thermal cloak in transient heat conduction both to suppress the disturbance of outer temperature distribution and to reproduce the time variation of the temperature field from the initial state to the steady state in a transient heat conduction. To suppress the temperature disturbance caused by a thermal insulator, the difference between cloaked temperature and that without disturbance in transient state is minimized as the objective function. Radial Basis Function (RBF) parameterized-level set method is employed as a structural modeling to reduce the number of design variables without sacrificing the accuracy of finite element analyses. A covariance matrix adaptation evolution strategy (CMA-ES) is employed to explore the optimal set of design variables because of its robustness to difficult properties such as multimodality, interdependence between design variables, etc. CMA-ES is a multi-point search that adapts its distribution parameters for sampling, i.e. the shape, size and center of the distribution of candidate solutions generated based on normally distributed-random numbers. The use of CMA-ES makes designers free from guessing the appropriate initial solution and adjusting strategy parameters.

ABSTRACT

The neutron irradiation embrittlement of reactor pressure vessel steels is known to be caused by an extensive formation of point defects due to the neutron irradiation. The point defects spontaneously generate their clusters by their self-diffusion and affect significantly the generation and behavior of dislocations [1]. One of the typical point defects formed by neutron irradiation is the Self-Interstitial Atom (SIA) in which an extra atom is inserted between crystal lattices. The diffusion behavior and activation energy of SIA in α-iron have been extensively studied by atomistic computer simulations with either the first-principle calculations or empirical interatomic potentials. However, the activation energy of SIA diffusion calculated by empirical interatomic potentials differs from the result of first-principles calculations. Therefore the diffusion behavior and activation energy of SIA calculated by the empirical interatomic potentials are not reliable [2].

On the other hand, owing to the development of machine learning technique in computational engineering and science, interatomic potentials for α-iron have recently been developed by the machine learning technique, and it has been shown that they can reproduce the behavior of screw dislocations, which could not be reproduced by empirical potentials, with the same accuracy as first-principles calculations [3]. In this study, we aimed to confirm the reliability of the machine learning interatomic potential in the numerical simulation of the diffusion of SIA in α-iron. We calculated the activation energy and reaction pathways associated with the diffusion of SIA and compared the results with those obtained by existing interatomic potentials and first-principles calculations. As a result, the activation energies calculated by the machine learning interatomic potentials showed good agreement with the first-principles calculations for all diffusion mechanisms. Furthermore, the minimum energy paths were calculated, revealing that all diffusion mechanisms can be reproduced by the repetition of the diffusion mechanism with the minimum activation energy.

CABANAPD: A MESHFREE GPU-ENABLED PERIDYNAMICS CODE FOR EXASCALE FRACTURE SIMULATIONS

Pablo Seleson[*1] and Sam Reeve*[1]

[1]*Oak Ridge National Laboratory*

ABSTRACT

Peridynamics is a nonlocal reformulation of classical continuum mechanics suitable for material failure and damage simulation, which has been successfully demonstrated as an effective tool for the simulation of complex fracture phenomena in many applications. However, the nonlocal nature of peridynamics makes it highly computationally expensive, compared to classical continuum mechanics, which often hinders large-scale fracture simulations. In this talk, we will present CabanaPD, a meshfree GPU-enabled peridynamics code for large-scale fracture simulations. CabanaPD is built on top of two main libraries: Kokkos and Cabana, both developed throughout the Exascale Computing Project (ECP). CabanaPD is performance-portable and exascale-capable, and it is designed to run on U.S. Department of Energy’s supercomputers, including Frontier, which is the first exascale machine and today's top supercomputer worldwide.

ALGORITHMS FOR LOCAL-TO-NONLOCAL COUPLING AND ADAPTIVITY

Pablo Seleson[*1]*

[1]*Oak Ridge National Laboratory*

ABSTRACT

Many problems in computational mechanics involve the use of nonlocal models. Examples include molecular dynamics at the atomistic scale and peridynamics at the continuum scale. Simulations based on these nonlocal models normally involve computations between particles and large neighborhoods, making them significantly more computationally expensive than simulations based on classical (local) partial differential equations (PDEs). A balance between numerical accuracy and computational cost can be attained by coupling local and nonlocal models, where nonlocal models are used where required, for example in regions where cracks develop, while classical PDEs are employed elsewhere in regions where the assumptions of classical continuum mechanics remain valid; in the case of molecular dynamics, such methods are referred to as atomistic-to-continuum (AtC) coupling methods. AtC coupling is a special case of local-to-nonlocal (LtN) coupling. In this presentation, we will provide an overview of LtN coupling methods, focusing on peridynamics, and discuss adaptive strategies for application to fracture simulations.

MULTIFIDELITY LINEAR REGRESSION VIA A COMBINED LOSS FUNCTION FOR DATA-CONSTRAINED APPLICATIONS

Vignesh Sella[*1], Anirban Chaudhuri[1] and Karen Willcox[1]*

[1]*The University of Texas at Austin*

ABSTRACT

Many-query tasks in science and engineering, such as uncertainty quantification, design optimization, and sensitivity analysis, involving an expensive-to-evaluate model are typically computationally prohibitive. One class of methods for reducing computational cost is by building surrogates, such as linear regression, for approximating the high-fidelity model outputs. However, accurate surrogate modeling remains a challenge for applications with limited training data. In this work, we develop a multifidelity linear regression method for applications where the capacity for high-fidelity data generation is significantly constrained. Typically, multifidelity surrogate models utilize multiple loss functions and combine the outputs of each underlying approximation via some model management technique, such as in the Kennedy-O'Hagan approach [1]. In contrast, the proposed work explores ways to create a single loss function for linear regression that combines many training data points from multiple low-cost, lower-fidelity information sources with few training data points from the high-fidelity source. One way to use a combined loss function is through weighted linear regression, where lower-fidelity models are assigned different weights as shown in Ref. [2]. The multifidelty setup also allows for the ability to fit higher-order polynomials by fitting one regression model that can utilize the larger sample pool available from the lower-fidelity models along with the high-fidelity data in a single training phase.

MULTISCALE MODELLING OF STRONGLY HETEROGENEOUS MATERIALS USING GEOMETRY INFORMED CLUSTERING

Jagan Selvaraj[1] and Bassam El Said*[1]

[1]*University of Bristol*

ABSTRACT

Heterogenous materials such as 3D woven composites are designed with yarns traversing in-plane and through the thickness. This internal material architecture provides an improved performance in transverse loading conditions. However, the materials and manufacturing induced heterogeneity originating from the yarn crimp, waviness, non-uniform levels of compaction and the associated localised deformations results in a significant challenge in modelling these mesoscale features at structural length-scales. Although the material architecture lacks periodicity, it is repetitive [1]. To enable modelling at larger length-scales, a multiscale method that identifies clusters within the internal material architectures to find the repetitive patterns in the mesoscale and perform macroscale computations using these patterns is developed [2]. 3D Voronoi cells are used as the geometric entities in the material clusters, since Voronoi cells tessellates the unit-cells and function as the building blocks of the woven material architecture. Using k-means clustering, the mesoscale woven architectures are clustered offline and stored along with their constitutive data. This data is stored in a kd-tree structure to enable fast searches across the database. When online macroscale computations are performed, an intermediate stage correlation modelling is performed using 3D image registration, which compares the data clusters not only in terms of geometry but also against the material property stored in the voxels. The rigid transformation used in this registration retains the material objectivity. Using a predefined correlation criterion, data clusters are retrieved from the database and online computations are performed without explicitly modelling the mesoscale material architectures. The steps of this multiscale framework are verified and validated with different examples. A three-point bending problem is modelled to demonstrate how macroscale computations can be performed with few Voronoi clusters and the corresponding ability to model shear dominated regions. Additionally, a twill weave material architecture, unknown to the framework before the start of the analysis, is also analysed. Overall, this method results in a 45% reduction in computational cost whilst retaining the numerical accuracy which is verified by comparing the element-wise error histograms in stress and strain against mesoscale models.

INCREMENTAL NEURAL CONTROLLED DIFFERENTIAL EQUATIONS FOR PATH-DEPENDENT MATERIAL BEHAVIOR

Shabnam Semnani[*1]*

[1]*University of California, San Diego*

ABSTRACT

Data-driven surrogate modeling has emerged as a promising approach for reducing computational expenses of multiscale simulations. Recurrent Neural Network (RNN) is a common choice for modeling of path-dependent behavior. However, previous studies have shown that RNNs fail to make predictions that are consistent with perturbation in the input strain, leading to potential oscillations and lack of convergence when implemented within finite element simulations. In this work, we leverage neural differential equations which have recently emerged to model time series in a continuous manner and show their robustness in modeling elasto-plastic path-dependent material behavior. We develop a new sequential model called Incremental Neural Controlled Differential Equation (INCDE) for general time-variant dynamical systems, including path-dependent constitutive models. INCDE is formulated and analyzed in terms of stability and convergence. Surrogate models based on INCDE are subsequently trained and tested for J2 and Drucker-Prager plasticity. The surrogate models are implemented for material point simulations and boundary value problems solved using the finite element method with various cyclic and monotonic loading protocols to demonstrate the robustness, consistency and accuracy of the proposed approach.

ABSTRACT

Using computational models serve as predictive tools for hemodynamic parameters, contribute to optimizing surgical plans, and improve our understanding of cardiovascular diseases. With increasing demand, researchers often seek for machine learning methods that capture key dynamics without overloading computational resources and with less clinical measurements.

In this study, we propose a method that synergistically integrates 1D blood flow equations with Physics-Informed Graph Neural Networks (PIGNNs) to estimate the propagation of blood flow velocity and lumen area pulse waves along human systemic arteries. Our methodology involves the creation of a graph based on arterial topology, where each 1D line represents edges and nodes in the blood flow analysis. The innovation lies in decoding the mathematical data connecting the nodes, where each node has velocity and displacement of lumen area waveform outputs. The training protocol for PIGNNs involves measurement data, specifically velocity waves derived from inlet and outlet vessels and diastolic lumen area measurements from each vessel. To optimize the learning process, our approach incorporates fundamental physical principles directly into the loss function. This comprehensive training strategy not only harnesses the power of machine learning but also ensures the PIGNNs respect fundamental laws governing fluid dynamics, resulting in a model that is not only data-driven but also physically grounded.

The proposed methodology's accuracy was tested in silico and in vivo for various arterial topologies, in silico models containing idealized aortic bifurcation and pelvic topologies with 7 vessels with 3 bifurcations. In such models, we obtained a wave similarity coefficient of determination (R2) with conventional 1D blood flow models, and PIGNNs prediction consistently exceeded 0.99. In vivo models, particularly mouse carotid and aortic bifurcations, showed a R2 greater than 0.90 and root mean square error for diastolic and systolic lumen area values less than 10^(−10) .

This research marks a significant advancement, showcasing the ability to calculate lumen area and blood flow rate in all vessels within a given topology by seamlessly integrating 1-D blood flow with PIGNNs, using only blood flow velocity measurements. Moreover, this study is the first to compare the PIGNNs method with other classic Physics-Informed Neural Network (PINNs) approaches for blood flow

simulation. Our findings highlight the potential to use this cost-effective and proficient tool to estimate real-time arterial pulse waves.

MICROMECHANICAL PROPERTIES PREDICTION OF MULTIPHASE FRP COMPOSITES USING CNN APPROACH

Dhiraj Biswas[1], Sathiskumar Anusuya Ponnusami[2] and Ganapathi A. Sengodan[1]*

[1]University of Salford
[2]University of London

ABSTRACT

A novel micromechanical characterisation technique is presented to predict the elastic modulus and failure initiation stress of two-phase fibre reinforced plastic (FRP) composites using the convolution neural network (CNN) technique. The proposed methodology can predict the stress-strain behaviour of a given microstructure under uniaxial tension or compressive loads. Macroscale properties of advanced FRP composites highly depend on the microscale arrangements, geometry and properties of the constituents. Current research on composite materials in the literature is heavily focussed on developing high-performance structural composites using highly toughened matrix materials with multifunctional capabilities. These new generation matrix materials exhibit a highly nonlinear behaviour under different loading conditions [1]. Mechanical characterisation of multi-phase materials is tedious due to the nature of diverse parameters controlling the effective properties, for example, manufacturing parameters and constituent properties. The phase materials, for example, toughened polymer matrices exhibit distinct deformation and failure behaviours under uniaxial loading conditions. Therefore, we propose a surrogate methodology to generate the stress-strain curve of the microstructures using statistical quantification followed by CNN.

A random fibre packing algorithm including the edge periodicity is employed to generate RVE of the microstructures comprising 40-70 % fibre volume fractions. Progressive damage analysis of the RVEs under tension and compression has been carried out using calibrated elastoplastic material models implemented in Abaqus/Explicit as a VUMAT user material subroutine. Homogenised stress-strain curves are then derived from the results of the elastoplastic RVE analyses. The generated RVE images and their corresponding stress-strain curves, constituting the dataset, are used to train the selected neural network architecture, i.e., CNN. The dataset comprises 2800 RVEs of various volume fractions are utilised for the study. The dimensions of the structure-property data are reduced by principal component analysis (PCA) technique before being fed into the CNN [2]. CNN models were then trained to accurately predict the elastic modulus, stress data at damage initiation and maximum stress before failure of FRP microstructures, with prediction errors of less than 10%. The proposed strategy can be used to design multi-phase microstructures and predict their non-linear stress-strain responses with better accuracy and minimal computational effort.

OPTIMIZATION OF RESISTANCE PERFORMANCE BY ALTERING THE SHAPE AND POSITION OF SKEGS FOR THE TRANSPORTATION BARGE

Janghoon Seo[1] and Dong-Woo Park*[1]

[1]*Tongmyong University*

ABSTRACT

Appendages attached to the ship are used for stationkeeping, maneuvering, and motion performance. However, these appendages can increase the resistance of ship, so they must be carefully considered in design and engineering stages. In particular, for the transportation barge, skeg is installed on the stern to ensure course stability during towing. As the size of skeg increases, course stability improves, but friction resistance increases as the wetted surface area of the barge increases. Therefore, optimization of the shape of skeg is required. In the present study, the optimization is performed by altering shapes of skegs on transportation barges. The position and shape of skegs are chosen as the design variables. The resistance of the barge and wetted surface area of skegs are considered as the objective function and the constraint variable, respectively. The resistance of the barge is derived using computational fluid dynamics (CFD), and the SHERPA(Simultaneous Hybrid Exploration that is Robust, Progressive and Adaptive) technique is employed for the optimization of the shape of skeg. As a result, the optimized skegs with improved performance of resistance are achieved. The developed optimization procedure is expected to be applicable to other ship appendages in the future.

MULTIPHYSICS COMPUTATIONAL MODELING OF INTRA-ANEURYSMAL THROMBOSIS BY FLOW DIVERTER STENTS

Jung Hee Seo[*1], Zulfikar Alamlah[1], Rajat Mittal[1], Justin Caplan[2] and Angad Grewal[2]*

[1]*Johns Hopkins University*
[2]*Johns Hopkins Medical Institute*

ABSTRACT

Flow diversion is a less invasive endovascular treatment for cerebral aneurysms. In the procedure, flow-diverter stents are placed in the parent artery at the level of the aneurysm neck to alter intra-aneurysmal blood flow, causing stasis and progressive intra-aneurysmal thrombosis. Subsequent occlusion of the aneurysm by thrombosis decreases the chances of aneurysm rupture. The intra-aneurysmal thrombosis and subsequent occlusion of the aneurysm depends on several factors including the shape and curvature of the parent vessel, the hemodynamic conditions of the parent vessel, the size and shape of the aneurysm, and properties of the flow diverter stent. The choice of appropriate flow diverter stent for the given morphology and hemodynamic conditions of the aneurysm is therefore important for a better outcome. Currently, device selection for this procedure depends heavily on the expertise of clinicians. High fidelity computational modeling and prediction of the effects of flow diverter stents on the hemodynamics and thrombosis in the cerebral aneurysms can provide valuable information for proper device selection. In the present study, we propose a patient-specific, multiphysics computational modeling of intra-aneurysmal thrombosis caused by flow diverter stents. Hemodynamics in the parent vessel and aneurysm is simulated by an incompressible, immersed boundary flow solver and the stent is modeled by immersed structures with line elements. Flow mediated thrombus formation is modeled by the coupled convection-diffusion-reaction equations for thrombin, fibrin, and platelets. Several different patient specific cases with various stent parameters are considered and the simulation results are discussed in terms of flow diversion and thrombosis effectiveness.

DEVELOPMENT OF A COMPUTATIONAL FLUID DYNAMICS MODEL FOR PREDICTING CO2 CONVERSION EFFICIENCY IN COKE OVENS

Sangjae Seo[*1]*

[1]*Korea Institute of Science and Technology Information*

ABSTRACT

The steel industry, a significant contributor to global CO2 emissions, faces the challenge of reducing its carbon footprint while maintaining production efficiency. One promising approach to mitigate this issue is the reuse of CO2 in coke oven gas. However, the experimental assessment of CO2 reduction potential in this context is costly and complex. Addressing this challenge, our study introduces a novel Computational Fluid Dynamics (CFD) model integrated with chemical reaction processes to predict the CO2 conversion efficiency in real coke ovens.

This research primarily focuses on the development and application of a CFD model that simulates the chemical and physical interactions in coke ovens, particularly the conversion of CO2. Our model incorporates complex chemical reactions associated with CO2 and coke oven gas, providing a detailed analysis of the gas dynamics and reaction kinetics. By simulating these processes, the model predicts the efficiency of CO2 conversion under various operational conditions, offering valuable insights into the optimization of this process.

A critical aspect of our study is the validation of the CFD model's predictions. We conducted a comprehensive comparison between the model's output and experimental data obtained from real-world coke oven operations. This comparison demonstrated a high degree of accuracy in our model's predictions, thereby establishing its reliability and effectiveness in estimating CO2 conversion efficiency in the steel production process.

By providing a cost-effective and accurate tool to predict CO2 reduction in coke ovens, our study opens up new avenues for the steel industry to mitigate its environmental impact. The CFD model can be adapted to various coke oven designs and operational settings, making it a versatile tool for iron and steel manufacturers worldwide.

In conclusion, our research contributes significantly to the field of environmental sustainability in the steel industry. By leveraging advanced CFD modeling techniques, we offer a practical solution to reduce CO2 emissions, thereby supporting the industry's transition towards more sustainable practices. Our findings hold the potential to revolutionize the way CO2 emissions are managed in the steel production process, marking a critical step towards a greener and more sustainable future.

DETERMINATION OF HIGH-ORDER FREQUENCY RESPONSE OF NONLINEAR SYSTEMS USING THE ARC-LENGTH METHOD

Lucas Pini Tanabe[1] *and Alberto Luiz Serpa**[1]

[1]*Universidade Estadual de Campinas - UNICAMP*

ABSTRACT

While linear systems have been extensively studied in the past few decades, they alone are often not precise enough to accurately describe the behavior of systems with strong nonlinearities. However, solving nonlinear equations usually demands an exponential increase in processing capacity and time when compared to their linear counterparts. As computers become more powerful, significantly more advanced nonlinear systems can be studied and analyzed, providing solutions that are more accurate for real-world applications.

When it comes to frequency analysis, nonlinear frequency response may show the phenomena of hardening or softening. In this case, the resonance peaks of the frequency response are tilted to the right or left, respectively, in comparison with the linear frequency response. The consequences of these phenomena might prove essential to the safety assessment of real-life structures as the resonance peak might greatly differ from those obtained in a linear analysis.

In this study, the high-order frequency response of the Helmholtz-Duffing oscillator is analyzed to evaluate its influence on the system. The oscillator exhibits symmetric nonlinearity represented by a cubic stiffness and asymmetric nonlinearity represented by a quadratic stiffness. The high-order harmonic balance method was used to determine the dynamic equation in the frequency domain. The nonlinearities were numerically integrated based on the coefficients of the Fourier series. Originally used to find the solution path of nonlinear static structural analyses, the arc-length method was adapted to determine the nonlinear frequency response.

The equations from the first-order harmonic balance method assume that the nonlinear system response, as well as the nonlinear forces, are dominated by the fundamental harmonic. In this case, high-order harmonics are neglected. When it comes to high-order frequency response, multiple harmonics are considered in the system response and the equations are derived from the high-order harmonic balance method. This study shows that the behavior of systems with cubic stiffness only is usually very accurate with the first-order analysis. However, when quadratic stiffness is present, multiple harmonics must be taken into consideration to accurately describe the system behavior. Otherwise, the frequency response is possibly inaccurate and sometimes chaotic, as it is not entirely dominated by its fundamental harmonic.

ON MODELING MICRO-SCALE STRAIN GRADIENT ELASTIC ADHESIVELY BONDED JOINTS

ABSTRACT

As a bonded structure scales down to the microscale, the role of the adhesive joint becomes more relevant concerning the overall performance of the microdevice. At the small scale, the microstructural and size-dependent properties of thin adhesives start to play a key role in the mechanical response of the layered assembly [1]. The present work focuses on the derivation of a soft imperfect interface law in a composite, constituted by two solids, separated by a thin adhesive layer in the framework of strain gradient elasticity. The model is obtained by means of the asymptotic methods. The contact laws, expressed in terms of the jumps and means values of the displacements, normal derivatives of the displacements, represent a formal generalization of the soft elastic interface conditions [2]. The present study reveals the stiffening behaviors of layered structures and size-dependent phenomena, typical of micro-scale structures [3].

PERFORMANT LOW-ORDER MATRIX-FREE FINITE ELEMENT KERNELS ON GPU ARCHITECTURES

Randolph Settgast[1], Yohann Dudouit[1], Nicola Castelletto[1], William Tobin[1], Ben Corbett[1] and Sergey Klevtsov[2]*

[1]*Lawrence Livermore National Laboratory*
[2]*Stanford University*

ABSTRACT

Numerical methods such as the Finite Element Method (FEM) have been successfully adapted to utilize the computational power of GPU accelerators. However, much of the effort around applying FEM to GPU's has been focused on high-order FEM due to higher arithmetic intensity and order of accuracy. For applications such as the simulation of subsurface processes, high levels of heterogeneity results in high-resolution grids characterized by highly discontinuous (cell-wise) material property fields. Moreover, due to the significant uncertainties in the characterization of the domain of interest, e.g. geologic reservoirs, the benefits of high order accuracy are reduced, and low-order methods are typically employed. In this study, we present a strategy for implementing highly performant low-order matrix-free FEM operator kernels in the context of the conjugate gradient (CG) method. Performance results of matrix-free Laplace and isotropic elasticity operator kernels are presented and are shown to compare favorably to matrix-based SpMV operators on V100, A100, and MI250X GPUs.

[3]*Skolkovo Institute of Science and Technology*

ABSTRACT

Laser therapies embody cutting-edge advances in non-invasive medical techniques. This study concentrates on enhancing precision thermal therapy by investigating the intricate interplay between laser radiation and the complex layers of human skin. Our method involves representing the skin as three layers —epidermis, dermis, and subcutaneous tissue—and strategically manipulating a range of wavelengths. We explore the subtle workings of absorption and extinction coefficients, with a specific focus on unraveling the scattering dynamics between these layers. The purpose of this research is to advance the development of thermal therapies, facilitating precise targeting of tissue depths.
To simulate heat distribution in multilayered skin tissue, we use a stepwise Heaviside Function to outline thermal and optical properties. We also incorporate a three-phase lag model to capture the time-dependent aspects of heat transfer. The solution to the governing equation, obtained via numerical simulation, indicates the possibility of selecting optimal laser wavelengths and characteristics. This approach enables us to attain desired temperatures at precise depths within the tissue, advancing our comprehension of customized thermal interventions in medical procedures involving laser technology.

EMERGENT NETWORK MORPHOLOGY IN SOFT MATERIALS: FROM BIOLOGICAL TO ROBOTIC SWARMS

Joe Sgarrella[*1], William Laplante[1] and Christian Peco[1]*

[1]*The Pennsylvania State University*

ABSTRACT

The allure of soft materials, characterized by low density, substantial deformability, and customizable properties, has captivated engineers. Conventional top-down engineering approaches face challenges in achieving intricate macroscale behaviors. In this work, inspired by biological bottom-up strategies, we delve into the concept of emergence, observing how internal networks in slime molds and fungi optimize transport, solve mazes, detect masses, and memorize periodic events. Our research presents a comprehensive theoretical and computational framework elucidating the interplay between macroscopic features and localized tuning of mechanical properties, resulting in an emergent and coordinated response in network morphology. To achieve high-fidelity simulations in three-dimensional space, we propose incorporating a phase-field scalar variable for network matrix evolution and a diffusive-advective process for nutrient distribution. This approach is particularly challenging due to the intricate interplay of coupled physics, high-order partial differential equations, and the evolving complexity of geometry. Upon grasping these fundamental principles, we employ neural networks to transfer knowledge gleaned from simulations, generating substantial data. This knowledge transfer plays a pivotal role in developing a cyberphysical system integrating robotic swarms, marking the convergence of theoretical insights with practical applications in soft material engineering.

ENHANCEMENT OF POWER FACTOR THE CONVERSION OF WASTE HEAT TO ELECTRICITY BY NANO-ENGINEERING OF THERMOELECTRIC CHALCOGENIDE MATERIALS

Wiqar Hussain Shah[1]*

[1]*International Islamic University, Islamabad*

ABSTRACT

Innovative transport mechanisms are the fountain of youth of TE materials research. In the past two decades, many potentially paradigm-changing mechanisms were identified, e.g., resonant levels, modulation doping, band convergence, classical and quantum size effects, anharmonicity, the Rashba effect, the spin Seebeck effect, and topological states. These mechanisms embody the current states of understanding and manipulating the interplay among the charge, lattice, orbital, and spin degrees of freedom in TE materials. Many strategies were successfully implemented in a wide range of materials. The electrical and thermal properties of the doped Tellurium Telluride (Tl10Te6) chalcogenide nano-particles are mainly characterized by a competition between metallic (hole doped concentration) and semi-conducting state. We have studied the effects of Sn doping on the electrical and thermoelectric properties of Tl10-xSnxTe6 (1.00 ≤x≤ 2.00), nano-particles, prepared by solid state reactions in sealed silica tubes and ball milling method. Structurally, all these compounds were found to be phase pure as confirmed by the x-rays diffractometery (XRD) and energy dispersive X-ray spectroscopy (EDS) analysis. Additionally crystal structure data were used to model the data and support the findings. The particles size was calculated from the XRD data by Scherrer's formula. The EDS was used for an elemental analysis of the sample and declares the percentage of elements present in the system. The thermo-power or Seebeck co-efficient (S) was measured for all these compounds which show that S increases with increasing temperature from 295 to 550 K. The Seebeck coefficient is positive for the whole temperature range, showing p-type semiconductor characteristics. The electrical conductivity was investigated by four probe resistivity techniques revealed that the electrical conductivity decreases with increasing temperature, and also simultaneously with increasing Sn concentration. While for Seebeck coefficient the trend is opposite which is increases with increasing temperature. These increasing behavior of Seebeck coefficient leads to high power factor which are increases with increasing temperature and Sn concentration except For Tl8Sn2Te6 because of lowest electrical conductivity but its power factor increases well with increasing temperature.

EXPLORING THE APPLICATION OF MIXED SOLVENTS IN LIQUID-PHASE EXFOLIATION OF GRAPHITIC CARBON NITRIDES WITH MOLECULAR DYNAMICS

Ehsan Shahini[*1], Narendra Chaulagain[1], Karthik Shankar[1] and Tian Tang[1]*

[1]*University of Alberta*

ABSTRACT

The quest to optimize the liquid-phase exfoliation (LPE) of graphitic carbon nitrides (g-C3N4) is critical for their application in nanotechnology. This study delves into the intriguing effects of mixed solvent systems on LPE. Based on a machine learning (ML) model developed in our prior research for single solvents [1] and using the simple rule of mixture, the free energy of exfoliation (ΔGexf) is predicted for a vast array of 200 solvent mixtures, each at a 50:50 volume ratio. Molecular dynamics simulations involving umbrella sampling and potential of mean force evaluations are performed to calculate ΔGexf for the mixed solvents, and the results are compared with the ML model prediction. Interestingly, our findings unveil that some systems deviate from the model prediction, suggesting synergy or antagonism between the two solvents in the binary mixture. In some systems, for example N-Methyl-2-pyrrolidone (NMP): Cyclohexane (CH), the efficacy of LPE is akin to the solvent with lower ΔGexf, indicative of better performance. While in some other systems, for example methanol (MET): Dichloromethane (DCM), the efficacy of LPE aligns with the solvent exhibiting higher ΔGexf, indicative of poorer performance. Our computational analysis and experimental investigations converge on the nuanced behavior of these mixtures, reinforcing the insights into solvent behavior and interactions during LPE. This study not only provides a thorough understanding into the molecular interactions driving solvent performance but also establishes a robust computational framework complemented by experimental verification. This approach opens avenues for the rational design of solvent mixtures to optimize exfoliation processes, crucial for the scalable production of two-dimensional materials.

TAILORED THERAPY: ADVANCING CANCER CARE WITH QUANTITATIVE SYSTEMS PHARMACOLOGY AND DIGITAL TWINS

Leili Shahriyari[*1]*

[1]*University of Massachusetts Amherst*

ABSTRACT

The development of a digital twin (DT) for cancer offers a groundbreaking approach to foreseeing the progression of an individual's cancer by simulating each tumor's unique attributes and its response to treatments. Leveraging recent advancements in computational methods, our approach integrates mechanistic modeling, machine learning, and stochastic techniques to construct a comprehensive DT platform. This platform harnesses a wide array of data, including biological, biomedical, and electronic health records (EHR), to generate personalized predictions.

A key component of our strategy is the integration of machine learning methods with mechanistic models grounded in quantitative systems pharmacology (QSP), a commonly used computational method for evaluating dose-response relationships in drug discovery and testing. However, a significant hurdle in QSP modeling is the accurate estimation of parameters. Traditional mechanistic models often operate under the assumption of uniformity across patients' diseases, leading to parameter calibration based on heterogeneous data sources.

To craft a truly personalized DT, we focus on utilizing individual patient data for parameter estimation, sensitivity analysis, and uncertainty quantification. For each patient, we tailor the QSP model parameters using their specific data. Through extensive multi-dimensional sensitivity analysis and uncertainty quantification, we identify crucial interactions within the model and establish confidence intervals for predictions. This personalized QSP model, enriched with data-driven insights into cellular and molecular interaction networks, ultimately enables us to predict the trajectory of cancer evolution in response to targeted therapies, marking a significant stride in personalized cancer treatment.

NON-LINEAR, RATE-INDEPENDENT MODEL OF FERROELECTRICITY

Mawafag F. Alhasadi[1], Leila Shahsavari[1], Qiao Sun[1] and Salvatore Federico[1]*

[1]University of Calgary

ABSTRACT

This work aims to establish a rate-independent non-linear model of ferroelectricity. The model is based on a phenomenological and continuum mechanical approach, to effectively account for switching phenomena and electrical hysteresis in ferroelectric materials. The switching phenomenon is due to an irreversible polarisation, occurring beyond a certain threshold value of the electric field, which can be reversed by changing the direction of the applied electric field. As a result, when a cyclic electric field is applied, a ferroelectric polarisation-electric field hysteresis loop is observed [1,2].

Inspired by the general methods of classical plasticity [3], we defined a yielding surface, such that states inside the surface have reversible behaviour and states on the surface can attain irreversible behaviour. Whether a state on the yielding surface is irreversible depends on the time derivative of the yielding function, the proposed evolution law for the irreversible polarisation, and the values and evolution laws of the hardening variables, i.e., isotropic and kinematic hardening. The isotropic hardening increases the threshold for irreversible behaviour (the electric field associated with the first yielding polarisation), whereas the kinematic hardening moves the centre of the yielding surface. The Kuhn–Tucker complementarity and consistency conditions are applied on the surface for loading/unloading circumstances.

The Finite Difference Method (FDM) and Finite Element Method (FEM) are utilised to illustrate the capability and the effectiveness of the proposed model in reproducing the non-linearity and electric field-polarisation hysteresis loop. These numerical methods are applied toa boundary value problem in which a cyclic electric potential was imposed on the boundary of the domain.

The FDM and FEM codes are run separately for solving the electric potential and electric field throughout the domain. In the interior, the electric potential and electric field are evaluated. The successive over-relaxation method is employed to find the electric potential and then the electric field is obtained by differentiation. Finally, the time behaviour of the yielding function and the polarisation field are evaluated. This model improves our previous work [1], and facilitates the development of a fully elastoplastic-ferroelectric model, which is our next goal.

APPLICATIONS OF A MULTI-RESOLUTION AND MULTIPHASE MESH-FREE PARTICLE METHOD TO GRANULAR GRAVITY-DRIVEN FLOWS

Herman Siaben Musumari[1], Mojtaba Jandaghian[2] and Ahmad Shakibaeinia[1]*

[1]Polytechnique Montréal
[2]National Research Council Canada

ABSTRACT

This paper applies a fully Lagragian and three-dimensional Mesh-free particle method to simulate landslides and the resulting impulsive wave. These phenomena represent one of the most serious geohazards and challenging gravities-driven flow. With the escalating impact of climate change likely to increase the frequency of such catastrophic events, developing accurate methods to comprehend the complex Multiphysics and predict tsunami-generated waves from landslides is imperative. The granular medium released undergoes significant deformation as it slides down, transferring high kinetic energy to the fluid medium upon impact. Traditional mesh-based methods struggle with these complex transitional flows, leading to mesh distortions and model instability.

To address large deformations, energy transfer, and strong fragmentation, a mesh-free multiphase particle method proves advantageous. Adopting a phase-dependent multi-resolution technique accommodates the varying length scales required for accurate representation of fluid and granular materials in complex multi-scale physics. Simulation scenarios encompass complete aerial landslides, submerged landslides, and partially submerged landslides and are validated against experimental tests conducted at the Polytechnique Montréal laboratory. The granular phase is modeled as a non-Newtonian flow mixture, considering different wetting stages.

Results from the three-dimensional multi-resolution and multiphase model align with experimental outcomes, attesting to its accuracy. This study emphasizes the suitability of the mesh-free particle method for capturing intricate dynamics involving granular material, deformations, and fluid interactions. The phase-dependent multi-resolution technique enhances the model's fidelity, making it a valuable tool for understanding and predicting the impacts of gravity-driven flows, especially in the context of increasing geohazards associated with climate change.

MOLECULAR DYNAMICS SIMULATIONS OF ICE GROWTH UNDER A STATIC ELECTRIC FIELD INDUCED BY TRANSMISSION LINES

Ruiqi Shang[*1] and Shaker Meguid*[1]

[1]*University of Toronto*

ABSTRACT

Icing accumulation on transmission lines and their insulating equipment poses a significant threat to power systems. Whilst the influence of unrealistic ultrahigh electric fields on supercooled water nucleation has been studied in earlier publications, there remains a critical gap in understanding the solidification mechanism under realistic electric fields; typically, around 105 V/m. It is therefore the objective of this study to uncover the reasons behind how static electric fields along distinct crystal planes catalyze ice growth and how they influence the resulting ice structure.

To achieve the above objectives, we embarked on extensive molecular dynamics simulations employing LAMMPS software. The TIP4P/Ice rigid water model was applied due to its proximity to the experimentally observed melting point. Long-range Coulombic interactions were computed employing the Particle-Particle Particle-Mesh method (PPPM) with a cutoff distance set at 0.8 nm. We focused out attention on two coexistence system: hexagonal ice-water and cubic ice-water; each comprising 432 and 576 water molecules, respectively. The liquid phase was associated with the secondary prism plane in both configurations. All simulations were performed at constant temperature (T) and under constant pressure (P) using the Nose-Hoover thermostat. The timestep of each simulation was taken to be 2 fs.

The radial distribution function was employed to analyze changes in the average structure of the system and ice structures are identified by the CHILL+ algorithm. The melting temperature, a critical factor affecting the degree of super cooling, was determined through the direct coexistence method. Distinct characteristics in the growing and melting processes of coexistence systems containing individual hexagonal and cubic ice were due to their unique anisotropic structures and growth modes.

Our molecular dynamics simulations reveal that the initial state of the ice crystal structure significantly impacts the subsequent ice formation process. Specifically, in systems containing hexagonal ice and liquid water, no cubic ice existed. Conversely, hexagonal ice was generated in cubic ice coexistence systems. This illustrates that the transformation of cubic ice to hexagonal ice is irreversible. Additionally, there exists a correlation between the direction of the static electric field and the liquid-ice interface that influences the crystal phase transformations. The electric field could alter the dipole orientation of interfacial water molecules and further change the interfacial free energy. Ice crystals exhibit preferred growth along certain crystallographic planes, which have specific orientations or arrangements and hence are more susceptible to external electric field.

DIFFERENTIABLE PHYSICS FOR A-POSTERIORI LEARNING OF TURBULENCE CLOSURES

Varun Shankar[*1], Venkat Vishwanathan[2] and Romit Maulik[3]*

[1]*Carnegie Mellon University*
[2]*University of Michigan*
[3]*Pennsylvania State University*

ABSTRACT

Differentiable fluid simulators are increasingly demonstrating value as useful tools for developing data-driven models in computational fluid dynamics (CFD). Differentiable turbulence, or the end-to-end training of machine learning (ML) models embedded in CFD solution algorithms, captures both the generalization power and limited upfront cost of physics-based simulations, and the flexibility and automated training of deep learning methods. We develop a framework for integrating deep learning models into a generic finite element numerical scheme for solving the Navier-Stokes equations, applying the technique to learn a sub-grid scale closure using a multi-scale graph neural network. We demonstrate the method on several realizations of flow over a backwards-facing step, testing on both unseen Reynolds numbers and new geometry. We show that the learned closure can achieve accuracy comparable to traditional large eddy simulation on a finer grid that amounts to an equivalent speedup of 10x. As the desire and need for cheaper CFD simulations grows, we see hybrid physics-ML methods as a path forward to be exploited in the near future.

ABSTRACT

Abstract: In the contemporary manufacturing era, marked by Industry 4.0, the utilization of deep learning models is fast gaining attention for comprehending and representing intricate systems due to their highly nonlinear nature. Integration of governing equations into such machine learning models, often termed as physics-informed learning, have become a powerful non-black box technique. It involves not only feeding input data into the learning model but also incorporating the fundamental equations that govern the physical behavior of the system. Unsupervised learning, in particular, demands consideration of such input-output governing equations. From an engineering applications perspective, in a typical forward boundary value problem, the objective is often to predict the system's behavior based on a given set of input variables. In an inverse problem, on the other hand, the challenge becomes determining the inputs that lead to a desired (often optimized) output, under prescribed constraints. In this study we discuss and exemplify the application of a new technique coupling multiple concurrent physics-informed neural networks (PINNs), each designed to address specific aspects of the forward and inverse problems in solid mechanics. By leveraging shared losses, these networks co-train collaboratively, harnessing the collective intelligence embedded in the data and governing equations. The approach holds promise in optimizing not only solid materials structures, but their manufacturing processes, especially in the face of data paucity.

COUPLING OF AN ENRICHED BEAM MODEL WITH A COMPRESSIBLE FLOW MODEL FOR FLUID-STRUCTURE INTERACTION IN PIPELINES

Mahshid Sharifi[*1], Frederic Daude*[21] *and Claude Stolz*[1]

[1]*IMSIA*
[2]*EDF Lab Paris-Saclay*

ABSTRACT

With the growing popularity of numerical modelling to ensure the safety measure in industry, the need of more accurate models is imminent. In particular, the numerical modelling of pipelines is under study in this work. The latter has often been conducted by the classical beam models that lack the kinematics of the cross-section of the tube structures. While, the use of shell elements in a three-dimensional model has improved the precision of the numerical studies, they have greatly increased the computational cost of the simulations. In this work, an enriched beam model has been employed [1]. The latter takes into account the variations of the cross-section by adding the shell kinematics to those of the classical beam model. A Fourier expansion is used for this purpose for which the number of cross-section modes can be truncated. The enriched beam model can particularly be useful in the fluid-structure interaction studies. Fluid transient events have traditionally been simulated using liquid single-phase flow models while the pipe wall motion is tackled by means of a one-dimensional beam model. The latter has been improved in the work of [2] who replaced the fluid model by a compressible two-phase flow based on the Homogeneous Equilibrium Model (HEM). In this work, the flexible tube structure is two-way coupled to the fluid using the previously mentioned one-dimensional beam model enriched with the kinematics of the cross-section shell elements. As it is done in [2], a finite volume and finite element approach were used for the resolution of the fluid and structure dynamics, respectively. Finally, the proposed coupled approach is assessed on water-hammer phenomena due to the damage they could cause the structure.

ADAPTIVE REFINEMENT WITH FINITE TIME LYAPUNOV EXPONENTS IN LAGRANGIAN NUMERICAL METHODS

Arjun Sharma[*1] and Peter Bosler*[1]

[1]*Sandia National Laboratories*

ABSTRACT

Finite Time Lyapunov Exponents (FTLEs) measure the maximum stretching of infinitesimal Lagrangian volumes advected by a dynamical system within a specified (finite) time horizon. These exponents are calculated from the eigenvalues of the system's Cauchy-Green strain tensor. Typically, FTLEs are used to identify the most repelling or attracting materially invariant coherent structures in fluid flow. In this study, instead of their traditional use as a flow diagnostic tool, we use FTLEs to trigger remeshing in a Lagrangian numerical method (LNM). One benefit of LNMs is that they are inherently multi-scale, i.e., they naturally cluster numerical particles in the locations requiring largest resolution such as the high-gradient regions. However, the distortion of the underlying mesh connecting these Lagrangian particles requires remeshing after a certain time. Previous implementations of LNMs have relied on heuristics to trigger remeshing in both time and space. In a Lagrangian simulation, where the trajectory of each numerical particle is known, FTLEs can be readily calculated. We use FTLE fields to both trigger remeshing and spatially redistribute numerical particles while demonstrating the enhanced numerical efficiency across different flows on a sphere. FTLE-aided simulations can be run for longer times, allowing novel vortex breakdown mechanisms on the sphere to be revealed.

FIBRO-POROUS ARCHITECTED HYBRID MATERIALS FOR MULTIFUNCTIONAL APPLICATIONS

William Johnston[1], Janith Godakawela[1], Bhisham Sharma[1], Carlos Gatti[2] and Suresh Keshavanarayana[2]*

[1]Michigan Technological University
[2]Wichita State University

ABSTRACT

Our work showcases the fabrication of fibro-porous materials using additive manufacturing—a process that intertwines a fiber mesh within the open cells of a foundational porous scaffold. The technique we introduce achieves an integrated fiber mesh with finely tuned characteristics into the scaffold, bypassing the need for any post-manufacturing modifications. Utilizing a gyroid design for the base scaffold, we explore the emergent acoustic absorption, pressure drop, mechanical rigidity, and energy absorption qualities. Our findings, gathered through two-microphone normal incidence impedance tube assessments, demonstrate notable acoustic absorption enhancements in comparison to heavier, non-fibered porous materials, while also reducing weight by 33%. Additionally, measurements of pressure drop and airflow resistance suggest that the addition of fibers narrows pore size and augments flow resistance, thereby amplifying lower frequency sound absorption. We observe substantial reinforcement in mechanical attributes, with a 27% rise in stiffness and a 37.85% increase in yield stress. The energy absorption capacity per unit volume also increases by 30%, owing to heightened resistance against deformation. Our study confirms the significant multifunctional advantages of fibro-porous materials without a major weight penalty, paving the way for the creation of intricate, tailored engineering structures with specific functional requirements.

[4]*The University of Texas at Austin*

ABSTRACT

Classical symplectic model reduction approaches employ linear symplectic subspaces for representing the high-dimensional system states in a reduced-dimensional coordinate system. While these approximations respect the symplectic nature of Hamiltonian systems, linear basis approximations can suffer from slowly decaying Kolmogorov N-width, especially in wave-type problems, which then requires a large basis size. We present two novel approaches for the symplectic model reduction of high-dimensional Hamiltonian systems using data-driven quadratic manifolds. The addition of quadratic terms to the state approximation, which sits at the heart of the proposed methodologies, enables us to better represent intrinsic low-dimensionality in the problem at hand. The proposed approaches are effective for issuing predictions in settings well outside the range of their training data while providing more accurate solutions than the linear symplectic reduced-order models. Both of these novel approaches together constitute a first step towards the model reduction of dynamical systems on nonlinear manifolds using interpretable (e.g., polynomial) manifold constructions that ensure that the approximate solution satisfies key physical properties as dictated by the original high-dimensional problem.

A PHYSICS-CONSTRAINED POLYNOMIAL CHAOS FRAMEWORK FOR DATA-DRIVEN MODELING AND UNCERTAINTY QUANTIFICATION

Himanshu Sharma[*1], Lukas Novak[2] and Michael Shields[1]*

[1]*Johns Hopkins University*
[2]*Brno University of Technology*

ABSTRACT

Polynomial chaos expansion (PCE) is a widely adopted surrogate modeling method primarily employed for uncertainty quantification (UQ) of complex physical systems represented by expensive computational models. PCE has also recently been used as a machine learning (ML) method in a purely data-driven setting. PCE surrogate model is trained using a limited number of deterministic simulations from computationally expensive models and provides an efficient estimation of various output statistics, such as its moments and sensitivity to different stochastic parameters. However, ensuring an accurate approximation of the underlying model may require a considerable number of computationally expensive simulations, which is often challenging with physics-based models. To reduce the training data requirement, we can supplement the limited data with the known physics of the model, thereby improving the accuracy and computational efficiency. This necessitates a novel framework that incorporates physics knowledge through constraints in the PCE model. To this end, we develop a novel physics-constrained PCE surrogate model that can effectively incorporate a variety of physical constraints, such as initial and boundary conditions, governing partial differential equations, and inequality-type constraints (e.g., monotonicity, convexity, non-negativity). We demonstrate that integrating physical constraints enhances the accuracy of UQ assessment while requiring significantly fewer expensive simulations during the training process. Moreover, it ensures physically realistic predictions across the entire domain in data-driven modeling. This makes the proposed method ideal for UQ and ML applications involving physics-based models. We further proposed a sparse implementation that effectively reduces the number of polynomial basis needed to accurately capture the output response, thereby facilitating the use of the proposed method for high-dimensional problems.

[3]*Technical University of Eindhoven, The Netherlands*

ABSTRACT

The state or combined state and parameter estimation of extreme scale nonlinear stochastic computational models (generally arising from the discretization of stochastic PDEs), sampling based non-Gaussian filters (e.g. particle or ensemble Kalman filters) can become computationally impractical. To alleviate the computational challenges at the forecast (prediction) step of nonlinear filtering for such models, a two-grid scalable solver using (sampling-free) intrusive stochastic Galerkin method is developed that leverages two-level Schwarz method for geometric decomposition and the algebraic multigrid solver (AMG) for the corresponding coarse problem. This two-grid solver demonstrates scalable performance for high resolution spatial and temporal discretizations, a large number of input random variables and higher order stochastic (i.e. polynomial chaos) expansion terms for the output of nonlinear stochastic PDEs.

Within the framework of the polynomial chaos Kalman filter, the distributed implementation of the update (analysis) step will be developed that exploits this two-grid scalable solver to condition the system state using observational data. We will also investigate a specific case where only spatially averaged aggregated data in sub-regions are available. Such cases arise in the context of mechanistic geospatial modeling of infectious disease spread whereby the testing data for infected population averaged over public health units (defining a sub-region) are reported by public health agencies.

Geometric mechanics formulations and structure-preserving discretizations for continuum mechanics and kinetic models

ON THE HAMILTONIAN STRUCTURE FOR A MODEL OF A CLOSED VORTEX SHEET AND A VORTEX PATCH IN AN IDEAL FLUID WITH A DENSITY JUMP

Banavara Shashikanth[*1]*

[1]*New Mexico State University*

ABSTRACT

The talk will discuss the Hamiltonian structure for the system of a closed vortex sheet dynamically interacting with a vortex patch in an ideal fluid. The equations of motion for a certain special configuration of this interaction, without reference to Hamiltonian form, was previously published with co-author Rangachari Kidambi. The closed vortex sheet separates an ideal fluid with two different densities, and the vortex patch is located either inside or outside the closed sheet. Following an introduction to vortex sheets and vortex patches, the talk will place this model in the framework of Hamiltonian fluid mechanics, in particular, in the modern symplectic mechanics framework of vortex dynamics.

Modern structure-preserving methods for PDEs

AN ADAPTIVE MOMENTS-BASED INTERFACE RECONSTRUCTION USING INTERSECTION OF THE CELL WITH ONE HALF-PLANE, TWO HALF-PLANES AND A CIRCLE

Mikhail Shashkov[*1]

[1]*Los Alamos National Laboratory*

ABSTRACT

We present a new adaptive moment-of-fluid (A-MOF) interface reconstruction method. It uses the zeroth, first, and second moments of the fragment of material inside a cell of the mesh to construct a shape that approximates the respective material fragment. The new method requires information about the material moments only for the cell under consideration. The adaptive method chooses between shapes obtained by the intersection of the cell with one half-plane, two half-planes, or a circle. The A-MOF method allows to exactly reproduce several convex shapes: corners, filaments, and their concave cell-complements; as well as pieces of the circles and its cell-compliments. Interface reconstruction is formulated as a local (for each cell), non-linear, equality constrained optimization problem, which does not require additional communication and allows for an efficient parallel implementation. In conclusion, we present an extensive set of test problems, both for interface reconstruction on a single cell, and for reconstruction of a variety of shapes on the entire mesh.

HYPOPTLIB: CRITICAL DESIGN INSIGHT INTO LARGE-SCALE DESIGN PROBLEMS IN TOPOLOGY OPTIMIZATION AND BEYOND

Aidan Sheedy[*1], Hazhir Aliahmadi[1] and Greg van Anders[1]*

[1]*Queen's University*

ABSTRACT

Systematically understanding the solution space of large-scale design problems is crucial for answering a range of design questions, including sensitivity, performance, etc. These questions are particularly pressing for design problems where the answer depends on a large number of design variables, e.g., high-resolution problems in topology optimization. We present HypOptLib, a C++/Python code that implements novel filtration approaches to explore the solution space of large-scale design problems. Rather than merely seeking an optimized solution, HypOptLib yields detailed insight into the structure of the solution space, a capability often overlooked in conventional optimization libraries. HypOptLib exploits a mapping of design variables in conventional problems in topology optimization to the dynamics of pseudothermal systems of “particles.” We implement design variable dynamics by adapting techniques from molecular dynamics. Using compliance minimization as a demonstration problem, we demonstrate that HypOptLib supplements problems typically studied via topology optimization with critical insights into the reliability and sensitivity of design solutions. The problem-independent algorithm makes HypOptLib adaptable to a wide range of large-scale design problems in topology optimization and beyond where understanding.

MODELING DAMAGE AND HEALING OF DISORDERED POROUS MATERIAL WITH HOMOGENIZED MICROSTRUCTURE USING PERIDYNAMICS

Shucheta Shegufta[*1] and Michael Zaiser*[1]

[1]*Friedrich-Alexander-Universität Erlangen-Nürnberg*

ABSTRACT

Microstructure geometry plays a crucial role in determining the mechanical behaviour of porous materials. In addition to porosity, the distribution of pores, which we quantify as disorder, is also a significant factor for these materials. Using artificially generated porous microstructures, it has been shown in previous studies[1] that the elastic modulus, peak strength and the work of failure of a porous material depends on the disorder. Similarly, peak stress and work of failure obtained from the simulations can be compared with findings by Kirsch[2], and considering multiple voids as equivalent to a single void. It is observed that for peak stress and work of failure, effect of disorder is even more pronounced than elastic modulus and for high disorder these values are much lower than as predicted by the mean field approach. At higher levels of disorder and porosity, probability of the existence of weak spots with high stress concentration increases, which causes a a knock-down effect. In the previous study, Peridynamics has been used to analyse the failure because of the ease with which it can capture damage and fragmentation. However, modeling porous microstructure in Peridyanmics comes with multiple caveats, such as the need for a very small discretization size to capture the geometrical details, leading to a small time step size for stability maintenance. This leads to very high computational costs and makes computation of large structures almost impossible. Therefore a homogenization technique is necessary in order to reduce the computational cost, without sacrificing the effects of microstructure geometry. To this end, the Intermediate Homogenization (IH) proposed by Chen et al.[3] has been used, where peridynamic bonds of a material point is deleted in a manner that the homogenized structure still carries some information about the microstructure, in our case porosity and disorder. In a similar fashion, bonds may also be created, to simulate healing of damaged structure. This technique is then used to simulate compression in snow, a process that undergoes both damage and healing. The results are then compared with experimental results.

PHYSICS-INFORMED MACHINE LEARNING MODEL FOR BRITTLE DAMAGE PREDICTION

Roozbeh Eghbalpoor[1] and Azadeh Sheidaei[1]*

[1]Iowa State University

ABSTRACT

Physics-informed Neural Network (PINN) has been introduced recently to predict and understand complex physical phenomena by directly incorporating feedback from governing equations. While PINNs offer remarkable capabilities, challenges arise when addressing discontinuities and heterogeneity, potentially compromising accuracy and reliability in prediction outcomes. In this study, a novel approach that combines the principles of peridynamic (PD) theory with PINN is presented to predict quasi-static damage and crack propagation in brittle materials. To achieve high prediction accuracy and convergence rate, the linearized PD governing equation is enforced in the PINN's residual-based loss function. The proposed PD-INN is able to learn and capture complicated displacement patterns associated with different geometrical parameters, such as pre-crack position and length. The computational method presented in this study can be implemented to any PD constitutive model like Bond-Based PD or State-Based PD as well as any horizon factor. Several enhancements like cyclical annealing schedule and deformation gradient aware optimization technique are proposed to ensure the model would not get stuck in its trivial solution. The model's performance assessment is conducted by monitoring the behavior of loss function throughout the training process. The PD-INN predictions are also validated through several benchmark studies, with the results obtained from high-fidelity techniques such as the PD direct numerical method and the Extended-Finite Element Method. Our results show the ability of the nonlocal PD-INN to predict damage and crack propagation accurately and efficiently.

Microstructures of chemically complex materials and their impacts on material properties from multiscale simulations

TEMPERATURE-DEPENDENT ELASTIC PROPERTIES OF BORON CARBIDE FROM FIRST-PRINCIPLES CALCULATIONS AND PHONON MODELING

Sara Sheikhi[*1], Wylie Stroberg[1] and James Hogan[1]*

[1]*University of Alberta*

ABSTRACT

Advanced ceramics, like boron carbide, exhibit high chemical and thermal stability, and abrasion resistance. These outstanding properties make them suitable for applications in extreme conditions, including thermal barrier coatings, aerospace applications, and as neutron absorbers. Understanding the behavior of boron carbide in extreme conditions is pivotal for accurately predicting its mechanical properties, a crucial step in designing and optimizing next-generation materials. In the limited literature, density functional theory (DFT) and molecular dynamics (MD) simulations have been used for investigating the microstructure and mechanical properties of boron carbide. The estimation of Cij at elevated temperatures is largely unexplored, except for MD simulations; however, these simulations can lack sufficient accuracy in interatomic potentials at different temperatures, particularly in the context of single-crystal boron carbide. The boron carbide's unit cell consists of a 12-atom icosahedral cage surrounding a 3-atom linear chain along the (111) rhombohedral axis. The chemical similarity between boron and carbon induces substitutional disorder, resulting in different structures in the thermodynamic limit. The concentration of carbon in the structures can vary from 6.66% to 26.66%; this variability results in a complex phase diagram, challenging the study of boron carbide's mechanical and electronic properties. In this study, temperature-dependent Cij, thermal expansion coefficient (TEC), Helmholtz free energy, entropy, and heat capacity at constant volume (Cv) of boron carbides with different stoichiometries have been predicted using first-principles quasi-harmonic phonon calculations. A combination of first-principles volume-dependent calculations, and phonon calculations, has been performed. Good agreement between elastic constants and structural parameters from static calculations is observed. The thermodynamic properties from phonon calculations show trends that align with the literature. As the temperature rises, we observe a decrease in free energy, while entropy and Cv increase. The temperature-dependent TEC trend shows a minimal increase below 100K, followed by a sharp rise until 500-700K and then a gradual increase until it approaches a nearly constant value. This trend is attributed to the transition from internal energy dominance to vibrational entropy dominance, indicating significant changes in the material's behavior as temperature increases. Temperature-dependent Cijs are predicted, enabling stress analysis at elevated temperatures. Below 100K, elastic constants remain nearly constant due to minimal atom vibration. All elastic constants decrease with increasing temperature, except C44, which exhibits almost no change, emphasizing boron carbide's anisotropic behavior. Overall, this study's outcomes can be used in performing mechanical and thermal stress analysis and optimizing design of boron carbide materials for elevated temperature applications.

EXPERIMENTAL AND MOLECULAR SIMULATION STUDIES OF METHANE ADSORPTION ON DEEP SHALES

Weijun Shen[1], Mingcang Wang[1] and Xu Yang[1]*

[1]*Chinese Academy of Sciences*

ABSTRACT

Understanding methane adsorption behavior on deep shales is crucial for estimating the original gas in place and enhancing gas recovery in deep shale gas formations. However, the methane adsorption behavior on deep shales under high pressure is challenging, and many uncertainties still exist in the process. In this study, the methane adsorption on deep shales within the Lower Silurian Longmaxi Formation from the Sichuan Basin, South China were conducted at pressures up to 50 MPa. The effects of total organic carbon (TOC), temperatures, clay minerals and moisture content on the adsorption capacity were discussed. Then the molecular models of kerogen nanopores with different shapes and sizes were constructed based on kerogen structure unit of deep shale from the Longmaxi Formation, and the methane occurrence were conducted by coupling a grand canonical Monte Carlo algorithm and a molecular dynamics algorithm. The results indicated that the methane excess adsorption on deep shales increased, then reached its peak and finally decreased with the pressure. The methane adsorption capacities exhibited strong positive correlations with the TOC content and negative relationships with clay minerals. The methane excess adsorption decreased as the temperature while the opposite trend would occur once it exceeded some pressure. The presence of the moisture content on deep shales sharply decreased the methane adsorption capacities, and the reduction of the adsorption capacity decreased with the pressure. The methane adsorption capacity in deep shales is negatively correlated with temperature, and high temperature will inhibit the affinity of methane molecules in pores.

STABLE AND EFFICIENT METHODS FOR 2D-3C CLAMPED PLATE AND SHALLOW SHELL MODELS

Xiaoqin Shen[*1]*

[1]*Xi'an University of Technology*

ABSTRACT

In this talk, we share our work on the numerical approximation for the two-dimensional three-component (2D-3C) clamped plate and shallow shell problems. The clamped plate and shallow shell structures are non-negligible in engineering, especially in architectural design, aerospace, and automated manufacturing. Therefore, it is crucial to develop efficient numerical algorithms to analyze their mechanical behavior accurately.

In solving such problems, we face two significant challenges. On the one hand, the complex variable coefficient system on the 2D surface complicates the discretization process. On the other hand, the displacement components have a high degree of regularity, further increasing the difficulty of discretization. We introduce discretization schemes of conforming, nonconforming, and virtual elements to meet these challenges. Moreover, the new contributions include well-posedness and stability for the approximate problem and analysis of the convergence of the numerical solution. Finally, numerical results show that the stability and convergence of the numerical schemes are verified.

CENTRAL WENO-ZN SCHEME WITH THE OPTIMAL ACCURACY ORDER AT HIGH-ORDER CRITICAL POINTS

Yiqing Shen[*1], Biao Zhou[1], Hao Jin[1], Yi Cheng[1] and Jianyu Qin[1]*

[1]Chineses Academy of Sciences

ABSTRACT

The high order critical points (the first n-th derivatives equal to zero while the (n+1)-th one does not) measure the different scales structures in the complex flow fields. The shock-capturing schemes with the highest possible accuracy order at critical points are so desired for the delicate simulations of compressible flows, such as the large eddy simulation and the direct numerical simulation of compressible turbulence. One kind of weighted essentially non-oscillatory(WENO) scheme (WENO-ZN[1,2]) was recently proposed to improve the accuracy of WENO schemes by using a high-order global smoothness indicator and to keep the ENO-property by an adaptive function.

This paper develops the high-order central WENO-ZN (C-WENO-ZN) scheme by combining the ideas of the WENO-ZN and OWENO[3] schemes. Different to that of the previous WENO-ZN schemes, the smoothness indicator of each candidate stencil is calculated by the half-point formula, the global smoothness indicator is calculated by a simplified but more effective form(compared to that of OWENO), and a corresponding adaptive function is also constructed to enhance the ENO-property. Numerical results are present to show that the proposed C-WENO-ZN scheme can achieve high order convergence rate at critical points, is high robust for solving various complex flow fields, and also has other advantages such as the low dissipation and favorable symmetry.

Key words: Weighted essentially non-oscillatory scheme, Critical point, Optimal accuracy, Low dissipation, Symmetry.

AN ACCELERATION SCHEME FOR THE PHASE FIELD FATIGUE FRACTURE SIMULATION

Shuo Yang[1] *and Yongxing Shen**[1]

[1]*Shanghai Jiao Tong University*

ABSTRACT

The fatigue fracture brings severe mechanical failures. In recent years, the phase field approach for fracture has been extended to fatigue fracture. In this study, we propose an efficient acceleration scheme for the phase field approach based on a concurrent time-scale homogenization theory. In this scheme, the fatigue fracture problem is decomposed into a macrochronological problem and a microchronological problem, and is accelerated with the macrochronological time steps adaptively determined. Throughout the whole simulation, the macrochronological time step is monitored, and is corrected by a predictor-corrector strategy if necessary. This scheme is able to accelerate fatigue fracture simulations without sacrificing much accuracy, and can be up to 200 times faster than direct numerical simulations in some cases. For certain force-controlled examples, the proposed scheme, equipped with the arc-length control, is able to reproduce Paris' law with a correlation coefficient higher than 0.91 in the logarithmic scale.

PREDICTION OF WRINKLE PATTERNS IN THIN FILM-COMPLIANT SUBSTRATE SYSTEMS: DIRECT NUMERICAL SIMULATIONS

Yu-Lin Shen[*1]

[1]*University of New Mexico*

ABSTRACT

Formation of wrinkles in thin-film structures has received considerable attention, due to their ubiquity in nature as well as in many modern devices in use or under development. It is a well-recognized form of deformation instability that can develop under mechanical or thermal loading. While wrinkling instability is frequently an undesirable feature, it has been increasingly exploited to create surface patterns with desirable optical, electronic, mechanical, or energy-harvesting functions. Depending on the loading condition and geometry, various 3D patterns and complex shapes may develop, the prediction of which is inherently challenging. In this presentation, we highlight our recent developments of a practical finite element based technique utilizing the embedded imperfections to trigger wrinkle formation. This approach leads to direct modeling from pre-instability to post-instability in a seamless manner, without the need of any cumbersome or multi-step procedure. It also gives new insights into the evolution of wrinkle patterns, and enables the prediction of global structural buckling which may coexist with surface wrinkles. Our studies include large-scale 3D simulations under general in-plane compression, spanning the entire biaxial spectrum in between the extreme cases of uniaxial and equi-biaxial loading. The effects of various material properties, deformation paths and loading sequences can also be analyzed, and the predictions can be correlated with experimental observations.

A COMPARISON OF THE COMBINED-PARTICLE ELEMENT METHOD AND THE GENERAL PARTICLE ALGORITHM IN EPIC FOR APPLICATION TO CONCRETE PENETRATION

Jesse Sherburn[1], Jean Santiago-Padilla[1] and Andreas Frank[1]*

[1]U.S. Army Engineer Research and Development Center

ABSTRACT

Concrete is the most-produced manmade material in the world and is typically an integral component of U.S. military assets. These assets are designed to resist extreme impulsive loads such as those from blast or penetration. The ability to understand and predict terminal ballistic effects on concrete is crucial for the design and analysis of protective structures. Computational modeling of high-velocity impact problems like penetration and perforation have shown increased accuracy over the years as methods such as the finite element, finite difference, finite volume, and meshfree methods have continued to improve. One of the difficulties in modeling these impact events is capturing rapidly changing surfaces within the numerical framework. Meshfree methods offer an advantage in dealing with these rapidly changing surfaces, since they are unbounded by a fixed grid. However, meshfree methods experience an efficiency penalty due to determining the continuously evolving change of neighboring points, requiring the determination of neighbors on the fly. A solution to this problem has been the introduction of hybrid methods, which take the best qualities of both finite element and meshfree methods. Two hybrid methods exist within the EPIC (Elastic Plastic Impact Computation) code and are known as the General Particle Algorithm (GPA) and the Combined Particle-Element Method (CPEM) [1-2]. GPA has been used historically in the past to model high-velocity impact, while CPEM is a newer method offering greater accuracy than GPA. This study will evaluate both GPA and CPEM methods in their ability to accurately capture concrete penetration events. A sensitivity study will be performed, and the results will be compared to relevant experimental data.

SHAPE DESIGN OPTIMIZATION OF BIMETAL COMPOSITE STRUCTURES FOR DYNAMIC COMPLIANCE MINIMIZATION

Jin-Xing Shi[1] and Haruki Igawa*[1]

[1]*Komatsu University*

ABSTRACT

Bimetals have been widely adopted and designed as parts or accessories in automobiles, aircraft, and marine engineering to meet specific requirements. Combining different material properties of two metals can generate new mechanical or physical behaviors.

The shape design optimization of bimetal composite structures plays a crucial role in achieving their optimal mechanical or physical performance. In our previous studies, we developed a gradient-based shape optimization method for composite structures with dissimilar materials, addressing stiffness maximization [1], thermal buckling [2], and control of vibrational eigenvalues [3] problems.

In industrial product design, vibration problems are critical and require careful consideration. Generally, vibration problems are classified into natural vibration, frequency response, and time response problems, with the time response problem being time-dependent and more complex than the other two.

In this study, we aim to extend the gradient-based method for shape design optimization of bimetal composite structures to address the dynamic compliance minimization problem, which falls under the time response category. The design problem is formulated as a distributed parameter optimization problem, and shape gradient functions, i.e. sensitivity functions, are theoretically derived for the shape variation to obtain the optimal interface and surface shapes of bimetals under two volume constraints for the different metals. The optimal results from numerical examples demonstrate that the dynamic compliance of bimetal composite structures can be significantly reduced by using the proposed shape optimization method.

AN IMPROVED SECONDARY BREAKUP MODEL APPLIED TO WATER DROPPING OF FIRE-FIGHTING AIRCRAFT

Yumeng Shi[1] and Fei Xu*[1]

[1]*Northwestern Polytechnical University*

ABSTRACT

When water is released from the fire-fighting aircraft, a large amount of water splits up into fine particles and spreads in all directions affected by aerodynamics of water. It is essential to accurately simulate the process of aircraft dropping water and establish precise droplet aerodynamics analysis. Aiming at the complex multi-phase flow problem of water dropping, the process of aircraft water dropping is numerically studied based on Euler-Lagrange coupling method. In the initial stage of water release, the formation of ligaments and large droplets is simulated using the Volume of Fluid (VOF) method. The Euler liquid portion is converted to discrete Lagrangian drops according to empirical correlations and the droplet breakup model is used to calculate the secondary stage by Discrete Phase Model (DPM) method [1]. Comparing the droplet diameter distribution with the experimental results from the referenced study [2], the calculated results of existing breakup models show significant inconsistency with the experimental results. To address this disparity, an improved secondary breakup model in this paper, incorporating the wave breakup model and Madabhushi breakup model. Numerical calculations using the improved model reveal better alignment with experimental results in terms of droplet diameter distribution. This improved secondary breakup model offers a more accurate and efficient means of evaluating droplet diameter distribution. The method can quickly obtain more accurate droplet diameter distribution. The method provides a reliable calculation for the density distribution and impact load of water, which helps determine how to release water from a fire-fighting aircraft to extinguish a fire more efficiently.

MULTISCALE MODELING STRATEGY FOR ACCURATELY PREDICTING FATIGUE LIFE OF STEELS

Kazuki Shibanuma[*1]

[1]*The University of Tokyo*

ABSTRACT

This study presents a multiscale modelling strategy for accurately predicting the high-cycle fatigue strengths of steels. In the proposed strategy, total fatigue life is estimated from crack growth life alone based on the experimental facts.
The entire model comprises three sub-models, for: (i) a macroscopic finite element analysis, (ii) microstructure, and (iii) crack growth. The required input data are only microstructural information, tensile properties, and loading conditions, without any adjustable material constants. The aim of the model for (i) a macroscopic finite element analysis is to define an active zone where sufficiently contains the whole of possible crack initiation area and to obtain the strain amplitude field in the active zone. In the model for (ii) microstructure, we employed a modeling strategy with two steps of 2D problems, which is modeling for surface and inside of material considering the features of actual fatigue crack initiation and growth behaviors. The Monte Carlo method is applied to simulate distribution of the microstructure, which is a nature of the scatter of fatigue life. In the model for (iii) crack growth, we employed the interaction theory between crack and grain-boundaries. The driving force of the crack growth is quantified using crack tip sliding displacement (CTSD) formulated based on the continuously distributed dislocation theory considering slip transmission between adjacent grains. The material resistance of each phase is determined as the friction strength to move dislocations. All the grains assigned in the surface of the active zone are assumed as possible crack initiation sites and the number of cycles to failure is determined based on the weakest link assumption.
The model was strictly validated against the results of experiments performed on three different steels under various loading conditions using four types of specimens. Although the experimental fatigue life results exhibited wide variation, the predicted and experimental data were accurately matched over the entire range. The notch sensitivity of the fatigue limits depending on the material strength were successfully reproduced by the proposed model. The transition of the crack growth rate was also accurately predicted compared with the experimental results.
The results demonstrate that the fatigue life of steels under high-cycle fatigue can be accurately predicted from crack growth life alone. Furthermore, the proposed strategy is capable of effectively explaining the dependence of fatigue strength on microstructure and loading conditions based on the advanced fracture mechanics.

ABSTRACT

This study enhances the boundary conditions of a multiresolution particle method that combines two-dimensional and three-dimensional subdomains [1]. The multiresolution method is based on the moving particle semi-implicit method and the overlapping particle technique for multiresolution simulation of particle methods [2]. The objective is to compute fluid phenomena related to water waves in coastal engineering with reduced computational cost while maintaining accuracy. Using these improvements, water waves mimicking a tsunami on a structure are simulated and the pressure acting on the structure is compared with experimental data.

In addition, a model of wave-dissipating blocks is developed to prevent the collapse of the blocks due to water waves and to elucidate the complex mechanisms involved. The wave-dissipating blocks are treated as rigid bodies using the energy-tracking impulse method for multiple-body contacts [3]. Coulomb friction is considered to account for the frictional force acting on the wave-dissipating blocks. Using this model together with the proposed multi-resolution particle method, the interaction between the wave-dissipating blocks and the water waves is computed, and the simulation results are compared with the experiment.

[5]*National Cheng Kung University*

ABSTRACT

As walking and cycling paths become more densely populated, the development of infrastructure is crucial to support the transition to these sustainable transportation options. However, various obstacles such as heavy traffic roads and rivers can hinder the movement of cyclists and pedestrians. This research aims to address urban traffic challenges by creating an innovative obstacle crossing technology that is cost-effective, easy to set up, and agile.

The design of pedestrian bridges is frequently limited by deformation, and it is crucial to uphold the bridge's lightweight properties while ensuring safety and comfort. The neutral equilibrium mechanism (NEM)[1] is a zero-power control mechanism capable of managing substantial forces with exceptionally low energy demands. This active control system adjusts the reactive force at specific locations of the bridge structure to compensate the deflection displacement of those points. The control system thus behaves as a "virtual pier".

In a closed-loop control system, stable feedback signals are crucial to the efficiency and stability of the control system. This study uses digital image correlation (DIC) technology to measure the deformation of the bridge, the measured displacements are thus used as input of the control system. These actions must be performed online, and the process of measuring the state and adjusting the reaction force needs to be completed in a very short time.

Since DIC is a computationally intensive image pairing technology, in order to achieve high-frequency measurements, we used CPU multi-thread parallel processing to complete the image pairing and the computational work of control commands.

In order to verify the control efficiency and stability of the NEM-based virtual pier, a series of experiments were conducted. Experimental results show that using DIC to measure bridge status signals can reflect the advantages of high sampling rate and low noise-signal ratio. Therefore, a higher control gain can be used to improve the deformation control effect while maintaining system stability. The test results of changing the load value and load movement speed show that the control technology proposed in this article can reduce the bridge mid-span deflection displacement by 97%, achieving the control goal of the virtual bridge pier. Repeated system stability experiments have also proven high system reliability. The proposed control system indeed improved the performance of the temporary pedestrian bridge.

FEATURE DISCOVERY USING MULTIMODAL AUTOENCODERS

Troy Shilt[*1], Elise Walker[1] and Carianne Martinez[1]*

[1]Sandia National Laboratories

ABSTRACT

Materials are often characterized by a variety of modalities, e.g., process parameters, material properties, microstructure, chemistries, and performance. Parsing this onslaught of disparate data is a time-consuming process traditionally tasked to subject matter experts. However, representation learning algorithms provide a potential alternative way to make sense of these multimodal datasets. We present physics-informed multimodal autoencoders (PIMA): a variational inference framework for discovering shared information in multimodal materials datasets. In this presentation we demonstrate various capabilities of PIMA, including training on datasets with missing modalities, constructing disentangled, interpretable latent spaces, performing informative cross-modal inference, and generating new experimental process conditions which suggest desirable material properties.

BRAIN TISSUE SOFTENING AFTER REPETITIVE HEAD IMPACT OBSERVED FROM SUBJECT-SPECIFIC FE MODELS GENERATED WITH DIFFUSION TENSOR MRI

Vickie Shim[12], Tayebi Maryam[2], Eryn Kwon[21], Justin Fernandez[1] and Samantha Holdsworth[21]*

[1]*University of Auckland*
[2]*Matai Medical Research Institute*

ABSTRACT

How do repetitive head impacts affect the developing brain? Participation in sports activities has sensorimotor and cognitive benefits, particularly in adolescents. However, such benefits come with the risk of brain injuries for collision sports. Some researchers suggested that the plasticity of the young brain increases the impact tolerance and recovery. Still, others suggested the opposite - that developing brains are more vulnerable than adults due to the immaturity of their nervous system. Our study aims to investigate the microstructural and tissue level changes in the brains of high school rugby players with subject-specific FE models generated with the players' diffusion tensor MR images.
We studied male high school rugby players (n=30) in Gisborne, New Zealand, for the past two years. The subjects were grouped into – 1) repetitive head impact (RHI) who did not experience brain concussion but still received sub-concussive head impacts during games and practices; 2) mTBI cohort who were clinically diagnosed with brain concussion; 3) age and ethnicity matched control cohort. The MRI scans were taken at three-time points – early, mid & post-season - to measure changes in the brain over the whole season. Players were also given a bespoke instrumented mouthguard (hitIQ, Australia) moulded to fit their oral cavity to measure the linear and angular acceleration of participant's head impacts. Players wore their mouthguards at all games and practices, allowing us to monitor the head impact frequencies and severity throughout the season.

We then used our validated semi-automated subject-specific finite element (FE) model generation pipeline [1,2]. We developed subject-specific brain FE models using their pre-, mid and post-season MRI to capture their geometry and material properties. A total of 90 subject-specific FE models were developed. These fully subject-specific model generated subjects' unique strain patterns when run with their impact profiles measured with instrumented mouthguard sensors. In particular, we observed brain tissue changes in those players after one season. When simulated with the same head impact, the brain models generated with post-season MRI scans showed much higher strain than the one developed with preseason MRI. This may mean brain tissue has become softer due to small but repetitive head impacts from games and practices. This finding and its potential biophysical meanings from multimodal MRI scans will be presented at the meeting.

TWO-SCALE DAMAGE PROPAGATION/STRENGTH ANALYSIS OF CFRP CONSIDERING RANDOMNESS OF FIBER DISTRIBUTION

Yukinobu Shimura[*1] *and Tetsuya Matsuda*[1]

[1]*University of Tsukuba*

ABSTRACT

Carbon fiber-reinforced plastics (CFRP) are used as structural materials in aerospace and energy applications, because of their higher specific strength, specific stiffness, and corrosion resistance compared to common metal materials. In general, CFRP are manufactured by stacking laminae (plies) which are submillimeter thick resin sheets unidirectionally reinforced by a number of carbon fibers with diameters of 5-10 micrometers. Thus, when CFRP are subjected to relatively large load, micro-scale damages such as resin cracking, fiber/resin interface debonding and fiber fracture firstly occur in laminae, and then they progress and accumulate, leading to macro-scale stiffness degradation and failure. Therefore, analyses considering microscopic damage behavior are required to predict damage/strength properties of CFRP.

For the above reason, this research group has developed a two-scale damage analysis method by introducing damage criteria into a two-scale analysis method based on a homogenization theory [1], which can explicitly couple microscopic damage propagation and macroscopic strength of CFRP. In this study, however, the randomness of fiber distribution observed in actual CFRP was not considered, and thus it did not accurately capture actual damage behavior of CFRP.

In this study, two-scale damage/strength analysis of CFRP that takes into account the randomness of fiber distribution is performed. For this, several unit cell models with random fiber distribution [2] are prepared as microscopic models of laminae. Then, they are randomly assigned at integration points in a macroscopic model of CFRP, and the two-scale tensile analysis of CFRP is performed. In the analysis, CFRP with several different laminate configurations are considered, and the effects of random fiber distribution on the damage and strength properties of the CFRP are investigated by comparing the results with and without considering the randomness of fiber distribution.

EXPANSION OF DEEP MATERIAL NETWORK FOR WOVEN COMPOSITE THERMAL CONDUCTIVITY HOMOGENIZATION

Dongil Shin[*1], Peter Creveling[1], Scott Roberts[1] and Remi Dingreville[1]*

[1]*Sandia National Laboratories*

ABSTRACT

Developing reduced-order models to accelerate simulations has garnered significant attention across diverse physics domains. Artificial intelligence has contributed significantly to this aspect of computational speed improvement in the last decades. One of the primary interests is micro- and mesoscale surrogate models for multiscale interpretation. Deep Material Network (DMN) represents a novel approach that goes beyond predicting homogeneous properties directly through physics-informed machine learning models. During the last few years, it has generated substantial interest in the mechanics of microstructures. However, existing DMN research has predominantly focused on network parameters related to mechanical behavior. This study seeks to extend DMN research to address thermal conductivity homogenization in woven structures. Through an in-depth study of DMN models, this research aims to concretize network and node parameters, providing a comprehensive framework for extending the DMN to other physics domains. To account for anisotropy, particularly relevant in the case of woven structures, we explore how expanding network parameters can enhance prediction accuracy, building upon existing research approaches. Our interpretation results showcase the ability to predict homogeneous and thermal conductivity properties over a thousand times faster, facilitating uncertainty quantification (UQ) studies and sensitivity analyses in coupled scale scenarios. This research contributes to the understanding that DMN is not limited to elastic problems but can be effectively applied to other physics when properly defining relationships between constitutive equations and network parameters. By demonstrating the potential for extending DMN to other physics domains and modeling degrees of freedom, this study lays the groundwork for solving multi-physics problems via DMN. Sandia National Laboratories is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

ANALYSIS OF THE DAMAGE BY THERMAL LOADING IN A HETEROGENEOUS INTEGRATION PACKAGE

Siham El Otmani[1] and Dong-Kil Shin[1]*

[1]Yeungnam University

ABSTRACT

A heterojunction package is one in which various types of individually manufactured chips are assembled and integrated to a level comparable to the size of a single chip. It integrates chips with various functions such as processor, memory, sensor, optical, and MEMS, and is electrically connected using rewiring, micro bumps, copper direct bonding, and through silicon via. Because the heterogeneous packages are manufactured considering complex factors such as various sizes, materials, process conditions, and manufacturing technology, it is considered important to secure mechanical reliability.

As the structure of the package becomes more complicated and the number of materials increases, it is vulnerable to damage depending on the manufacturing process and user usage environment. This has led to changes in both the microstructure and mechanical properties of interfaces and joints in the package. The creep behavior of solder joints is particularly important to predict due to the complex time-temperature dependence of solder behavior.

In this study, a numerical analysis was performed in order to evaluate the damage in the heterogeneous integration package. The structures of the packages were designed and corresponding manufacturing processes were considered. The constitutive models for material properties were developed. Damage response was used to gauge the rate of degradation and predict the life of the joints. Numerical results were verified by the measurement of thermal deformation.

ACOUSTIC BARRIER DESIGN WITH TOPOLOGY OPTIMIZATION BASED ON DEEP REINFORCEMENT LEARNING

Myung Shin[1] and Gil Ho Yoon*[1]

[1]*Hanyang University*

ABSTRACT

This research employs a topology optimization based on deep reinforcement learning technique to design sound barriers for noise reduction. Reinforcement learning is a type of machine learning in which an agent gradually learns to find the optimized solution through various experiences in a situation where there is no data. Reinforcement learning can be applied by decomposing the topology optimization process into iteratively adding elements. In this study, we delve into the topology optimization of acoustic systems using Double Deep Q-Network (DDQN), a famous algorithm in deep reinforcement learning. The agent in reinforcement learning observes the acoustic fields, boundary conditions, noise source positions, and the location of the target area. The RL agent takes actions to add solid materials starting from an empty design space. The reward is defined as the difference in the objective function before and after material addition. The goal of the reinforcement learning agent is to find a solid element addition policy that achieves the maximum cumulative reward, which ultimately finds the topology of the barrier structure that minimizes the sum of the absolute values of sound pressure in the target area at multiple frequencies. Through numerical examples of sound barrier design, this study validates the reliability of the reinforcement learning-based acoustic topology optimization technique. The results demonstrate that the reinforcement learning agent effectively performs multi-frequencies acoustic topology optimization in various boundary conditions, locations of noise source and objective areas.

A CDM-LIKE CONSTITUTIVE LAW COMBINED WITH TRESCA YIELD FUNCTION TO PREDICT SHEAR-LIP FRACTURE ALONG WITH STRAIN LOCALIZATION

Yuichi Shintaku[*1], Reiya Tao[1] and Kenjiro Terada[2]*

[1]*University of Tsukuba*
[2]*Tohoku University*

ABSTRACT

We present a continuum-damage-model-like constitutive law embeding cohesive cracks with Tresca yield function to predict shear-lip fracture along with localization. The proposed constitutive law accommodates a hyper-elasticity based plastic model with the use of the deformation gradient multiplicatively decomposed into separation-induced, elastic and plastic parts. The elastic–plastic deformation along with isotropic hardening is represented by a Hencky-type model combined with the Tresca yield function. In addition, the strain softening due to the shear-lip fractur along with the strain localization is represented by the introduction of the shear-induced damage variable into the Tresca yield function. The evolution of the shear-induced damage variable is represented by the damage-loading function corresponding to the plastic energy release based on thermodynamics. On the other hand, the stress release process caused by flat fracture is realized by cohesive traction separation law and the assumption of the local equilibrium state between the principal stress and cohesive traction. By comparing with results of a CDM-like constitutive law combined with Mises yield function, the capability of our proposed model is demonstrated throughout the various types of specimens under different stress states.

MULTITASK REPRESENTATION LEARNING FOR STRUCTURAL DESIGN

Kohei Shintani[*1] and Yohei Morikuni*[2]

[1]*Toyota Research Institute, Inc.*
[2]*Toyota Motor Corporation*

ABSTRACT

In product development, it is necessary to design structures that satisfy multiple constraint conditions. In the early stages of product development, where the actual product is not available, evaluation using CAE is employed. By incorporating CAE results and updating the shape accordingly, it is possible to design an optimized shape that meets the objectives. However, if the need for shape changes arises during the product development process, it requires a reevaluation involving the aforementioned shape design and CAE evaluation.

In this study, we propose a Neural Network model, that simultaneously achieves the tasks of automatic shape generation and inference of CAE evaluation results. With the proposed model, it is possible to generate a modified shape, predict the distribution of corresponding physical quantities, and estimate the cost function in real-time. This capability contributes to smoothing the designer's workflow and enhancing the efficiency of the development process.

The proposed model utilizes a shape representation based on point clouds, consisting of an encoder that extracts the latent vector of object shape from the point cloud and a decoder that reconstructs the point cloud from the latent vector. Additionally, the model includes regression models to determine the physical quantities at each point of the point cloud from the latent vector and to calculate the cost function value.

In the algorithm for shape generation, this study proposes intentionally adding points sampled on the boundary of the shape, in addition to uniformly sampling points on the conventional shape surface during point cloud creation. The intentional inclusion of boundary points through focused sampling is expected to improve the reproducibility of shapes and enhance the prediction accuracy of CAE results on the boundary.

To verify the effectiveness of the proposed method, a practical numerical example is demonstrated.

HIERARCHICAL REDUCED ORDER MODELING FOR DISTRIBUTED MEMORY PARALLEL COMPUTERS

Kyohei Shintate[*1], Naoki Morita[1], Shigeki Kaneko[2] and Naoto Mitsume[1]*

[1]*University of Tsukuba*
[2]*University of Tokyo*

ABSTRACT

Model order reduction techniques represent a very effective approach for computationally intensive applications involving the repeated solution of parametric Partial Differential Equations (PDEs), which arise from various fields such as optimal control, shape optimization, fluid dynamics, and structural dynamics. On the other hand, the efficiency of these systems is constrained by the curse of parameter dimensionality due to the complexities of PDEs and high computational costs in the offline stage. To tackle these issues, the combination of Reduced Order Models (ROMs) and Domain Decomposition Methods (DDM) has been explored to reduce the parameters and degrees of freedom in parametric PDEs. The common idea behind these methods is to construct local reduced spaces on each decomposed subdomain and combine these spaces across interfaces. Although various coupling methods such as iterative Schwarz method or Lagrange multiplier method exist, there are few examples implemented in distributed memory parallel computers, which are highly valuable for memory usage. Additionally, there is a lack of discussion on parallel computational performance, a critical aspect in DDM.

In this study, aiming to fundamentally address memory usage and computational bottlenecks, we propose an overlapping DDM for distributed memory computers, based on generalized hierarchical graph decomposition. Hierarchical graphs consist of a three-level architecture corresponding to mesh nodes, ROM computation subdomains, and parallel computation subdomains, respectively, which are associated using DDM. The proposed method employs Local Proper Orthogonal Decomposition (LPOD)[1] as the basis selection method for ROM computation subdomains, allowing the independent determination of bases for each one. Since it interacts only with neighboring subdomains, the POD computation subdomain is considered a graph node. The hierarchical graph structure of our proposed method allows independent definitions of POD computation subdomains and parallel computation subdomains. By representing these relationships as a graph, we successfully enable parallel computation in distributed memory computers. We discuss the computing efficiency and parallel computational performance through its application in fluid analysis.

THE PHASE FIELD APPROACH FOR MIXED-MODE FRACTURE MODELLING TO UNDERSTAND INSTABILITY IN THE MATERIALS

Mrunmayee Shiradhonkar[*1] and Rajagopal Amirtham*[1]

[1]*Indian Institute of Technology Hyderabad*

ABSTRACT

The instability is the unexpected deviation in crack growth process. The deviation in the crack growth is seen due to the stress state of the crack front. The crack kinking is the effect of the stress state parallel to the crack front. This stress is responsible for the instability of the crack path. In the case of the materials with interfaces, crack propagation is seen in the events of penetration and deflection (Hutchinson, 1989) . The competition of penetration of the crack inside the material and deflection of the crack along the interface depend on the fracture toughness of the interface and material. As the crack progresses, the energy release rate increases more than the critical fracture toughness of the material. The excess energy is responsible for the crack to meander in the form of oscillations. Sometimes, the crack tip of the accelerating crack becomes blunt and splits into the branches, creating a crack-branching event. These events are seen in brittle materials like glasses.

The study aims to understand the point of instability in the crack propagation process. The phase-field framework can be used to model the instability in crack propagation. The stress-based failure criterion can be used to track the nucleation and evolution of the crack growth process (T. Clayton, 2022). The anisotropic nature of the material can be given in the total energy equation of the system (Shariff, 2022). This equation can then be used for solving the evolution of the crack.

ABSTRACT

In recent years, along with climate change related to global warming, natural disasters have become more frequent and severe, and numerical simulations are required to accurately predict disaster damage of unknown scale that may occur in the future. The particle method is suitable for tsunamis, flooding, and sediment disasters because it is good at representing intense deformation such as splitting and merging, but it is prone to accuracy degradation and numerical instability due to disorder in the particle placement. To solve these problems, SPH(2) has been proposed, which enables highly accurate operation even in the particle placement disorder. The SPH(2) gives a better accuracy and convergence property compared to traditional SPHs, but it still has a limitation to overcome the numerical instability. Particle Shifting Techniques has been proposed to keep a better particle homogeneous particle placement, but long-term volume conservation has not been discussed carefully. On the other hands, a stabilized ISPH[1], in which an artificial source term to satisfy the density invariance in the pressure Poisson equation is introduced, can control the total volume.In this study, we propose a new Particle Shifting without the artificial source term of the pressure Poisson equation. This is a simple combination of the existing Optimized Particle Shifting (OPS) [2] and the Density-based PS[3] to simultaneously improve particle placement and volume conservation. Finally, the numerical stability and accuracy improvement of the proposed method are demonstrated by rotating square patch of fluid and dam break simulations.

MULTISCALE MODELING OF MICROSTRUCTURED BEAMS BASED ON MICROMORPHIC THEORY

Mohammad Shojaee[1] and Oliver Weeger*[1]

[1]*Technical University of Darmstadt*

ABSTRACT

Metamaterials are artificial materials with novel properties and functionalities not found in natural materials. They have potential applications in various fields, including acoustics, optics, mechanics, and thermodynamics. However, analyzing metamaterials is challenging due to the complex interactions between the macro and micro scales [1]. Here, we investigate an efficient multiscale model for metamaterial beams' linear and nonlinear bending and vibration behavior.
A micromorphic beam theory is developed from the conventional Timoshenko beam theory using independent axial and shear strains and rotations at the microscale level [2]. This enables an accurate description of the deformation of the microstructured beams with only a few unit cells through the thickness direction. The micromorphic Timoshenko beam captures size effects and is more computationally efficient than 2D or 3D micromorphic continuum models.
One of the main aspects of this research is to identify micromorphic material parameters by comparing them with representative volume elements of the microstructure. This is done by using a differential quadrature method to numerically discretize the governing equations for static deformations as well as vibrations. The numerical examples demonstrate the accuracy of the method in obtaining deflections, linear eigenfrequencies, and nonlinear frequency responses for metamaterial beams with weakly separated macro- and microscales.
Our work is a contribution to the field of the theory of micromorphic beams and the multiscale modeling of metamaterials. The proposed approach is efficient and accurate in capturing the nonlinear beam behavior. A systematic procedure for identifying micromorphic material parameters from the microstructure is also provided.

ABSTRACT

Solving Partial Differential Equations (PDEs) is essential for understanding the behavior of physical systems. However, large-scale solutions of PDEs, even with state-of-the-art discretization techniques, remain costly. We propose a novel physics-constrained neural network (NN) approach for solving PDEs without labels, facilitating high-throughput solutions for design and decision-making. Unlike traditional physics-informed NN approaches that rely on the strong or weak form of PDEs for the loss function, our method constructs the NN's loss function using the discretized residual of PDEs, implemented efficiently through a convolutional, operator-based, and vectorized approach. In addition to a deterministic model, we develop a probabilistic model by incorporating Bayesian NNs (BNNs) to quantify the epistemic uncertainty from model parameters and aleatoric uncertainty from data noise. For BNNs, the discretized residual forms the basis of the likelihood function. Our approach utilizes deterministic and probabilistic convolutional layers to learn the applied boundary conditions (BCs) and identify the problem domain. With Dirichlet and Neumann BCs as inputs, a single NN can address similar physics across various BCs and problem domains. The trained surrogate PDE solvers can interpolate and extrapolate predictions for BCs beyond their training exposure. This is particularly useful for problems requiring repetitive solutions of similar PDEs with minor variations. We demonstrate the effectiveness and performance of our framework on a range of steady-state and equilibrium boundary value problems, encompassing diffusion, linear elasticity, and nonlinear elasticity.

OPTIMIZING FIBRILLAR ADHESION DESIGN USING SUPERVISED MACHINE LEARNING

Mohammad Shojaeifard[*1], Mattia Bacca[1] and Matteo Ferraresso[1]*

[1]*University of British Columbia*

ABSTRACT

Fibrillar adhesion is a natural phenomenon found in many living organisms, including flies, spiders, and geckos. This adhesion mechanism relies on small hair-like structures, called fibrils, attached to a backing layer which enhances adhesion to surfaces, allowing these organisms to climb vertical surfaces. Inspired by this mechanism, there are many applications that utilize fibrillar adhesion to increase their adhesion performance, including in robotics and medical devices. The stiffness of the fibrils and backing layer, along with the length, distance, and configuration shape of the fibrils, are critical structural parameters that determine the maximum adhesive strength of the fibril array [1]. However, optimizing the structural design of fibrillar adhesives to enhance their adhesive strength is a challenging task, due to the large computational cost of current numerical models. In this study, various supervised machine learning (ML) models, including linear and non-linear regressions, as well as neural networks, including ANN, DNN, and CNN, were trained to generate a reliable and fast approximation of the maximal adhesive force of a given fibrillar adhesive. The results show that deep neural networks perform best, yielding up to 10 times improved mean absolute test error compared to the baseline. The faster model provides accurate results when predicting different sizes of fibrils, different distances between fibrils, and diverse geometrical shapes of the arrays. In the next step, I designed a framework containing two DNNs with same structure and hyperparameters to optimize the fibril length distribution, for any arbitrary shape of the backing layer with fibrillar array on top to find the highest possible adhesion force in the structure. The first DNN is to be trained on training set and hyperparameter tuning and the second DNN is designed to solve the inverse problem to find the optimum solution by cutting down computation time from minutes/hours to seconds [2]. Overall, the study highlights the potential of using machine learning techniques to optimize the design of fibrillar adhesives, which could have important implications for the development of new and improved adhesives in various fields, such as robotics, medical devices, and space exploration.

PARALLELIZATION OF THE FINITE ELEMENT-BASED MESH WARPING ALGORITHM USING HYBRID PARALLEL PROGRAMMING

Abir Haque[1] *and Suzanne Shontz**[1]

[1]*University of Kansas*

ABSTRACT

Parallel dynamic meshes are essential for computational simulations of large-scale scientific and engineering applications involving motion, such as the launch of a rocket into outer space, the swaying of a building due to an earthquake, and the beating of a human heart. Although there are several parallel implementations of mesh warping algorithms in existence, all of them have been developed for enhanced scalability exclusively for shared or distributed architectures. None of them have been designed to take advantage of MPI-3's shared memory programming, an all-MPI alternative to MPI/OpenMP programming. For example, they do not consider the remote memory access (RMA) or shared memory (SHM) communication features available in MPI-3. Considering that the core count in compute nodes, from laptops to high-end servers, continues to increase, we hypothesize that utilizing MPI RMA and SHM features will provide a superior solution, in terms of scalability, over existing approaches to parallel mesh warping algorithms that utilize exclusively shared or distributed memory programming.

In this talk, we discuss our parallelization of the finite element-based mesh warping (FEMWARP) algorithm, which was proposed by Shontz and Vavasis. Our parallel implementation takes advantage of the features of MPI RMA and SHM communication to solve a Poisson boundary value problem for the deformed mesh. The first step of the FEMWARP algorithm is to compute a set of local weights for each interior node which describe the relative distances of the node to each of its neighbors. This involves generating a global stiffness matrix and solving for the sets of weights in an embarrassingly parallel manner. To assist in the computation, the neighbor lists for each interior node are pre-computed using hybrid parallelism. The second step of the FEMWARP algorithm is to apply the boundary transformation from the application in an embarrassingly parallel manner. Finally, new coordinates for the interior nodes are computed by solving a system of linear equations with multiple right-hand sides that is based on the weights and boundary deformation. A Preconditioned Block Conjugate Gradient Method is used to solve equations. Our numerical results demonstrate good efficiency and strong scalability of parallel FEMWARP on up to 256 cores on the KU Community Cluster.

IMPACT CRATERS OF THE MOON WITHOUT SIGNS OF THE MATTER MELTING AND THE MATTER EMISSIONS

Michael Shpekin[*1] and Ricardo Tomas Ferreyra*[2]

[1]*Kazan Federal University*
[2]*Universidad Nacional de Córdoba*

ABSTRACT

The classic idea of impact craters is that all craters are divided into two groups: simple and complex. However, the achievements of orbital observations in recent years have made it possible to detect craters that do not belong to these two groups.
The authors examined the area of "bulbous fields" at the bottom of the young Aitken crater to understand the unusual topography of a group of 5 small craters included in the named area. During the analysis, one of the five craters attracted attention by the topography of the bottom. There was no melt of matter in the form of solidified magma at its bottom, as happens in simple craters. But there are no also central peak there! Instead, a smooth convex surface covered with small impact craters is confidently visible. It is also characteristic that in the vicinity of this crater there is no material of the substance ejected as a result of the impact that led to the formation of the crater. As a working hypothesis, the authors suggested that the described crater contains the body of the impactor, which deepened when falling into the molten lake of the Aitken crater bottom.
At the same time, the impactor did not undergo destruction. This could be due to the fact that at the time of the shock of the drummer, the surface of the Aitken bottom had not yet completely cooled down, and the melt substance was in a viscous state. As a result of the introduction of the impactor's body into the Aitken bottom, a shock wave arose, which led to the formation of domes of "bulbous fields". The energy of this shock wave was apparently enough not only to form domes, but also to penetrate the coating of the Aitken bottom in two places near the edges of craters with domes and create lava tubes, which are clearly visible in ultra-high resolution images.
Our report attempts to find similar craters in other regions of the Moon. The presence of such craters on the Moon is not only of theoretical interest, since it expands and complements the generally accepted idea of simple and complex craters. The practical significance of such craters lies in the fact that small asteroids, meteorites or fragments of them may turn out to be preserved impactors.
Then such craters appear to be objects of increased interest for upcoming lunar expeditions

LEARNING PROCESS-STRUCTURAL-PROPERTY RELATIONS IN MICROSTRUCTURES THROUGH MULTI-MODAL BASED MACHINE LEARNING.

Ankit Shrivastava[*1], Matias Kalaswad[1], Marta D'Elia[2], David Adams[1] and Habib Najm[1]*

[1]*Sandia National Laboratories*
[2]*Pasteur Labs*

ABSTRACT

This presentation will discuss a multi-modal-based machine learning approach for building the process-structural-property relations for the Molybdenum (Mo) thin films fabricated using various physical vapor deposition (PVD) processing conditions.

Material such as Mo thin films, due to their excellent physical properties, play a crucial role in the semiconductor industry. Consequently, there is a growing interest in producing these films with exceptional properties to enhance the efficiency and reliability of semiconductor devices. However, producing thin films with desired properties requires knowledge of process-property relationships. Machine learning models are highly efficient in learning complex relations between diverse processing conditions and multiple properties. To increase confidence in these machine learning models, they must be enabled to capture and disseminate knowledge that is interpretable by material science experts. This knowledge is mainly desired through PSP linkage (Process-Strcture-Property). In the existing research, the machine learning models used to study PSP correlations have been limited, likely because of the multi-modal nature of microstructural data.

In order to utilize the multi-modal information, a multi-modal-based machine learning approach was developed that predicts the properties and microstructural characteristics of the Mo thin films from the given PVD processing conditions. First, a multi-modal deep learning model is used to learn a joint latent representation of the multi-modal microstructure data. Then, another deep learning model is used to learn a relationship between the processing parameters and the joint latent representation. The predicted joint latent representation for given processing conditions can be then reconstructed into original multi-modal structural information that is interpretable by material science experts.

The Mo thin films were deposited onto Si wafers using the PVD technique for various Ar pressures and sputter powers. Here, the processing conditions, pressure, and power are input for the deep learning model that predicts a joint latent representation of the multi-modal information about the thin films. The multi-modal structural information about thin films is obtained using high-throughput experimentation. The information consists of 1D spectral data in the form of X-ray diffraction (XRD), 2D images in the form of scanning electron microscopy (SEM) and transmission electron microscopy (TEM), and scalar dataset in the form of resistivity.

MECHANISTIC STUDY OF THE DEGRADATION MECHANISM OF LITHIUM-ION BATTERIES

Sourav Das[1] and Pranav Shrotriya[1]*

[1]Iowa State University

ABSTRACT

Lithium-ion batteries (LiBs) are stable portable energy sources and finding increased use across the industry from consumer electronic segment to electric vehicle (1). LiBs suffer from challenges in reliability during fast charging, long repeated cycles, high temperature operation and low temperature operation. The repeated charging and discharging of the LiBs result in capacity loss due to the deposition of cyclable lithium as solid electrolyte interface (SEI) layer on the anode surface and cathode interface layer (CEI) on the cathode (2). Additionally, lithium ions are also susceptible to deposition as Li Metal on anode surface during fast charging or lower temperature charging resulting in large capacity losses. The mechanical stress associated with intercalation and deintercalation of lithium from the electrode particles may result in particle cracks. The dendrite growth due to lithium plating may impact separator integrity and increasing risks of runaway heating and catastrophic failure. Hence, understanding the capacity loss due to electrolyte interface growth and plating is essential to ensure safe operation of LiBs.

We utilize a previously reported single particle model (SPM) that incorporate battery damage mechanism of SEI growth, SEI cracking, lithium plating to estimate capacity losses and battery degradation during repeated fast charging of batteries (3). The model predictions are compared to experimental measurements of capacity losses to validate the modeling assumptions and determine the parameters required to describe the damage models. The experimentally validated SPM model is utilized to get critical insight of the behavior of the different degradation phenomena during repeated cyclic operation. The model is used to characterize irreversible plating growth with C rate, SEI film growth rate and film resistance variation rate, the loss in capacity and cell voltage characteristics with the experimental result across different spectrum of C rate 0.1C to 6C. The close agreement between the model predictions and experimental result showed model's capability to characterize the performance degradation of LiBs.

LEVERAGING GANS AND CNN FOR STRESS MITIGATED DESIGN GENERATION

Sania Shujaat[*1] and Ikjin Lee*[1]

[1]*KAIST*

ABSTRACT

Abstract:
Design generation and optimization using state-of-the-art deep learning (DL) methods, especially generative designs (e.g., generative adversarial networks (GANs)), have emerged as a powerful tool in engineering. However, ensuring the structural integrity of these GAN-generated designs remains a challenge to overcome. This work proposes an innovative approach that integrates a Convolutional Neural Network (CNN) based predictive model and generative adversarial network to iteratively generate designs with improved structural reliability. This work aims to employ Convolutional Neural Networks (CNNs) for predicting stress levels in designs generated by GANs and utilize these predictions to mitigate overall stress. The CNN model is trained on a dataset of stress-annotated designs, enabling the model to learn complex patterns between design features and corresponding structural stress. Once trained, the CNN becomes a stress prediction tool. When the GAN generates a design, it undergoes stress assessment through the CNN. The predicted stress value is used as a threshold to reduce the induced stress in each design. Integrating CNN-based stress prediction into the GAN workflow results in designs with lower stress levels while maintaining structural robustness and design diversity.

This research has profound implications, especially in industries requiring rapid generation of optimized designs, such as aerospace and automotive engineering. By utilizing CNNs to predict and minimize stress in GAN-generated designs, the approach enhances the efficiency and reliability of the design generation process. It ultimately improves product performance and safety. This research introduces a novel methodology for integrating CNN-based stress prediction into GAN-generated designs, showcasing its potential to revolutionize design optimization across various engineering domains.

ABSTRACT

Guided Waves form an efficient method for Structural Health Monitoring (SHM) and Non-Destructive Evaluation (NDE) of thin plate structures. This technique exploits the favorable properties describing the propagation of Lamb waves, such as low geometrical damping, which permits the coverage of extended areas with few low-cost PZT sensors, and a short wave length, which enables the detection of minor defects. The latter leads to drawbacks regarding the forward simulation of the wave propagation phenomenon, which is though an essential task when a model-based method is adopted. Model-based schemes can offer advantages over purely data-driven schemes, since they offer the potential for extrapolation and response estimation in unmeasured location. However, as short wave lengths require a fine discretization in space and time, they are linked with a high numerical toll; this poses a significant obstacle in the implementation of computationally intensive tasks, such as inverse problem solutions related to localization and quantification of defects.

A surrogate model can be deployed to expedite the task of forward simulation, which forms a necessary part of any inverse setting. Within an inverse formulation, such a surrogate needs to be parameterized concerning the characteristics of candidate defects, e.g. in terms of the defect positioning and size, in order to ensure rapid evaluations. This contribution presents a surrogate model, which couples ray tracing of Lamb waves with Frequency Response Functions (FRFs) to get the response at various sensor locations. The method enables the simulation of multiple defects and features within plate geometries, such as rivet holes. The efficiency of the surrogate in an inverse setting is demonstrated in a synthetic, numerical example with conical notches and conical holes as defects.

STUDY OF THE DYNAMIC BEHAVIOR OF CELLULAR STRUCTURES FOR THE ABSORPTION OF MECHANICAL VIBRATIONS

Marcelo Silva[*1] and Lucas Ramos*[1]

[1]*Federal University of ABC*

ABSTRACT

In the structural engineering, vibration can be a problem that can cause serious problems and even endanger human life if not properly considered in the design phase. Several active and passive mechanisms have been developed over time to damp its effects, however, most of them have some drawbacks, such as low static stiffness, complex design, attenuation in a limited frequency and more. As additive manufacturing was developed, cellular structures became possible to be manufactured in a single piece. In order, to overcome limitations of current attenuating mechanisms, the use of local resonators within the cellular structure had been proposed to combine the advantages of repetitive structure with the advantages of the resonators through the elastic band gap effect. Therefore, the focus of this work was to evaluate the dynamic behavior of 2D cellular structures using the finite element method, with local resonators calibrated to damp vibrations at a specific excitation frequency, to understand their advantages and capabilities. Even though some unexpected effects of signal amplification may happen in frequencies not originally considered, attenuation of specific excitation frequencies in a simple way by using local resonators associated with cellular structures was observed.

MODEL COMBINATIONS USING FUZZY CONTROL

Renato Silva[*1]*

[1]*Laboratorio Nacional de Computacao Cientifica*

ABSTRACT

Combining forecasts from multiple models is a commonly used method to achieve more accurate results than relying on a single model. This approach is widely adopted in fields such as meteorology, hydrology, and economics. It is established that using model combinations in practical applications typically leads to better performance compared to using a single selected method. However, the real advantage of combining models lies in their ability to mitigate risk, offering a more reliable outcome than the selection among individual models.

In our work, we use models that consider uncertainties represented by fuzzy numbers, so our Quantity of Interest is also represented by fuzzy numbers. Our primary focus is to explore how to combine these fuzzy numbers. There are various techniques available to combine them. However, all of these techniques assume that all fuzzy numbers have equal reliability. In some cases, this assumption can be incorrect, posing a potential risk in the combination process. To avoid risks, we will use a compatibility function to determine whether all information can be fused or whether it is too conflicted to make an adequate combination.

To address the inherent subjectivity and uncertainty inherent in assessing information reliability, we employ fuzzy control, a widely recognized method for managing systems characterized by imprecise components.

In our work, the decision on what and how to combine is made by a fuzzy control. This control selects which models to combine based on a conflict measure. Additionally, the control determines the fusion strategy to be employed.

We illustrate the implementation of this control in tackling the heat exchanger fouling problem, a problem that has multiple sources of uncertainties that can profoundly affect the efficiency and performance of various industrial processes.

TOPOLOGY OPTIMIZATION APPLIED TO 3D COMPRESSIBLE SUBSONIC ROTOR DESIGN USING FINITE DIFFERENCE ADJOINT APPROACH

Felipe Silva Maffei[*1], Carlos Massaiti Okubo Junior[1], Julio Romano Meneghini[1] and Emílio Carlos Nelli Silva[1]*

[1]*University of São Paulo*

ABSTRACT

One of the main challenges of topology optimization for turbulent compressible flow problems is to have an efficient way to calculate the sensitivities in such flow conditions. The present paper extends the work of Okubo et al. [1] (compressible laminar flow) by incorporating turbulence in the sensitivity calculation (via the discrete adjoint method), making it possible to evaluate the sensitivities considering this phenomenon. The methodology can be summarized as follows. The forward problem is solved using the finite volume method. Using the discrete set of governing equations, the adjoint system is mounted (with the terms of the derivatives being approximated by finite differences) and solved. With the adjoint field and the gradient of residual w.r.t design variable, the sensitivity is evaluated. Then the design variables are updated, and the loop continues until the termination criteria are achieved. In this work, the forward problem takes advantage of the already implemented parallel computing of OpenFOAM. The MMA solver is used to update the design variables. The methodology is applied to 3D rotors, i.e. a practical example of compressible turbulent flows. Two objective functions are used: the minimization of entropy flux and the minimization of total pressure flux.

NUMERICAL AND PHYSICAL ASPECTS ON ADHESIVE AND FRICTIONAL INTERACTION FOR ROUGH CONTACT SIMULATION

[1]*University of Porto*
[2]*Institute of Science and Innovation in Mechanical and Industrial Engineering*

ABSTRACT

Understanding the interplay of adhesion and friction in the contact of rough surfaces is still an open challenge within the tribology community. Specialised computational tools designed towards this purpose are becoming more valuable in building accurate and robust simulations of adhesive effects in complex multi-physical and multi-scale systems. Particularly, the development of numerical models at finite strain incorporating roughness, adhesion and friction is still an actively researched problem [1].

In our approach, we propose an implementation of the Raous, Cangemi, and Cocus (RCC) model [2] under the finite deformation dual-mortar contact framework. By combining Frémond's adhesion intensity concept, which models adhesion through a damage-like state variable, with strict inequalities for unilateral contact and Coulomb friction conditions, this model seamlessly combines adhesion with sliding friction. To enforce the RCC constraints a nodal lumping technique is used and a primal-dual active set strategy is derived by introducing two novel modifications to the non-linear complementary functions.

This research explores the numerical and physical performance of the RCC model for roughness simulations. The study investigates the effect of different mortar-based kinematic variables used for the treatment of the adhesive components for a sound space discretisation. In addition, it explores the mechanism of adhesion reconstruction and bond formation to obtain stable solutions and accurate physical trends. Numerical stabilization procedures based on viscosity and inertial effects are also employed. Finally, the validity of the developed framework is assessed by comparing numerical and mechanical responses against other well-established models in the literature.

[1]Federal University of Ouro Preto
[2]Federal University of Lavras

ABSTRACT

The present work aims at the implementation and validation of a displacement-based two-dimensional numerical formulation including several sources of non-linearities in steel-concrete composite frames, such as second-order effects, plasticity and beam-to-column semi-rigid connections. The co-rotational-based approach is used to describe the finite element formulation, allowing large displacements and rotations in the numerical model. Two rotational pseudo-springs in series are positioned in the finite elements ends (Chan and Chui, 2000). One of them is used to include the gradual loss of stiffness determined by the cross-sectional plastification. The limiting of the uncracked, elastic and plastic regimes is defined in the Normal Force-Bending Moment diagram. In the cross-sectional analysis, the Strain Compatibility Method (SCM) is used to capture the axial strains in the section components. In this way, the constitutive models of the materials are described by continuous functions. The cracked effect is considered by the effective moment of inertia of the concrete cross-section (Branson and Metz, 1963). The other spring includes the effects of the semi-rigid beam-to-column connections through the moment-rotation relationship. A multi-linear model for beam-to-column connections is used. To validate the proposed numerical formulation, the results obtained are compared with numerical and experimental data available in the literature. Since the model proposed here starts with the concentrated simulation of nonlinear effects, an examination of the finite element mesh refinement is also carried out. These comparisons indicated for the validation of the numerical procedure proposed and implemented here, highlighting the precision of the formulation in both the pre- and post-critical structures behavior.

[1]*RPTU Kaiserslautern-Landau*
[2]*ENSTA Paris*

ABSTRACT

This presentation is concerned with modeling, simulation and experimental validation for the meniscus regeneration and involved cell and tissue-level phenomena. The motivation for this work stems from clinical studies indicating that partial and total meniscectomies lead to prevalence of premature osteoarthritis in knee joints. Accordingly, substantial efforts are being made towards finding adequate regenerative tissue for meniscus replacement. Most regenerative approaches are clinically motivated and focus rather on the practical application than on the micro- and macroscopic cellular mechanisms and the interactions with the scaffold material. Our work is innovative in the sense that it aims to understand the basic control mechanisms in cell-scaffold interactions under different environmental parameters, thus providing a selective prognosis of the most significant combinations of these parameters. With respect to the in-silico modeling and simulation, a major challenge lies in the well-posed and numerically efficient coupling of the processes at the cell level with the macroscopic behavior and the mechanical properties of the tissue. The active processes at the cell level, such as cell differentiation and matrix synthesis, have a strong impact on the resulting tissue structure and quality, while macroscopic effects in turn are important stimuli for the processes at the microscopic level. Moreover, the time scales of the different processes differ vastly and call for appropriate co-simulation strategies. The presentation will first give an overview of the mathematical model that we have established so far and that forms a coupled system of time-dependent partial differential equations where cell densities play a dominant role. The main focus will then be placed on the numerical challenges, along with a report on the computational results that we have obtained so far and their validation with respect to experimental data. Also, recent results on non-intrusive model order reduction methods will be introduced. These turn out to be essential when tackling the parameter identification problem along with the computation of parameter sensitivities.

DATA-DRIVEN OPERATORS FOR ELASTIC AND ELASTIC-PLASTIC SOLIDS

*Hari Simha**[1]

[1]*University of Guelph*

ABSTRACT

The governing equations of continua can be discretized into a system of ordinary differential equations when discretized in time. The system describes evolution of state variables such as displacements and temperatures, and their evolution can be described by operators. We show how to construct such operators for solid mechanics using displacement vector data, and for thermal systems using temperature data. The operators can reconstruct the fields as a function of space and time. No knowledge of the material properties (thermal conductivity, elastic moduli), boundary conditions, or solution of the conservation equations is required.
For linear-elastic solids, the Dynamic Mode Decomposition [1] algorithm is used. Field data is acquired as snapshots and arrayed as vectors. Time-shifted data matrices whose columns are the snapshots is set up. The algorithm operates on the matrices and obtains a low-rank operator that can reconstruct the field values as function of space and time. Dynamic Mode Decomposition obtains an approximate finite dimensional Koopman operator for linear systems. We illustrate the process for simple structures - flat tensile specimen and plate with hole using data obtained from finite element computations and from experiments using Digital Image Correlation. Additionally, we show a thermal system with multiple thermal conductivities using data obtained with an infrared camera. Unsupervised rank truncation is also outlined using the Gavish-Donoho method [2].

In the case of non-linear solids, a special observable function, taken as a neural network here, is learned from the data and an approximate, finite-dimensional Koopman operator is shown to “linearize” the non-linear system of ODEs. The latter allows linear superposition to be used for elastic-plastic solids.

Key contributions in this work are the development of data-driven operators that could serve as reduced-order models for linear and non-linear solids.

MODELING CONTINUUM DAMAGE COUPLED TO PLASTICITY IN PAPER

Birte Boes[1], Mossab Alzweighi[2], Artem Kulachenko[2] and Jaan-Willem Simon[1]*

[1]University of Wuppertal
[2]KTH Stockholm

ABSTRACT

There is an increasing need, particularly among packaging manufacturers, for simulation tools that can enable efficient structural calculations for paper and cardboard structures. Nevertheless, although the field of application for paper and paperboard is very broad, the modeling of its material behavior – particularly its damage and failure response – has not yet been sufficiently researched [1].

The material behavior of paper is anisotropic and characterized by elasto-plasticity coupled with progressive damage mechanisms, which results in stiffness reduction [2, 3]. The main challenge in describing these phenomena for paper is that model approaches already established for other materials cannot simply be transferred because the underlying physical effects are determined by the intrinsic microstructure of the material. On the microscale, paper is a network consisting of interconnected fibers, which behaves fundamentally differently from the crystal lattice of metals, for example, where dislocations and plastic slip can occur. It is therefore necessary to develop completely new approaches for paper.

In this work, we aim to investigate the damage behavior of paper and develop a numerical modeling strategy that enables an efficient description of the material response, taking into account both anisotropic plasticity and anisotropic damage development. Since large deformations occur during forming processes, the modeling approach should account for large strain kinematics. Further, in order to ensure mesh-independent results, the model is regularized using the enhanced gradient damage approach.

PATIENT-SPECIFIC LONG-TERM SIMULATION OF TRANSCATHETER EDGE-TO-EDGE MITRAL VALVE REPAIR

Natalie Simonian[*1], Sneha Vakamudi[2], Mark Pirwitz[2] and Michael Sacks[1]*

[1]*The University of Texas at Austin*
[2]*Ascension Texas Cardiovascular*

ABSTRACT

Mitral regurgitation (MR) is a highly prevalent and deadly cardiac disease affecting over 2% of the global population. Transcatheter edge-to-edge repair (TEER) has emerged as a generally safe and effective treatment option, where the mitral valve (MV) leaflets are clamped together with a clip device. However, long-term outcomes have been suboptimal, largely due to the heterogeneity of the patient population. Moreover, the MV has demonstrated a capacity to remodel in response to sustained changes in homeostasis, and the long-term impact of the permanent TEER device on the mechanics of the MV leaflets has never been studied. In this study, we have developed a patient-specific, predictive simulation of long-term postoperative MV function based primarily on preoperative, standard-of-care clinical imaging data.
We acquired 3D transesophageal echocardiography (TEE) imaging for five patients undergoing TEER, and additional follow-up imaging at 3-months post-repair. Following our previously published methods, we built a full MV apparatus model for each patient, simulated preoperative systolic closure, and predicted the immediate postoperative MV state by implementing 3D models of the TEER device onto the MV leaflets [1]. Next, we used the follow-up imaging data to fit the plasticity rate constant in our MV plasticity model and applied this model to predict the patient's MV leaflet geometry and deformation at 3-months post-repair [2].
In our predictive follow-up simulations, we were able to reproduce key effects of TEER repair at the 3-month time point using our plasticity model when compared to simulations that directly applied the follow-up boundary conditions. We noted substantial changes in MV function over time not only during systolic closure, but also in diastole when referenced to the preoperative diastolic state, indicating strains that are principally induced by permanent distortions in geometry. Specifically, we observed highly compressive circumferential strain on both leaflets in the region of the clip, and slight radial extension in the same region.
Here, we have presented a novel approach for predicting the postoperative state of the MV apparatus at 3 months post-repair using standard-of-care, preoperative clinical imaging alone. Our results, which reveal continued MV plastic deformation in response to TEER, underscore the importance of a long-term view of repair success in the context of MV function and elucidate potential mechanistic drivers of repair failure, which constitute key targets for optimized treatment durability and efficacy.

GRAPH ATTENTION EMBEDDINGS AS A CAUSAL LENS IN TEMPORAL LINK PREDICTION

Dan Krofcheck[1], Matthew Sweitzer[1], Sarah Simpson[1], Asmeret Naugle[1], Kate Cauthen[1] and Marco Campos[1]*

[1]Sandia National Laboratories

ABSTRACT

Graph representations of complex systems are an incredibly powerful tool for modeling a broad set of domains, with wide adoption seen in application across social networks, behavioral sciences, trade, transportation, logistics, and cyber networks. However, while these state of the art graph representation methods have shown to be performant, they critically lack the ability to contextualize inference in any sort of causal framework, instead relying strictly on correlations to execute tasks such as classification and prediction. Most state of the art solutions leverage algorithms such as graph attention to generate latent representations from both the structural and temporal aspects of change. Those embeddings are then leveraged for downstream tasks, such as classification and prediction. Here, we explore the potential of these latent representations from graph attention based models to serve as a starting point for extracting causal structure from model inference. Specifically, we investigate leveraging the structural and temporal attention coefficients from state of the art models including DySAT and analogous representations in TGN, to propose a mechanism for causal model inclusion in existing link prediction frameworks.

Our initial investigations are focused on the manner in which the embedded relationships change as node or edge attributes are enriched using additional data about the system. For this study, we explore the inclusion of static and temporally evolving exponential random graph model (ERGM) derived node features to structure experiments comparing 1) the predictive potential of the resulting embeddings, and 2) our ability to explain link prediction tasks given the ERGM statistic inclusion in the node representations. Our results here are largely exploratory, with a focus on the conceptual approach and initial demonstration of techniques to extract causal relationships from link prediction tasks in graph attention based embedding models.

ESTIMATING SURFACE-LEVEL WINDS FOR STORM SURGE SIMULATIONS USING A CYGNSS-INFORMED PARAMETRIC MODELING APPROACH

Aaron Sines[1], Ethan Kubatko[1], Suranjan Nepal[1], Mohammad Al-Khaldi[1] and Younghun Kang[2]*

[1]The Ohio State University
[2]The University of Texas at Austin

ABSTRACT

Many different parametric tropical cyclone (TC) models have been constructed with the intent of providing accurate wind and pressure fields for engineering applications. Regardless of which model is chosen, typical storm characteristics (e.g., intensity and size) are utilized to first generate the so-called gradient winds, i.e., the winds at the gradient height (~300 m above sea level for normal (non-TC) conditions). From there, the constructed gradient winds are adjusted to provide surface-level (=10 m) winds. One simple approach that is often used to make the adjustment from gradient to surface-level winds is the application of a fixed wind reduction factor (WRF); however, such an approach fails to take into account the dependence of the WRF on storm characteristics, as suggested in previous research.

Therefore, in this work, using surface-level wind speed data retrieved from NASA's Cyclone Global Navigation Satellite System (CYGNSS) mission, thirty-six storms, between the years of 2018 and 2022, were analyzed against the gradient winds produced from the classic Holland parametric TC wind model to derive an empirical relationship between the WRF and the storms maximum sustained wind. The derived WRF relationship is implemented into the ADCIRC storm surge model and tested on a number of hurricanes that made landfall on the US East Coast, where the obtained results are compared to the "standard" technique of using a fixed WRF.

CHANCE CONSTRAINED OPTIMAL DESIGN FRAMEWORKS IN THE FACE OF HIGH-DIMENSIONAL UNCERTAINTY

Pratyush Kumar Singh[*1] and Danial Faghihi*[1]

[1]*University at Buffalo*

ABSTRACT

This work introduces computationally efficient frameworks for the optimal design of thermal insulation components of buildings to achieve target insulation performances while retaining sufficient mechanical stability. The thermomechanical behavior of the component is governed by a multi-phase continuum model as partial differential equations (PDE). The model incorporates uncertain parameters related to the elasticity and thermal conductivity of solid and fluid phases, with the spatial distribution of porosity over the insulation components' domain as the design parameter. The design and uncertainty parameters are both space-dependent fields that, after finite element discretization, result in a high-dimensional design problem. To this end, a risk-averse cost functional is employed to achieve both target performances and mitigation of uncertainty during the design process. Additionally, to avoid stress concentration chance constraints are incorporated into the optimization formulation, ensuring that the probability of a certain function exceeding or going below a threshold value. Finally, to promote sparsity in the design solution, a phase-field regularization function is utilized via a continuation numerical scheme. Two efficient and dimension-independent solution algorithms are proposed for the resulting PDE-constrained optimization under uncertainty. The first approach is based on second-order Taylor approximation of the design objective that solves a generalized eigenvalue problem using a randomized algorithm that only requires the action of the Hessian on a small number of random directions. The second approach is based on approximating the PDE solution using a scalable neural operator that reduces the computational cost of the optimization while provides information about the derivative of parameters with respect to the design parameters. The accuracy, efficiency, and scalability of the proposed design under uncertainty frameworks are demonstrated with examples of various building insulation scenarios. The numerical results indicate that using the proposed approximations leads to computational savings up to several orders of magnitude in the optimization solution.

MULTIMATERIAL TOPOLOGY OPTIMIZATION WITH PRE-EXISTING INTERFACIAL CRACKS

*Sukhminder Singh**[1,2]

[1]*Friedrich-Alexander-Universität Erlangen-Nürnberg*
[2]*Technical University of Denmark*

ABSTRACT

Topology optimization offers a powerful tool for designing high-performance structures and metamaterials, composed of one or more base materials. However, the distinct elastic and fracture properties of the interfaces can significantly affect the overall behavior of the structure. While traditional SIMP-based topology optimization methods assume perfect interfaces, real-world scenarios often involve pre-existing cracks, which may compromise the fracture resistance of the structure. This work presents a multi-material topology optimization framework that incorporates pre-existing interface cracks into the optimization process. We utilize density smoothing and projection schemes to directly embed information about the location and geometry of cracks, eliminating the need for crack nucleation and growth simulations. The crack length is controlled by the filter parameters. The minimum compliance problem with volume constraint is considered, while an aggregated stress constraint is incorporated to limit the stresses at the crack tip and resist further crack propagation. The gradients of the objective and constraints are computed using the adjoint sensitivity analysis. Results demonstrate the framework's ability to generate optimized structures with significantly improved fracture resistance, in the presence of pre-existing interfacial cracks. This work paves the way for the design of more resilient and damage-tolerant structures in various engineering applications.

OPTIMIZING ROTATING MACHINERIES: A STUDY ON NATURAL FREQUENCY CONSTRAINTS APPLIED IN TOPOLOGY OPTIMIZATION OF FLUID-STRUCTURE INTERACTION PROBLEMS

Lucas Siqueira[*1], Anderson Azevêdo[1], Emílio Silva[1] and Renato Picelli[1]*

[1]*University of São Paulo*

ABSTRACT

In some rotating machinery, the operation assembly presents tight tolerances, leading to wear problems caused by excessive vibrations. In this context, it is crucial to enhance the design of these components to reduce vibration levels and avoid resonant conditions. Based on that, this study focuses on topology optimization for turbulent swirl flow in fluid-structure problems considering natural frequency constraints applied to the 2D axisymmetric solids. The optimization problem proposed is compliance minimization subjected to a volume constraint and a frequency constraint applied to the three lowest natural frequencies. To ensure that the frequencies of interest are properly restricted, the modal assurance criterion-based (MAC-based) mode-tracking method is used to identify mode crossing during the optimization process. The governing equations are solved using separate domains and the k-ω turbulence model with standard wall functions. The optimization method employed is the Topology Optimization of Binary Structures with Geometry Trimming (TOBS-GT), which separates the Finite Element Analysis (FEA) module (COMSOL Multiphysics) from the optimization module (MATLAB), providing more accurate mesh analysis. Compliance sensitivities are computed through automatic differentiation using the adjoint method, while natural frequency sensitivities are derived through automatic differentiation using the forward method. Both sensitivities calculations are provided by a built-in optimization module in COMSOL Multiphysics. Numerical results explore the optimization of 2D axisymmetric solids subjected to a turbulent swirl flow, encompassing the stiffer design of the structure adhering to predefined natural frequency constraints. Three numerical examples are explored to study the design of the rotating wall through topology optimization, considering a Fluid-Structure Interaction (FSI) problem. These examples include the rotating wall, the rotating and stationary wall system, and the stator structure. The results ensure that the method works to increase the natural frequency of structures subjected to a turbulent fluid flow. The optimizer provides stiffer structures ensuring the predefined natural frequency constraint. However, the manufacturing of these structures is complex. Another point is that the wet optimization tends to worsen the fluid flow optimization. Then, a complementary analysis considering the stator as design domain was carried out.

ESTIMATION OF BIOMECHANICAL PARAMETERS IN THE PROSTATE USING PHYSICS INFORMED NEURAL NETWORKS (PINNS)

ABSTRACT

In the quest for innovative approaches to tackle soft tissue and organ simulation, Physics Informed Neural Networks (PINNs) emerge as a promising tool. These algorithms provide a novel perspective on solving differential equations by utilizing neural networks to directly approach solutions associated with deformations, as opposed to traditional methods such as the Finite Element Method (FEM). This shift towards artificial intelligence in biomechanical modeling is part of the contemporary evolution in scientific research.

While Finite Element Methods (FEM) have been instrumental in tissue simulation, their applicability may be constrained in demanding scenarios like real time simulations. PINNs, on the other hand, present themselves as an alternative capable of overcoming these limitations by harnessing the neural networks' capacity to learn complex patterns, thus accelerating inference times.

In comparison to conventional data-driven approaches, which often necessitate extensive datasets for model training, we advocate for the utilization of Physics Informed Neural Networks. Our work delves into the potential of PINNs in solving differential equations for soft tissue deformation, with a particular focus on organs like the prostate. It examines how these neural networks can guide resolution based on underlying physical laws for both the direct and inverse problems, enabling faster and more efficient estimation of biomechanical parameters, turning them into trainable parameters of the network.

This research aims to advance the understanding and modeling of biomechanical phenomena, emphasizing its real-world application for tissue, and promoting the application of PINNs as an effective tool in this context, for future real-time and geometry-free soft tissue simulations in a clinical work environment.

INTRINSIC MULTI-DIMENSIONAL ELASTIC COUPLING VIA ENRICHED CONTINUA

Adam Sky[1], Jack S. Hale[1], Andreas Zilian[1], Stephane Bordas[1] and Patrizio Neff[2]*

[1]*University of Luxembourg*
[2]*University of Duisburg-Essen*

ABSTRACT

The problem of coupling multi-dimensional continua in a single computational model is commonplace in structural analysis, where one-dimensional models such as Timoshenko-Ehrenfest beams, two-dimensional models such as Reissner-Mindlin plates [1], and the full Cauchy-continuum are coupled to represent one structural design. Although solutions do exist, for example via intermediate finite elements, or more recently with mortar approaches [2], these require either a sophisticated adjustment of the computational domain or modifications of the original problem, e.g., via Lagrange multipliers. In this work we present an alternative approach by employing a mathematically enriched continuum model [3]. The kinematical reduction of the model to lower dimensional domains leaves its fundamental degrees of freedom intact. Consequently, the degrees of freedom intrinsically agree even at the interface with a domain of a different dimensionality. We introduce the derivations of all models of various dimensions, present applications with numerical examples, and conclude the talk with an outlook on possible future developments.

DEVELOPING A FRACTURE PROBABILITY CURVE BASED ON OBSERVABLE MICROSTRUCTURE IN ADDITIVELY MANUFACTURED CERAMICS

Elizabeth Smith[*1]*

[1]*Sandia National Laboratories*

ABSTRACT

Accurately predicting fracture of additively manufactured ceramics is an essential step to their adoption in industrial and other high precision environments. As a relatively young innovation, there is high variability in manufacturing techniques, potential base materials, and subsequent mechanical properties of additively manufactured ceramics. However, additive manufacturing can create high precision geometries impossible with conventional methods that have potential applications in fields such as aerospace and biomedical engineering. In addition to the variability between components, additive manufacturing can introduce anisotropy as a consequence of layer deposition methods. We developed a method to use statistics based on observable microstructural properties, including pore and grain size distributions, to estimate a fracture probability distribution under a prescribed loading in an anisotropic material. The entire process from model creation to microstructural analysis to development of the fracture distribution curve will be demonstrated.

Microstructure data is taken from SEM images of relevant samples. Image processing techniques and EBSD are then used to generate profiles for grain and pore geometry distributions. This data is then used to inform strength variations for an anisotropic material based on methods presented by Takeo et al (2019) and Gavazzi and Lagoudas (1990). Using FEA, a stress field is obtained and compared to the strength distribution to generate a failure of probability under a given loading. This method can be applied to any geometry and loading. This workflow enables relatively rapid and efficient prediction of fracture using observable properties of an individual sample.

UNCERTAINTY ANALYSIS IN THE PRESENCE OF MODEL-FORM ERRORS

Ralph Smith[*1]*

[1]*North Carolina State University*

ABSTRACT

Model discrepancies, or model-form errors, can dominate parameter and observation error uncertainties for many models. These errors are generally epistemic, rather than aleatoric, and can significantly diminish the sole reliance on statistical analysis when calibrating models for subsequent predictions. Moreover, unaccommodated model discrepancy can significantly diminish the accuracy of prediction intervals for model responses and limit the degree to which they can be employed for model validation. Whereas solely data-driven techniques can be effective for certain interpolatory predictions, they generally fail when extrapolating outside the data, which is the case when predicting future behavior using time-dependent models. In this presentation, we will detail some of these issues and discuss techniques to quantify model discrepancy to improve the accuracy of extrapolatory predictions and uncertainty analysis. This generally relies on identifying and improving the accuracy of model components determined to be producing epistemic errors. We illustrate these techniques using a variety of models having highly nonlinear parameter dependencies.

AN APPROACHABLE PROBLEM FOR THE BAYESIAN ANALYSIS OF A VARIETY OF UNCERTAINTIES IN HIERARCHICAL PHYSICAL MODELS

Sean Smith[*1], Giridhar Gopalan[1] and Devin Francom[1]*

[1]*Los Alamos National Laboratory*

ABSTRACT

This presentation will introduce a simplified model of an industrial fixed-bed ethylene-oxide reactor with coupled sub-models for: particle-film mass transfer, pore diffusion, turbulence & reaction kinetics. The analysis will also account for experimental data corresponding to a subset of the sub-models as well as pilot-scale data for the coupled system. We will discuss the interaction of various sources of uncertainty, such as: parameter uncertainty, model-form uncertainty, surrogate-model/emulator uncertainty, experimental uncertainty, instrument-model uncertainty and prediction-scenario uncertainty. The meaning of the words aleatory & epistemic within a Bayesian context will be briefly addressed. Various techniques from the Bayesian UQ literature for handling the complicating sources of error will be presented in the context of this model, such as: emulation, dimension reduction, parameterizing a model's output errors into its inputs, identification & propagation of discrepancy (model-form error) for the sub-models, and feedback cutting.

EFFICIENT COMPUTATIONAL MULTISCALE ANALYSIS FOR THE HOMOGENIZATION OF NONLINEAR SOLIDS USING SAMPLING STRATEGIES OF MICROSCOPIC MODELS

Yujin So[*1], Suhan Kim[2], Hyunseong Shin[2] and Jaehun Lee[1]*

[1]*Dongguk University*
[2]*Inha University*

ABSTRACT

In this study, we introduced the model order reduction method at the microscale level to improve the computational efficiency of the multiscale finite element analysis. Recently, various industrial applications have been using multi-scale analysis that reflects the characteristics of microstructures to predict the behavior of structures made of composite materials. Among the several multiscale analyses, the multiscale finite element analysis is one that analyzes the macroscale equivalent structure through the microscale analysis, which solves the two-scale boundary value problem. This method performs repetitive computations of the microscopic self-equilibrium equation at every integration point in the macroscale structure. Therefore, we require high computational costs. A significant amount of computational resources is especially required for the multiscale analysis, considering the nonlinearities in both macro and microscopic domains. Thus, in this study, we applied the reduced-order model technique to reduce the computation time of multiscale finite element analysis considering the nonlinearities.
We propose introducing reduced-order modeling of the representative volume element model in microscale using nonlinear reduced-order modeling to improve the efficiency of multiscale finite element analysis. We obtain the computational efficiency in the online stage. Since the unit cell deforms according to the macroscale strain, we derive a reduced-order model corresponding to the macroscale strain. Significantly, the size of the reduced-order model used to simulate a wide range of deformation can be large, which affects computational efficiency, so we conducted research to reduce its size. In the offline stage, we construct the reduced-order model of representative volume element through full-order representative volume element model analysis. Then, we perform the multiscale finite element analysis in the online stage using the reduced-order model of representative volume element. We verify the proposed method comparing accuracy and efficiency with those of full multiscale finite element analysis investigating microscopic and associated macroscopic models.

AN ENHANCED FULLY-ADAPTIVE EXPLICIT-IMPLICIT TIME-MARCHING FORMULATION FOR ELASTODYNAMICS

Delfim Soares[1], Lucas Pinto[2], Isabelle Sales[2] and Webe Mansur[2]*

[1]*Federal University of Juiz de Fora*
[2]*Federal University of Rio de Janeiro*

ABSTRACT

In this work, an explicit-implicit time-marching formulation, which adapts to the model's properties, its adopted spatial and temporal discretizations, and its computed responses, is studied for elastodynamic analyses. Explicit-implicit approaches have become referred to as effective time-domain solution methodologies since they allow combining the advantageous features of both explicit and implicit formulations, such as reduced solver efforts and guaranteed stability, providing very attractive techniques. The here discussed time-domain hybrid solution procedure is based on three simple single-step recurrence relationships, which are formulated considering three locally-defined time-integration parameters, namely α_0^e, α_1^e and α_2^e, and each one of these time-integration parameters is adaptively determined for each element “e” of the adopted spatial discretization. In this context, the α_0^e parameter distinguishes explicit ($\alpha_0^e=0$) and implicit ($\alpha_0^e\neq0$) elements, while α_1^e and α_2^e delineate non-dissipative ($\alpha_1^e=\alpha_2^e=0$) and dissipative ($\alpha_1^e\neq0$ and $\alpha_2^e\neq0$) elements. The adopted non-null expression for α_0^e ensures that, in the absence of numerical dissipation, the critical sampling frequency of the method aligns with the maximum sampling frequency of the element, allowing the element to operate as if provided with its critical time-step value. This configuration not only ensures stability, but also better counterbalances the errors of the considered temporal and spatial discretization procedures, enhancing the overall accuracy of the computed discrete solution. On the other hand, the non-null expressions that are defined for α_1^e and α_2^e are designed to set the bifurcation sampling frequency of the method equal to the maximum sampling frequency of the element and its bifurcation spectral radius to zero. This configuration maximizes numerical dissipation for the element's maximum sampling frequency, effectively dissipating spatially unresolved high-frequency modes while accurately evaluating important low-frequency modes, since the developed adaptive formulation ensures that dissipative elements are activated only when and where it is necessary in the analysis. In addition, an optimal time-step value for maximal computational efficiency is also evaluated in the proposed solution methodology, based on the “particle swarm optimization” algorithm, which minimizes the expected total number of operations in the hybrid solution process. In this case, the optimal time-step value is determined so that the most efficient distribution of explicit and implicit elements is considered in the analysis, providing a highly effective, fully-adaptive and entirely automated, time-domain solution procedure. At the end of this work, numerical results are presented and compared to those of standard time-marching procedures, demonstrating the excellent performance of the reported adaptive hybrid approach.

TOPOLOGY OPTIMIZATION FOR FLUIDIC DIODE DESIGN WITH DISSIPATION AND VORTICITY FUNCTIONS VIA SEQUENTIAL APPROXIMATE INTEGER PROGRAMMING

Anderson Soares da Costa Azevêdo[*1], Eduardo Moscatelli[1], Luís Fernando Nogueira de Sá[1], Emilio Carlos Nelli Silva[1] and Renato Picelli[1]*

[1]*University of São Paulo*

ABSTRACT

Recent advancements in computational tools and additive manufacturing have expanded design possibilities on fluid devices to industrial applications. In this context, gas fluidic diodes emerge as a potential sealing mechanism to guarantee rotating machinery performance and reduce environmental pollution. In this study, novel trends in topology optimization applied to fluidic diode design are explored. We propose cutting-edge strategies to address challenges observed in traditional fluid flow optimization procedures. The main challenges for labyrinth seal designs are: i) physical modeling for moderate and high fluid flow speed, ii) bad local minimum of fluid inlet/outlet closure, iii) absence of interlocked labyrinth-like solid regions, and iv) capture the main dissipative effects produced by flow recirculation and throttling along the two-dimensional axisymmetric geometry in a suitable objective function. We demonstrate the TOBS (Topology Optimization of Binary Structures) method potential to provide innovative designs and solve each of the discussed issues. One of the advantages of this discrete approach is the explicitly defined domains during the entire optimization due to the absence of intermediate density values (e.g., gray-scale region), consequently easing the prototypes manufacturing and allowing surface tracking (useful to apply design-dependent boundary conditions). In order to provide a comprehensive guideline for the labyrinth seal geometry dissipative effects for low to high flow regime: energy dissipation, vorticity, and flow velocity components are investigated as single and multi-objective expressions. The sensitivity field of objective functions is computed via automatic differentiation. Fluid flow volume or the minimum gap between the stationary and rotatory solid phases is chosen as the constraint function according to the example. In our approach, the fluid flow governing equations are solved using the Finite Element Method and the optimization problem via Integer Linear Programming. The problem discretization is performed using regular mesh on jagged patterns assuming a laminar regime and adaptive smoothed boundary fitting mesh assuming turbulence wall models.

AN AUTOMATED COMPUTATIONAL FRAMEWORK RELYING ON A NON-ITERATIVE MESHING ALGORITHM FOR MODELING MATERIALS WITH COMPLEX MICROSTRUCTURES

Soheil Soghrati[1], Salil Pai[1], Pengfei Zhang[1], Balavignesh Vemparala[1] and Kartik Kashyap[1]*

[1]*The Ohio State University*

ABSTRACT

An integrated computational framework relying on virtual microstructure reconstruction and parallel mesh generation algorithms will be presented to simulate the multiscale failure response of composite materials. A virtual reconstruction algorithm is developed to synthesize various material microstructures, particulate, fiber-reinforced, and woven textile composites. This approach first employs a virtual packing algorithm to build an initial microstructural model with arbitrary-shaped embedded fibers/particles, followed by a reduced-order finite element (FE) compaction simulation to synthesize microstructures with densely packed inclusions. A genetic algorithm (GA) based optimization phase is then utilized to replicate target statistical microstructural descriptors such as the volume fraction, spatial arrangement, and orientations of embedded inclusions. Unlike most reconstruction algorithms, the output of this algorithm is presented in the form of NURBS patches or STL files to represent material interfaces for the subsequent mesh generation explicitly.

Conforming FE meshes for the resulting complex material microstructures are generated using a non-iterative, parallel meshing algorithm, coined Conforming to Interface Structured Adaptive Mesh Refinement (CISAMR). The CISAMR algorithm automatically transforms a structured background grid into a high-quality tetrahedral conforming mesh using customized h-adaptivity, r-adaptivity, element-deletion, and sub-tetrahedralization algorithms. We present several new algorithmic features of the CISAMR, including a Kirigami-inspired algorithm for efficient sub-tetrahedralization of background elements, handing material interfaces with sharp edges/corners, and modifications to automatically handle resin interstices and yarn interpenetrations (an artifact of the compaction phase of the microstructure reconstruction process) in woven textile composites. In addition to the application for meshing composite material microstructures, we discuss expanding the CISAMR algorithm for modeling polycrystalline microstructures and crack growth problems. Various example problems are provided to demonstrate the application of this reconstruction-meshing framework for modeling real-world materials systems.

META-MODELS PREDICTING GAS DYNAMIC PERFORMANCE OF A HYDROGEN RE-CIRCULATION EJECTOR IN A FUEL CELL SYSTEM

Ilyoup Sohn[*1], Hoyoon Kim[1] and Jihong Jung[2]*

[1]*Korea Institute of Science and Technology Information*
[2]*HongsWorks Corporation*

ABSTRACT

As a climate crisis is recognized as one of the most important issues on global economy, eco-friendly vehicle systems have become a new trend among global vehicle manufacturing companies. Instead of a high-performance and low-emission internal combustion engine, full electric vehicles powered by lithium-ion batteries have been considered to be the next automobile system in the near future. This can be proved by the fact that the number of customers seeking electric vehicles has increased. Hydrogen fuel-cell vehicles are also electric-powered vehicle system, however, there is a significant difference in electricity generation between lithium-ion batteries and fuel-cells. Since fuel-cells consume hydrogen and oxygen to generate electricity, and the hydrogen gas has low density compared to the oxygen or other gases, it must be treated very carefully. In other words, a hydrogen gas ejector supplying the hydrogen gas into the fuel-cell system needs to be precisely designed.

This work discusses a meta-modelling and optimization process with respect to the design parameters of the hydrogen re-circulation ejector to predict the gas dynamic phenomena inside the ejector. The hydrogen re-circulation system means that the hydrogen gas which remains after being consumed in the fuel-cell module is returned to the ejector. Re-circulation ejector enables the hydrogen gas to be efficiently worked for the generation of electricity in the fuel-cell. Computational fluid dynamic (CFD) analysis based on finite volume discretization is adopted to simulate the hydrogen gas flow inside the ejector. Some of design parameters which significantly influence the re-circulation rate, a key performance of the hydrogen ejector, are selected. Combinations of design variables are finally sampled using a design of experiments (DoE) and gas flow simulations are made for each set of design variables.

Mathematical formulations in terms of design variables for predicting the performance of the hydrogen re-circulation ejector are derived by meta-modeling techniques. The coefficients of prognosis (CoP) from the derived meta-models and the sensitivity of design variables are examined. The meta-model with the best accuracy is used to determine the final design variables that allow the best performance of the ejector. Through these meta-models and optimization processes, the initial design of the hydrogen gas ejector, which supplies the hydrogen gas into the fuel-cell system, would be noticeably improved.

MICRO AND MACRO SCALE TOPOLOGY OPTIMIZATION OF MULTI-MATERIAL FUNCTIONALLY GRADED LATTICE STRUCTURES

Jeronimo Santos[1], Abdolrasoul Sohouli[2] and Afzal Suleman[2]*

[1]Instituto Superior Tecnico
[2]University of Victoria

ABSTRACT

Lattice structures are gaining popularity as a favored design approach across various engineering applications. The growing appeal is primarily attributed to their high specific strength and stiffness, effective heat dissipation, and relatively lightweight nature, among other advantages. The use of additive manufacturing techniques has allowed for increased flexibility and resolution, leading to the development of more detailed and better-performing lattice structures. Material unit cell designs without restrictions are frequently linked to challenges such as high computational demands and connectivity issues. On the other hand, highly constrained lattice unit cell designs, despite their lower computational cost, may not attain the optimal desired properties.

This study aims to enhance the flexibility of a restricted unit cell design while maintaining a lower computational cost. The approach involves a two-scale concurrent optimization of the lattice structure, simultaneously optimizing the topology at both macro and micro scales to attain an optimal configuration. To ensure a continuous optimization process, surrogate models are employed to define material and geometrical properties. The elasticity tensors for a lattice unit cell are derived using an energy-based homogenization method combined with voxelization. A multi-variable parameterization of the material unit cell is established to enable the synthesis of functionally graded lattice structures. Therefore, the compliance is considered as the objective function, while relative density and aspect ratio are two key design variables. The proposed topology optimization framework is employed for different case studies.

OVERVIEW OF MULTIPHYSICS COUPLING EFFORTS AT LLNL FOR ADVANCED ENERGY APPLICATIONS

Jerome Solberg[*1]*

[1]*Lawrence Livermore National Laboratory*

ABSTRACT

Various multiphysics coupling efforts exist at LLNL aimed at advanced energy applications. An ongoing effort has coupled the LLNL multiphysics code Diablo to Nek5000 focused on various fluid-structure interaction applications emanating from such applications. This effort has largely used bespoke coupling algorithms within Diablo and Nek5000. A more recent set of work has coupled OpenFOAM and Diablo in the context of coupled thermofluid/structural calculations, with a more nascent effort to also include electromagnetic effects. We discuss the relative merits of different approaches along with the ongoing challenges and future work.

MODELING A PULSATILE SHEAR-THINNING 2D CHANNEL FLOW WITH PHYSICS-INFORMED NEURAL NETWORKS.

Junwon Son[1], Nayeon Park[1] and Jaewook Nam[1]*

[1]*Seoul National University*

ABSTRACT

Our study delves into the investigation of shear-thinning fluid flow, which is common in various industrial applications such as transport of battery slurries or usage of polyacrylamide solutions in heavy oil recovery. Specifically, the focus is on pulsatile shear-thinning flows through a straight channel. While previous studies have relied on traditional methods such as the finite element method to study the topic [1], this study introduces the use of physics-informed neural networks (PINNs) as a novel approach to solve the complex fluid flow. Since its inception, PINNs have been successfully employed to model a diverse range of fluid flow problems, including modeling a time-dependent flow around a cylinder [2], or simulation of steady-state flows in channels of varying width [3].

To ensure an accurate simulation of the time-dependent shear-thinning flow, we optimized the hyperparameters of the PINN model such as implementation of the boundary conditions, neural network structure, number of training points, and loss weights in the loss function. This optimization process was carried out through a series of case studies, each supplemented with Gaussian processes-based Bayesian optimization. The findings suggest that augmenting the number of training points is more beneficial than using large networks for the problem at hand. Additionally, the use of swish activation, hard-REQ constraints for boundary condition enforcement, and assigning large loss weights for the continuity loss term significantly improves the model's performance. A good agreement is achieved between the reference solution and the finalized PINN model, indicating that properly trained PINNs can be used as effective surrogates for simulating pulsatile shear-thinning flows.

A SCALED BOUNDARY FINITE ELEMENT FRAMEWORK TOWARDS FULLY AUTOMATED ENGINEERING ANALYSIS

Chongmin Song[*1]

[1]*University of New South Wales*

ABSTRACT

A scaled boundary finite element framework towards fully automated engineering analysis

Chongmin Song
University of New South Wales, Australia
Email: c.song@unsw.edu.au

The process of computational engineering analysis includes the discretization of geometric models and the solution of partial differential equations using numerical methods. In the popular finite element method, a geometric model is discretized into a mesh of elements of simple geometries (triangles and quadrilaterals in 2D, and tetrahedrons and hexahedrons in 3D). With increasingly affordable computer power, the human effort required in mesh generation becomes increasingly critical in terms of both cost and time. Furthermore, geometric models in digital image, STL format and point clouds are becoming more and more popular in engineering applications and present challenges to well-established numerical methods.

This presentation covers the development of the scaled boundary finite element method [1], aiming to fully automate the process of engineering analysis directly from common formats of geometric models. The scaled boundary finite elements require the discretization of boundary only and can have any number of faces, edges and vortices, leading to a much higher degree of flexibility in mesh generation than standard finite elements. This allows the use of simple and efficient quatree/octree algorithm for fully automatic mesh generation of digital images, STL models, point clouds and traditional CAD models in a unified approach. Moreover, the algorithm is suitable to high-performance computing (HPC) [2]. Some salient features and HPC performance of the proposed technique will be demonstrated by numerical examples.

DEVELOPMENT OF A CELL-BASED MATERIAL POINT METHOD AND CONTACT TECHNIQUE

Jae-Uk Song[*1] and Hyun-Gyu Kim*[1]

[1]*Seoul National University of Science and Technology*

ABSTRACT

Recently, particle-based methods have been developed to overcome the limitations of the FEM. Among these particle-based methods, the material point method (MPM) has been proposed to efficiently solve large deformation problems by combining the advantages of Lagrangian and Eulerian descriptions of motion. In the MPM, the continuum is discretized into material particles carrying all state variables, and the weak form of the governing equations is solved on a background grid. Since the deformation field of the MPM is computed on a background grid, element distortion and mesh entanglement in the FEM do not occur in the MPM simulation of large deformation problems. Using the advantages of the MPM, it has been applied to solve problems with complicated deformations, crack propagation, contact and fluid-solid interactions.

Although the MPM has an ability to solve large deformation problems, the error caused by cell crossing of material particles and the error in numerical integration of the weak form lead to the degradation in the performance of the MPM. The cell-crossing error occurs when material particles cross the grid cell boundaries due to the lack of smoothness of the piecewise linear shape functions defined on a background grid. Several studies have been carried out to reduce the cell-crossing error by replacing the piecewise linear shape functions with other smooth functions. Another important issue in the MPM is that the accuracy of numerical integration of the weak form can be poor and fluctuating in the spatial domain when material particles are unequally placed over a background grid.

In this study, a new cell-based integration scheme is developed to improve the convergence of implicit MPM computations for large deformation static problems and eliminate cell-crossing errors. The increment weak form based on the updated Lagrangian approach is formulated for the implicit MPM. In order to eliminate the cell-crossing error and to reduce the integration error, numerical integration of the incremental weak form is performed on grid cells. Additionally, a nodal volume-based boundary definition method is developed to apply contact boundary conditions to cell-based MPM. A contact analysis technique using the penalty method is developed using boundaries defined in the background grid.

INTRINSIC DEFORMATION ASYMMETRY FROM SYMMETRY BREAKING IN ORDERED INTERMETALLIC ALLOYS: ATOMISTIC ORIGINS AND CONTINUUM MODELING

Jun Song[*1] and Cheng Chen*[2]

[1]*McGill University*
[2]*Northwestern Polytechnical University*

ABSTRACT

We have performed a comprehensive investigation of symmetry breaking in the interactions between dislocation and various superlattice planar faults in intermetallic alloys, to reveal the underlying dislocation mechanisms that govern intrinsic plastic deformation asymmetry, employing both large-scale atomistic simulations and continuum dislocation theory. Ni-based and Ti-based alloys, of different crystal structures, were examined, with two primary symmetry breaking effects, i.e., translational and three-fold rotational symmetry breaking considered. Detailed asymmetrical dislocation reactions and the corresponding dislocation bypassing mechanisms have been elucidated, shown to be highly dependent on the geometrical configuration of the precipitate and the relative magnitudes of fault energies. A continuum model framework was then developed, which, for the first time, provides accurate and quantitative predictions of the threshold conditions triggering critical asymmetrical dislocation slips, verified to be in good agreement with the simulation results. The findings provide critical new understanding of deformation asymmetry in intermetallic alloys.

APPLICATION OF WORST-CASE LOAD UNCERTAINTY IN INDUSTRIAL ROBOTS DESIGN OPTIMIZATION

Wei Song[*1], Zhengxing Chen[1], Zhengyang Zhang[1], Wenjie Chen[1] and Wenjing Wu[1]*

[1]*Midea Corporate Research Center, Midea Group*

ABSTRACT

Facing various application scenarios, industrial robots need to perform multiple different trajectories, or cycles. At the same time, in order to improve the payload-to-weight ratio and reduce energy consumption, it is necessary to lightweight the robot as much as possible while fulfilling the requirements of multiple cycles. Hence, the optimal design of the industrial robot structure still faces many challenges, such as the high computational cost required for analyzing and optimizing the different robot configurations corresponding to different cycles. In this paper, the nominal value and variation of loads (including forces and moments) are defined to represent the deterministic part and uncertain part of the loads respectively, serving as a method to describe the uncertainty of the robot loads. On the other hand, during implementation of cycles by industrial robots, the loads on each link change over time continuously. By employing inverse dynamics, loads that vary with time can be calculated on all joints and joints. These time-varying loads are converted into a nominal value and a variation via time-domain calculations, thus converting the time-varying loads under different robot cycles into an uncertainty. Subsequently, by computing the worst-case loads scenario on robot links, the magnitudes and directions of the worst-case loads under the current structural design and load uncertainty can be determined, along with the calculation of their sensitivities. Furthermore, a comparison is completed between the unidirectional maximal load method and the proposed method for calculating the worst-case loads, and then it is followed by stress analysis using the respective loads and to demonstrate the effectiveness of this new method. Finally, the new method is applied to a typical robot link topology optimization as an example, and the results are compared with the counterpart exploiting the unidirectional maximal load method.

REVEALING MICROSCOPIC DYNAMICS: IN-SITU LIQUID-PHASE TEM FOR LIVE OBSERVATIONS OF SOFT MATERIALS AND QUANTITATIVE ANALYSIS VIA DEEP LEARNING

Xiaohui Song[*1]

[1]*Hefei University of Technology*

ABSTRACT

In various domains spanning materials synthesis, chemical catalysis, life sciences, and energy materials, in-situ transmission electron microscopy (TEM) methods exert a profound influence. These methodologies enable the real-time observation and manipulation of gas-phase and liquid-phase reactions at the nanoscale, facilitating the exploration of pivotal reaction mechanisms. Fundamental research areas like crystal nucleation, growth, etching, and self-assembly have greatly benefited from these techniques. Additionally, their applications extend across diverse fields such as catalysis, batteries, bioimaging, and drug delivery kinetics.

However, the intricate nature of 'soft matter' presents a challenge due to the unique molecular properties and dynamic behavior of these substances that remain insufficiently understood. Investigating soft matter within in-situ liquid-phase TEM settings demand further exploration and advancement compared to other research domains. This research harnesses the potential of in-situ liquid-phase TEM technology while integrating deep learning methodologies to comprehensively analyze the quantitative aspects of soft matter dynamics.

This study centers on diverse phenomena, encompassing surfactant molecule nucleation, block copolymer behavior, confinement-driven self-assembly, and drying processes. Furthermore, deep learning techniques are employed to precisely analyze Ostwald ripening and digestive ripening dynamics. The outcomes of this study not only deepen the understanding of soft matter at its fundamental level but also serve as a pivotal foundation for developing innovative functional materials and cutting-edge devices.

Keywords: liquid phase TEM, big data, block copolymer, self-assembly, deep learning,

[5]York University

ABSTRACT

The friction stir welding process can be modelled using a system of heat transfer and Navier-Stokes equations with a shear-dependent viscosity. Finding numerical solutions of this system of nonlinear partial differential equations over a set of parameter space, however, is extremely time-consuming. Therefore, it is desirable to find a computationally efficient method that can be used to obtain an approximation of the solution with acceptable accuracy. In this talk, we present a reduced basis method for solving the parametrized coupled system of heat and Navier-Stokes equations using a proper orthogonal decomposition (POD). In addition, we apply a machine learning algorithm based on an artificial neural network (ANN) to learn (approximately) the relationship between relevant parameters and the POD coefficients. Our computational experiments demonstrate that substantial speed-up can be achieved while maintaining reasonable accuracy.

[2]*University of Houston*
[3]*Rice University*
[4]*University of Pittsburgh*

ABSTRACT

Modeling the flow of liquid, aqueous, and vapor phases through porous media is a complex and challenging task that requires solving nonlinear coupled partial differential equations. In this talk, we propose a second-order accurate and energy-stable time discretization method for the three-phase flow problem in porous media. We prove the convergence of the subiterations to resolve the nonlinearity, and show that the time-stepping method mimics the energy balance relation that the continuous problem satisfies. Our spatial discretization uses an interior penalty discontinuous Galerkin method, for which we establish the well-posedness of the discrete problem and provide error estimates under certain conditions on the data. We validate our method through numerical simulations, which show that our approach achieves the expected theoretical convergence rates. Furthermore, the numerical examples highlight the advantages of our time discretization over other time discretizations.

NUMERICAL MODELLING OF FRAGMENT AND BLAST LOADED CONCRETE STRUCTURES USING MASSIVELY-PARALLEL COUPLED CFD-CSD TECHNIQUES

Orlando Soto[*1], Joseph Baum[1] and Rainald Lohner[2]*

[1]Applied Simulations Inc. (ASI).
[2]George Mason University

ABSTRACT

This paper describes the numerical formulation of a state-of-the-art coupled computational fluid dynamics (CFD) and computational structural dynamics (CSD) methodology, to the simulation of steel case fragmentation and explosively loaded reinforced concrete structures.

ASI (Applied Simulations Inc.) have developed a numerical methodology that couples state-of-the-art CFD and CSD methodologies [1]. The flow (CFD) code solves the time-dependent, compressible Euler and Reynolds-Averaged Navier-Stokes equations. The CSD code solves the large deformation, large strain, solid dynamic equations on an unstructured grid composed of bricks and tetrahedral elements. VMS (variational multi-scale) stabilization is utilized to improve the robustness and stability of the numerical CSD solution. The codes are coupled via a ‘loose coupling’ approach which decouples the CFD and CSD sets of equations and uses projection methods to transfer interface information between the CFD and CSD domains. Both codes are parallelized using a hybrid MPI/OpenMP methodology. The final presentation will describe in detail the implementation of the concrete fracture, weapon fragmentation and contact algorithm on the mentioned MPI/OpenMP parallelization frame, which allows spectacular simulation speed-up for real life applications. An improved first principles fragmentation scheme, which enforces mass conservation and compare very well qualitatively and quantitatively with experimental results (fragments size distribution), will be shown too.

Finally, a steel case weapon simulation inside a reinforced concrete structure is shown to demonstrate the overall scheme. The simulation addresses the steel case fragmentation, air blast and fragments impact on the concrete structure, structural response, structural failure, debris launch, and propagation of air blast to the far field. The predicted structural disassembly agrees well with the high-speed photography. The predictions exhibit similar failure mechanisms, failure locations and times of failure. The initial structural debris, the weapon fragmentation size distribution, and the weapon fragment velocities follow the experimental ones too. The far field pressures exhibit similar decay with range as the experimental data.

[3]*Université de Montréal*

ABSTRACT

Most science and engineering problems are modeled by time-dependent and parametrized nonlinear partial differential equations. Their resolution with traditional computational methods may be too expensive, especially in the context of predictions with uncertainty quantification or optimization, to allow for rapid predictions. In this talk, we will overview data-driven methods aimed at representing high-fidelity computational models by means of reduced-dimension surrogate ones. Different approaches will be presented for the uncertainty quantification for reliable predictions and forecasts in inundation problems.

Particularly, a non-intrusive reduced-order model based on convolutional autoencoders is proposed as a data-driven tool to build an efficient nonlinear reduced-order model for stochastic spatiotemporal large-scale physical problems. The method uses two-level autoencoders to reduce the spatial and temporal dimensions from a set of high-fidelity snapshots collected from an in-house high-fidelity numerical solver of the shallow-water equations. The encoded latent vectors, generated from two compression levels, are then mapped to the input parameters using a regression-based multilayer perceptron. The accuracy of the proposed approach is compared to the linear reduced-order technique-based artificial neural network (POD-ANN) on benchmark tests (the Burgers and Stoker's solutions) and a hypothetical dam-break flow problem over a complex bathymetry river. The numerical results show that the proposed nonlinear framework presents strong predictive abilities to accurately approximate the statistical moments of the outputs for complex stochastic large-scale and time-dependent problems, with low computational cost during the predictive online stage.
The challenge that remains is the long-term temporal extrapolation for problems marked by sharp gradients and discontinuities. Our recent studies explore forecasting convolutional architectures in space and time (LSTM, TCN, CNN, Self-Attention, and Transformers) to obtain accurate solutions for time-steps distant from the training domain, on advection-dominated test cases. To evaluate the epistemic uncertainties in the predicted solutions, the methodology of deep ensembles is adopted.

COMPARISON OF REISSNER-MINDLIN AND KIRCHHOFF-LOVE THEORIES BY A SIMPLE NONLINEAR SHELL TRIANGULAR ELEMENT

Cinthia Sousa[*1] and Paulo Pimenta*[1]

[1]*University of São Paulo*

ABSTRACT

In solid mechanics, shells are a particularly important model because many structures in engineering can be associated with them: sheet metal products, slabs, thin-walled pressure vessels and other objects with one of their dimensions significantly smaller than others. The Shell models can be adapted for finite element use, but it is important to consider peculiarities such as locking behaviour.
The objective of this work is to examine the behaviour of a nonlinear formulation for shell models using a new displacement-based triangular shell element with 6 nodes. The formulation of the element is implemented in both Reissner-Mindlin and Kirchhoff-Love kinematic assumptions and an initial plane reference configuration for the shells.
The proposed formulation also accounts for finite strains, large displacements, and rotations. The rotation field has been re-parameterised using the Rodrigues rotation vector, resulting in a simpler update of rotational variables.
The computational implementation of the new elements is achieved through automated finite element methods, with some numerical examples. Furthermore, a comparison between these numerical examples and both theories is performed.

PRECONDITIONERS BASED ON MULTISCALE DOMAIN DECOMPOSITION METHODS FOR POROUS MEDIA FLOWS

Fabricio Sousa[*1], Pablo Carvalho[1], Rafael Guiraldello[2], Roberto Ausas[1], Gustavo Buscaglia[1] and Felipe Pereira[3]*

[1]University of São Paulo
[2]Piri Technologies LLC
[3]The University of Texas at Dallas

ABSTRACT

Multiscale domain decomposition methods have already shown great scalability in parallel high-performance simulations of heterogeneous subsurface flows [1] at the cost of accuracy compared to the solution of the undecomposed discretizations. In order to take advantage of the excellent scalability properties of multiscale methods without the loss of accuracy, we introduce a family of preconditioners based on multiscale domain decomposition methods for solving heterogeneous single-phase subsurface flows. We build the preconditioners using the Multiscale Robin Coupled Method - MRCM [2], a domain-decomposition method based on the imposition of Robin-type boundary conditions on each subdomain. Depending on the choice of the Robin parameter, the MRCM can reproduce the results of other well-known multiscale methods within the same framework, directly affecting the performance of the resulting preconditioner. This method is combined with iterative linear solvers, such as the Preconditioned Conjugate Gradient method, to solve the linear systems arising from the (undecomposed) Finite Volume discretization of heterogeneous porous media flows. The results show that multiscale methods can be successfully used as preconditioners to improve efficiency when combined with different smoother methods, reducing the number of iterations. Results also demonstrate the flexibility of the MRCM preconditioners as a viable alternative compared to other existing techniques.

DYNAMICS OF PRESTRESSED STEEL-CONCRETE COMPOSITE MEMBERS

João Batista Sousa Jr[*1]

[1]*Universidade Federal do Ceará*

ABSTRACT

Composite steel-concrete beams may improve their mechanical behavior through application of post-tensioning, allowing longer spans, a larger elastic range and better fatigue behavior, either as building elements or after strengthening/repair. A particular characteristic of composite beams is the possibility of slip or partial interaction between the components as a result of the flexible connection between steel and concrete. Several studies have dealt with these elements recently, but very few addressed the dynamic analysis of such members.
The purpose of this work is to present a numerical scheme for the dynamic analysis (modal analysis, free and forced vibration) of posttensioned steel-concrete composite beams under nonlinear material and geometrical assumptions, considering also partial interaction. The numerical model employs beam-column elements for the steel and concrete sections and a tendon element for the prestressing, taking into account the variation of the tendon stiffness in a consistent fashion. The robustness of the numerical procedure is assessed by means of some examples and parametric studies.

INVESTIGATING THE DOMAIN OF ATTRACTION OF SDRE APPLIED TO A CUBESAT ATTITUDE CONTROL SYSTEM DURING LAUNCH ORBIT PHASE BASED ON COLD GAS THRUSTERS

Luiz Carlos Souza[*1] and Alessandro Gerlinger Romero*[2]

[1]*University of ABC*
[2]*National Institute for Space Research*

ABSTRACT

The precision of controlling the attitude of a CubeSat during the injection phase in orbit is of fundamental importance for the success of the mission. In general, the CubeSat starts this phase with high angular velocity, and then the controller needs to maneuver the CubeSat to its nominal mode of operation, which is characterized by an attitude of small angles. One way to achieve such a transition between these two modes is by using cold gas thrusters. In this paper, we investigate the Domain of Attraction of State-Dependent Riccati Equation (SDRE) applied to the Attitude Control System (ACS) algorithm during Launch and Early Orbit Phase which has nonlinear dynamics due to the high angular velocities and perturbations. The SDRE controller is based on cold gas thruster torques to perform the large-angle maneuver in order to reduce the high angular velocities. The main result of this investigation is the approach to numerically approximate the Domain of Attraction.

INTEGRATING MATERIAL SELECTION WITH TOPOLOGY OPTIMIZATION OF MULTI-ALLOY STRUCTURES VIA NEURAL NETWORKS

Saketh Sridhara[1] and Krishnan Suresh*[1]

[1]*University of Wisconsin, Madison*

ABSTRACT

The design of high performance components such as turbine blades often entails optimizing the geometry as well as selecting the most appropriate alloy(s) for the application. Traditionally, the steps of material selection and geometry optimization are done sequentially, which results in sub-optimal performance. Further, advancements in metal additive manufacturing have enabled the realization of multi-alloy structures, which offer superior performance over single alloy components when the candidate alloys are optimally located.

Towards this end, we propose an integrated approach using variational autoencoders (VAE) and gradient-based optimization methods, to simultaneously select alloys and optimize the topology of parts. In the first step, we consider a database of all candidate alloys described by performance characteristics like yield strength and melting temperature, manufacturing attributes such as feasibility for multi-alloy additive manufacturing, and supply chain attributes such as criticality index. The VAE maps these materials to a continuous, low-dimensional space which can be explored by gradient-based optimization algorithms. This latent space is then coupled with a neural network [1], embedded with a differentiable finite-element solver, to simultaneously optimize the material and topology of the component. Various numerical examples demonstrate the efficacy of the proposed method. Possible extensions to large scale and multi-physics topology optimization are also discussed.

APPLICATION OF BOUND-PRESERVING LIMITERS TO THE NONLINEARLY STABLE FLUX RECONSTRUCTION HIGH-ORDER METHOD

Sai Shruthi Srinivasan[*1], Alexander Cicchino[1] and Siva Nadarajah[1]*

[1]*McGill University*

ABSTRACT

The flux reconstruction method has gained popularity in the research community as it recovers promising high-order methods through modally filtered correction fields, such as the Discontinuous Galerkin (DG) method, on unstructured grids over complex geometries. Under a class of energy stable flux reconstruction (ESFR) schemes, the flux reconstruction method allows for larger time-steps than DG while ensuring stability for linear advection on linear elements. For nonlinear problems, split forms and entropy-conserving flux differencing approaches have become popular as they guarantee robustness for unsteady problems on coarse unstructured grids.

Nonlinearly stable flux reconstruction (NSFR) combines the key properties of provable nonlinear stability and the increased time-step from ESFR. NSFR has successfully been applied to unsteady compressible flows in arbitrary curvilinear coordinates with low-storage weight-adjusted approaches to scale efficiently with low memory consumption.

NSFR can also be used in conjunction with bound-preserving limiters to satisfy the maximum principle for scalar conservation laws and preserve positivity in the case of hyperbolic conservation laws. Bound-preserving limiters within an NSFR framework allow for a robust solution to be obtained while preserving the desired properties and maintaining a high-order of accuracy. This study incorporates the implementation of bound-preserving limiters within the NSFR framework to observe the shock capturing capabilities of NSFR. Due to the nature of NSFR and the bound-preserving limiters, solutions for problems involving strong discontinuities are obtained without the use of artificial viscosity or a TVD property while maintaining a high order of accuracy. This study also aims to observe the impact of the flux reconstruction (FR) parameter by implementing the FR parameter adaptively using a shock sensor. The adaptive implementation of the flux reconstruction parameter will allow for more robust solutions. Applying NSFR in the context of shock-capturing encourages the extension of this scheme to a wide range of applications such as compressible turbulence, aeroacoustics, and high Mach number problems. The study is currently performed with preliminary results for 1D and 2D inviscid cases, but the limiter will also be used to extend the NSFR scheme to problems involving complex interactions between viscous shocks, contact waves and viscous boundary layers. The preliminary results include the 1D Sod Shock Tube, Leblanc Shock Tube, Shu-Osher problems as well as the 2D Double Mach Reflection and Mach 3 Wind Tunnel with a Step cases. Results will be provided for the preliminary cases as well as the 2D Daru-Tenaud Viscous Shock Tube case.

MODELLING THE FLOW OF FLUIDS THROUGH POROUS SOLIDS EXHIBITING NONLINEAR RESPONSE IN THE SMALL STRAIN REGIME

Shriram Srinivasan[*1]*

[1]*Los Alamos National Laboratory*

ABSTRACT

Considerable experimental evidence in a variety of porous materials (concrete, ceramics, bones, rocks) that undergo infinitesimal deformations makes it clear that material moduli depend on the density (identified as density dependence of Young's modulus).

This is especially relevant for subsurface flows through geological media which have experienced deformation over millenia, and damage or aging manifests in the form of inhomogeneities, and thus density-dependent material moduli.

The fundamental implication of these experiments is the nonlinear mechanical/stress response of the porous solid within the context of “small" deformation. However, the traditional (Biot) theory assumes that mechanical response of porous materials must be linear within the regime of small deformation. Specifically, the porous solid is assumed to be a linearized elastic solid with constant values of material properties such as Young's modulus.

Moreover, incorporating a density-dependent Young's modulus is inconsistent with the assumption of infinitesimal deformation. How can we then have a constitutive theory for porous media that allows nonlinear response within the regime of small deformation ? Furthermore, will the predictions from a nonlinear theory set within the regime of small deformation deviate significantly from that of the (currently used) traditional model ? I propose to definitively answer this question.

INSTABILITY-INDUCED DEFORMATION OF LAYERED CRYSTALS

Miloš Dujović[1], Mayank Chouksey[1], Miladin Radovic[1] and Ankit Srivastava[*1]*

[1]Texas A&M University

ABSTRACT

A family of ternary carbides and nitrides, known as MAX phases, exhibit some of the best attributes of metals and ceramics. Like ceramics, they are lightweight, elastically stiff, thermodynamically stable, and refractory; and like metals, they are damage-tolerant, pseudo-ductile, and machinable. The unique set of properties of MAX phases is generally associated with their layered hexagonal crystal structure, which combines strong intralayer and weak interlayer atomic bonds. Mechanical tests on bulk polycrystalline MAX phases have shown that, unlike their counterpart binary carbides (MX), MAX phases undergo basal slip, cleavage, buckling of layers, and kink-banding. Micromechanical single-crystal level tests have shown that grain-level deformation and failure mechanisms of MAX phases depend on both the crystallographic orientation and deformation constraint of the grains. Building on these recent works, we further analyze the effects of deformation constraints on the mechanical response of single-crystal MAX phases through a series of unconventional small-scale mechanical tests and crystal plasticity finite element analyses. The small-scale tests include three distinct specimen types designed to impose various constraint levels: free-standing micro-pillars, unconstrained micro-walls, and constrained micro-walls. The crystal plasticity finite element analyses employ a non-Schmid crystal plasticity constitutive model, which, based on experimental observations, assumes that the evolution of slip system strength/resistance in MAX phases comprises two components. The first component is the classical element, which depends on the Taylor cumulative shear strain, while the second is the non-Schmid component, which depends on the stress normal to the slip plane. Our primary focus is on understanding the onset of kink-banding, which is essentially an instability. This is motivated by the fact that a few recent experiments have suggested that MAX phases exhibit unconventional damage tolerance because of kink-banding, even in the presence of very weak interlayer bonds. To this end, the focus is confined to a particular crystallographic orientation where the basal planes are parallel to the imposed loading direction. This orientation is the most susceptible orientation for the onset of any instability. Our results show that, regardless of the constraint level, the specimen consistently exhibits susceptibility to the onset of instability. However, the response varies depending on the degree of constraint, with the specimen either undergoing easy cleavage and/or kink-banding. Notably, the crystal plasticity finite element simulations not only replicate the onset of instability in line with experimental results but also approximate the location of these instabilities.

GRAPH CALCULUS NEURAL NETWORK FOR REPRESENTATION OF PHYSICAL SYSTEMS

Siddhartha Srivastava[*1], Elizabeth Livingston[2] and Krishna Garikipati[1]*

[1]*University of Southern California*
[2]*University of Michigan*

ABSTRACT

Universal approximation theorems have advanced the use of Neural networks for parametric interpolation of functions. Among them, Graph neural networks (GNN) are the popular choice for data-driven physics problems for their capability of naturally treating unstructured data. However, many of these physical problems admit to a Partial differential Equation model, desiring the approximation of differential operators in comparison to algebraic functions. The errors in the traditional GNNs due to this limitation are typically mitigated by making the network larger to enrich its representation capacity. The obvious downside of this approach is the inflated demand for training data for these complex networks.

In this talk, we present Graph Calculus Neural Network (GCalcNN) that utilizes a non-local calculus on finite weighted graphs [1] to approximate differential quantities within the network layers. This graph-theoretic framework for modeling builds off on our recent work for representation, exploration, and analysis of computed states of physical systems [2]. We analyze the consistency of the non-local derivatives in this setting, a crucial requirement for numerical applications. We show that the weight of the graph can be fine-tuned to achieve arbitrary order of accuracy in any number of dimensions without any assumptions of symmetry in the underlying data [3]. We first demonstrate the representation capability of GCalcNN for differential operators. Finally, we present three example applications for utilizing this differential representation in learning (1) reduced order models for PDEs, (2) representations for differentiable quantities of interest, and (3) surrogate models for the evolution of PDEs.

PHYSICS INFORMED NEURAL NETWORKS IN THE CONTEXT OF COMPUTATIONAL FLUID DYNAMICS SOLVERS

Rahul Halder[1], Gabriele Codega[1], Giovanni Stabile[*2] and Gianluigi Rozza[1]*

[1]International School for Advanced Studies
[2]University of Urbino

ABSTRACT

This contribution focuses on developing a physics-informed neural network (PINN) by incorporating a physics-based loss term derived from an external computational fluid dynamics (CFD) solver, such as OpenFOAM. Building upon our prior research [1], which explored the integration of discretized governing equations with both Artificial Neural Network (ANN) and Long-Short-Term-Memory (LSTM) based neural networks, this work addresses challenges encountered when coupling PINN with external forward solvers.

A significant obstacle in this coupling arises from the difficulty of incorporating the discretized form of the governing equation from the external solver into the computational graph of the PINN. This limitation poses a considerable challenge to the conventional automatic-differentiation-based computation of derivatives for the physics-based loss term concerning the weight matrix and bias vectors in neural networks. To address this, we propose modifying the physics-based loss term to consider the residual generated by the external solver, enabling the computation of the necessary derivatives for the optimization process.

To tackle issues related to high dimensionality, the governing equations are transformed into linear and nonlinear manifolds. The resulting reduced equation form is utilized as a residual for the physics-based loss term in the PINN.

While the advantages of the discretized physics-based neural network are detailed in [1], the primary objective of this work is to integrate available numerical data with established forward solvers for various inverse and ill-posed problems. This approach delegates the tasks of residual computation, handling boundary, and initial conditions to dedicated external forward solvers, such as OpenFOAM, eliminating the need for additional implementation of governing physics within the conventional PINN framework.

Our proposed methods' potential and implementation details are thoroughly examined across several benchmark applications.

DEEP LEARNING-BASED SUPER-RESOLUTION FRAMEWORK FOR HYDRODYNAMIC DOWNSCALING

Nelson Stache[*1], Julie Carreau[1] and Ahmad Shakibaeinia[1]*

[1]*Polytechnique Montreal*

ABSTRACT

Understanding fluvial hydrodynamics is crucial for various engineering, hydro-environmental, and geomorphological applications. Physics-based hydrodynamic models predominantly rely on numerically solving the 2D Shallow Flow equations, also known as Saint-Venant equations, derived by depth-integrating the Navier–Stokes equations.
Accurate hydrodynamic simulations depend on high-resolution models, which are prohibitively expensive due to the large temporal and spatial scales involved. On the other hand, low-resolution, computationally affordable models provide only a general perspective of the flow field. In this study, we aim to address this challenge by developing and evaluating physics-aware, deep learning-based super-resolution models. These models generate high-resolution flow fields through downscaling (resolution refinement) of low-resolution, computationally inexpensive, yet inaccurate hydrodynamic simulations. We tested the proposed model across various synthetic and natural domains to identify the strengths and weaknesses of different architectures in different hydrodynamic contexts.

A MIXED NONLINEAR ISOGEOMETRIC PLATE FORMULATION EMPLOYING DUAL BASIS FUNCTIONS

Lisa Stammen[*1] and Wolfgang Dornisch*[2]

[1]*Brandenburg University of Technology Cottbus-Senftenberg*
[2]*Brandenburg University of Technology*

ABSTRACT

Employing mixed formulations, variables from different fields are discretized independently. Thus, a separate selection of the corresponding interpolation orders is enabled. Determining these independent approximation orders corresponding to the shear-strain equation counteracts shear-locking effects, which occur for standard formulations. In order to improve the accuracy of results further, in isogeometric analysis, non-uniform rational B-splines (NURBS) are selected for the geometry representation and as basis functions that offer a high continuity during analysis. As the additionally introduced parameters increase the computational effort, performing static condensation may be employed to reduce this effect. In nonlinear analysis, this involves determining the inverse of parts of the system matrix in each iteration step of the Newton-Raphson procedure. By selecting dual basis functions for the interpolation of the secondary variables, the relevant matrix part is lumped into a banded matrix with low bandwidth, reducing the complexity of the required matrix inversion. This approach can be employed to increase the efficiency of mixed nonlinear formulations.

In this contribution, the ability of a mixed nonlinear plate element to counteract shear-locking effects and the effectiveness of the proposed condensation procedure in an isogeometric framework are studied for a benchmark example. Therefore, the governing equations for nonlinear plate problems are derived and the shear forces are introduced as additional field. The independent interpolation orders are determined such that they result in matching orders in the shear-strain equation. Furthermore, dual basis functions are employed for the interpolation of the introduced shear parameters, in order to enable an efficient static condensation in nonlinear analysis.

EFFECT OF LONG-TERM SEA WATER EXPOSURE ON DIELECTRIC MATERIALS

Eugenia Stanisauskis Weiss[*1], Eric Warner[1] and Valentina Rossell-Olmos[1]*

[1]Naval Undersea Warfare Center - Newport

ABSTRACT

Dielectric materials, which are commonly used in capacitors, could increase energy storage density on a per volume basis in film capacitors compared to current technologies accommodating the ever-increasing power demands. Recent work in this area has brought about dramatic increases in the dielectric permittivity and moderate increases in dielectric loss, leading to increased material performance on a per volume basis. However, little is known about the aging and breakdown of these materials, which could decrease the performance of these films over time due to decaying dielectric loss and energy storage density. A basic study of the aging and breakdown of two different state-of-the-art dielectric materials, 3M's Very High Bond (VHB) 4910, commonly used in actuator applications, and bi-axially oriented polypropylene (BOPP), commonly used in large wound film capacitators, is completed. To begin, accelerated life tests using distilled water are conducted to simulate the aging of these materials in a marine environment. Both cyclic and non-cyclic tensile loading testing are used to characterize the material behavior of the unaged vs aged samples and to determine how the material properties (e.g., tensile strength and viscoelasticity) change over time. For VHB, aging seems to transition the hyperelastic (non-linear) behavior to purely elastic (linear) behavior. In addition, the point of maximum elongation decreases as the amount of aging increases and fracture increases with increasing aging and increasing stretch rate. Elastic modulus also increases with either increasing aging level or increasing stretch rate for VHB 4910. Similar observations can be noted for BOPP, although the effect of its bi-axial orientation must be taken into account. Regardless of stretch rate, decreases in stress and hysteresis are observed as aging time increases. Overall, stretch rate causes an increase in elastic modulus, and the effect of aging looks to be dependent on orientation where for the orientation normal to the long axis, the elastic modulus increases as aging increases and for the orientation parallel to the long axes, the elastic modulus decreases as aging increases. We note that, in every case for BOPP, orientation plays a greater effect on stress and elastic modulus than aging or stretch rate. The success of this work could actively exhibit the promise of these materials in microelectronic uses.

Emerging topology and shape optimization techniques in computational design of materials and structures

ACHIEVING PRECISION IN COMPLIANT MECHANISM DESIGN: TOPOLOGY AND SHAPE OPTIMIZATION WITH STRESS AND CURVATURE CONSTRAINTS

Gabriel Stankiewicz[1], Chaitanya Dev*[1] and Paul Steinmann[1]*

[1]*Friedrich-Alexander-Universität Erlangen-Nürnberg*

ABSTRACT

Compliant mechanisms (CMs) perform actuation through elastic deformation at flexure hinges. Therefore, precise geometry design of these hinges is crucial for reliable and failure-free operation. Extensive literature has explored the design of CMs, often employing topology optimization. However, applying topology optimization to design flexure hinges presents challenges, primarily due to the absence of an explicit boundary. This difficulty is particularly evident in computational accuracy and determination of the boundary.

In this study, we utilize a sequential topology and shape optimization framework for the CM design [1, 2]. Our focus is on the precise design of flexure hinges through shape optimization in a geometrically nonlinear context. We introduce adaptive shape and domain refinement strategies in the embedding domain discretization method (EDD) to attain both numerically and geometrically accurate designs of the flexure hinges. Additionally, to address the durability and manufacturability of the flexure hinges, we incorporate local stress constraints and a curvature constraint. The design update is implemented by adapting the traction method to the specifics of EDD [3]. Consequently, the curvature constraint is introduced into the auxiliary boundary value problem of the traction method through a penalty functional, instead of being expressed as a response.

As a result, we obtained CMs with smooth and durable flexure hinges due to the presence of stress and curvature constraints. The efficiency and accuracy of the computations were guaranteed with adaptive domain and shape refinements within EDD.

This work introduces the following novelties:

• Extension of shape optimization using EDD to nonlinear elasticity and compliant mechanism design;
• Regularization of the sensitivities via adapted traction method with curvature constraint;
• Adaptive refinement strategies for the computational domain and the embedded shape, tailored for complaint mechanism design.

ABSTRACT

Simulation of flow, reactive transport, and biomass growth in naturally occurring porous media is of critical importance to several subsurface applications such as CO2 geological storage, oil and gas production and recovery, and groundwater bioremediation. In this talk, we propose a micro-continuum formulation of coupled flow and bio-geochemical reactive transport at the pore-scale, in which the reactive transport model is fully coupled with a biomass-nutrient growth model. The models are implemented into the open-source software BioReactPy. The goal of this talk is twofold. First, we present simulations results of an application case concerning subsurface biomineralization in reactive silicate rocks. Second, we address the important topic of model verification by replicating an experimental setup of calcite dissolution from microscale measurements obtained through atomic force microscopy.

NONLINEAR INTERACTION IN COMPOSITES USING PHYSICS INFORMED NEURAL NETWORKS

Georgios Stavroulakis[*1], Aliki Mouratidou[1] and Georgios Drosopoulos[2]*

[1]*Technical University of Crete*
[2]*University of Central Lancashire*

ABSTRACT

Interaction between adjacent constituents within a composite at every scale can be described by nonlinear laws, including unilateral contact and friction that lead to nonsmooth mechanics problems. Numerical evaluation is based on specialized algorithms based on complementarity formulations and nonsmooth optimization, variational and hemivariational inequalities and specialized numerical algorithms which have shown their ability to capture highly nonlinear effects. Alternatively, if one wants to use classical Newton-type algorithms, one may use appropriate penalty functions in order to enforce inequality and complementarity restrictions [1]. Beyond classical numerical approaches, usage of neural networks for calculation of an approximate solution becomes popular, especially within a framework of multiscale finite elements. In the latter case the effect of microstructure, including possible nonlinear interactions, for various loadings is transferred to the homogenized medium through the Representative Volume Element RVE technique. The solution at the RVE level along the iteration steps tolerates some inaccuracies, especially if data-driven constitutive laws are adopted [2]. Usage of physics-informed neural networks, combined with complementarity or penalty formulations for the contact problem is proposed here for the numerical solution of the problem of numerical homogenization including nonlinear interactions at the RVE level. In this context, PINN training [3] can be incorporated at the RVE level in order to provide an approximate solution of the mechanical problem and, subsequently, be integrated within the FE-2 method. Performance comparisons of various alternatives and discussion for further work in the data-driven framework are included.

EVOLVING FINITE ELEMENTS FOR ADVECTION DIFFUSION WITH AN EVOLVING INTERFACE

Pierre Stepanov[*1], Charles Elliott[1] and Thomas Ranner[2]*

[1]*University of Warwick*
[2]*University of Leeds*

ABSTRACT

The aim of this presentation is to introduce a numerical scheme to approximate evolving interface problems for parabolic equations based on the abstract evolving finite element framework proposed by C M Elliott and T Ranner in "A unified theory for continuous-in-time evolving finite element space approximations to partial differential equations in evolving domains" (IMA J. Numer. Anal. 3 (July 2021), 1696–1845). An appropriate weak formulation of the problem is derived for the use of evolving finite elements designed to accommodate for a moving interface. Optimal order error bounds are proved for arbitrary order evolving isoparametric finite elements. The paper concludes with numerical results for a model problem verifying orders of convergence.

Some of the principal contributions of this work are:
- An ALE approach based on evolving isoparametric finite element spaces attached to evolving sub-domains. The evolving mesh is based on moving the Lagrange nodes with a given known smooth velocity. Achieving a higher order method requires a good initial mesh.
- We provide a robust error bound which demonstrates the error in an L_2 norm is bounded, up to a constant, by h^(k+1), where h represents the mesh size and k is the degree of polynomials used both for the discretisation of the domain and the solution. This is the same order error as if we interpolated a known smooth solution.

Methods for identification, machine learning, and uncertainty quantification of reduced order models of coupled systems

OVERVIEW OF THE LATEST FEATURES AND CAPABILITIES OF THE DAKOTA SOFTWARE

John Stephens[1]*

[1]*Sandia National Laboratories*

ABSTRACT

The Dakota software package is an open-source and widely used collection of tools for performing uncertainty quantification, optimization, sensitivity analysis, and model calibration on black box computational simulations. Begun as an internal research project at Sandia National Laboratories almost 30 years ago, we estimate it now has thousands of users worldwide in academia, government, and industry. This talk is a brief introduction to and review of Dakota's history and capabilities. Special attention is given to recent developments in algorithms and in Dakota's general usability.

PREDICTING RESIDUAL STRESS FIELDS USING A MULTIPHYSICAL MODEL WITH ADAPTIVE REMESHING: MODEL CONSTRUCTION AND VALIDATION

Andrew Stershic[*1], Christopher D'Elia[2], Lauren Beghini[1] and Michael Hill[2]*

[1]*Sandia National Laboratories*
[2]*University of California, Davis*

ABSTRACT

Prediction of residual stresses is critical in the design and analysis of manufactured components. The locations and magnitudes of these fields carries implications for the component strength margins and durability, especially in the presence of notches and flaws.

In this presentation, we construct a multiphysical finite element model to predict the deformed configuration and residual stress fields in a pressure-vessel component resulting from a resistance forge weld in its manufacture. A microstructural constitutive model, BCJ_MEM [1] (adapted from Bammann, Chiesa, and Johnson [2]), is employed to capture microstructural phenomena in the material during the weld process, such as dynamic recrystallization. Adaptive remeshing is employed to ameliorate the significant mesh distortion that results from shear localizations in the Lagrangian finite element model. A mesh convergence study is performed to verify the model predictions and prove mesh insensitivity.

The model construction is complemented by a suite of experimental validation techniques, including physical measurement of displacements and three methods to quantify residual stresses: slitting method, contour method, and neutron diffraction. The model compares favorably to the measurements, and factors that contribute to differences are identified.

AUTOMATED MODEL DISCOVERY FOR PROTEIN MISFOLDING IN ALZHEIMER'S DISEASE

Charles Stockman[*1], Alain Goriely[2] and Ellen Kuhl[1]*

[1]*Stanford University*
[2]*Oxford University*

ABSTRACT

Over the last years, extensive research has supported the tau hypothesis, suggesting that the aggregation and accumulation of hyperphosphorylated tau plays a key role in Alzheimer's disease. However, the intricate dynamics of tau in the human brain remain inadequately understood. To enhance our understanding of the timeline of this process, we discover the best model and parameters to describe the temporal evolution of misfolded tau proteins in different brain regions.

First, based on longitudinal AV1451-PET data from a cohort of n = 162 subjects from the Alzheimer's Disease Neuroimaging Initiative, we create a single heatmap of tau concentrations for all 162 brains across 83 brain regions over the study period varying between three and six years.

Second, we map the data per region into the {c,\dot{c}} space to visualize the characteristic relationship between the concentration of tau and the change in its concentration. In addition, we determine accurate baseline values and carrying capacities per region. This enables us to automatically discover the model and parameters that best describe this relationship across all brains and regions, allowing to quantify the goodness of fit based on data of all subjects.

Third, we partition the entire dataset into Amyloid-β positive and negative status, and explore the effect of amyloid pathology on tau dynamics. We again discover model and parameters for the individual subgroups, systematically comparing the results of these distinct groups. As a result, we create a local, subject-specific model capable of predicting the temporal evolution of misfolded tau proteins in each brain region.

This study not only contributes to advancing our understanding of Alzheimer's disease pathology, but also builds further on a novel approach, integrating a global model with region-specific considerations and automated discovery of the appropriate functions. By linking the specific brain regions to their physiological function, the model enhances the interpretability of Alzheimer's neurodegenerative pathway, allowing for more targeted interventions and personalized treatment strategies in the future.

PREDICTING EXTRUSION FLOW SHAPES USING DEEP LEARNING

Dan Stoecklein[*1], Yulin Zhou[1] and Philip Pounds[1]*

[1]*Rose-Hulman Institute of Technology*

ABSTRACT

Fluid flow that extrudes through a shaped nozzle can exhibit a different cross-sectional shape than the nozzle itself due to fluid-structure and fluid-fluid interactions after transiting the orifice. These effects have contributed to long-standing problems in manufacturing, particularly in glass/fiber drawing [1], additive manufacturing [2], and microparticle fabrication [3]. Currently, designing nozzles for extrusion flow requires experiments and/or full 3D numerical simulations to determine the extruded fluid flow shape for a given nozzle, which leads to a slow and tedious trial-and-error design process. In this work, a deep learning model based on the U-Net architecture is developed as a standalone solver to predict low-Reynolds number extrusion flow shapes for nested co-axial extrusion flows [3] with remarkable accuracy in a matter of seconds. Although this deep learning model uses full 3D Navier-Stokes simulations for training, once deployed, it completely replaces the computationally intensive tasks of meshing, 3D flow simulation, and streamtracing, enabling rapid design of nozzle geometries and flowrate ratios for desired extrusion flow shapes. The deep learning extrusion flow model developed in this work is validated against both 3D flow simulations and experimental extrusion flow shapes created for bioengineering applications.

[2]*The University of Texas MD Anderson Cancer Center*
[3]*Health Research Institute of Santiago de Compostela*

ABSTRACT

Neoadjuvant therapy (NAT) is the standard-of-care for treating patients with locally advanced triple-negative breast cancer (TNBC), yet less than half of these patients achieve a pathological complete response (pCR) upon completion of NAT [1]. Thus, it would be highly beneficial to identify early during NAT whether a patient will achieve pCR, as this would enable adapting the treatment to maximize therapeutic outcomes. This study seeks to predict NAT response by improving the mechanical coupling between tumor-induced tissue deformation and tumor dynamics in our previous modeling efforts [2].

We use a reaction-diffusion model to quantify spatiotemporal changes in tumor cellularity as the sum of tumor cell diffusion, proliferation, and death due to NAT. Using two imaging visits (before NAT and after 2 NAT cycles), we calibrate diffusivity, proliferation, and drug efficacy on a patient-specific basis. The model is then run forward in time until a third imaging visit (after 4 NAT cycles) to test predictive accuracy. In [2], the diffusivity was exponentially dampened via the von Mises stress and calibrated globally (i.e., one value per tumor), the proliferation rate was calibrated locally (i.e., one value per voxel in the tumor), and drug efficacy was calibrated globally for each drug. Here, we extend this model to exponentially dampen a globally calibrated proliferation rate via both von Mises and hydrostatic stress to account for compressive stresses within the tumor. Additionally, we locally calibrate the drug efficacy as our sensitivity analysis finds it to be the most sensitive parameter in the model.

We present preliminary results for ten patients comparing predictions from the previous model [2] and the proposed model. When comparing modeled and measured change in total tumor cellularity between the first and the third imaging visit, the concordance correlation coefficients were 0.94 and 0.97 for the previous model and the proposed model, respectively. Thus, our initial investigation into a more comprehensive characterization of mechanical changes during NAT of TNBC showed improved accuracy in tumor cellularity predictions. Future work will aim at further investigating the mechanical coupling on the diffusivity and proliferation rate, adding an advection term, and including an Allee effect in our proliferation term. Then, we plan to construct a model family investigating a subset of these additions and assess the accuracy of various models over the large TNBC dataset.

THE MECHANICAL SIGNATURE OF REAL AND PLANT-BASED MEAT

Skyler St. Pierre[1], Ethan C. Darwin[1], Divya Adil[1], Magaly C. Aviles[1], Archer Date[1], Reese A. Dunne[1], Yanav Lall[1], Maria Parra Vallecillo[1], Valerie A. Perez Medina[1], Kevin Linka[1], Marc E. Levenston[1] and Ellen Kuhl[1]*

[1]*Stanford University*

ABSTRACT

Plant-based meat products have a 50% lower environmental impact than real meat; yet, their adoption into people's diets is globally still low although the market for these products is growing rapidly [1, 2]. The sensory experience, including taste and texture, is rated as one of the most important reasons for choosing which product to eat [2]. Here, we sought to understand the fundamental mechanical properties that characterize real and plant-based based meat products. We tested five plant-based meat products, tofurky, sausage, hotdog, firm and extra firm tofu, and three real meat products, SPAM turkey, hotdog, and sausage, in tension, compression, and shear. In tension, we tested the products until failure, while for compression and shear, we tested to 10% stretch or shear. We found that real meat products tend to have a higher peak stress, but a comparable stretch at peak stress compared to plant-based products. At 10% stretch, real meat products displayed the highest tension/compression asymmetry and were all stiffer in tension than in compression, while some plant-based products were stiffer in compression than tension. We used an 8-term isotropic, incompressible constitutive artificial neural network [3] composed of I_1 and I_2 raised to the power 1 or 2 activated by the identity or exponential function to identity the best constitutive model for each product. Using L_0 regularization, we probed all single- and two-term combinations and collected the mean-squared error of the simultaneous fit to the tension, compression, and shear data. The best models for all meat products included the I_1 term, with all products except firm tofu finding the best fit with two terms. The models for the plant-based products were (I_1, I_2) for tofurky, (I_1, I_2) for sausage, (I_1, I_1^2) for hotdog, (I_1) for firm and (I_1, $\exp(I_1)$) for extra firm tofu. The models for the real meat products were (I_1, I_1^2) for SPAM turkey, (I_1, I_2^2) for hotdog, and (I_1, $\exp(I_1^2)$) for sausage. Two terms, $\exp(I_2)$ and $\exp(I_2^2)$, were never discovered for any products. Understanding the mechanical differences between real and plant-based meat products can guide the design of improved plant-based products to better mimic the mechanical signature of real meat.

CIFEM: ELUCIDATING THE ROLE OF LOCAL THERMAL ENVIRONMENT ON MULTI-TRACK MELT POOL MORPHOLOGY VARIATION FOR INCONEL 718 LASER POWDER BED FUSION

Seth Strayer[1], Alaaeldin Olleak[1], Praveen Vulimiri[1], Shawn Hinnebusch[1], William Frieden Templeton[2], Florian Dugast[1], Sneha Narra[2] and Albert To[1]*

[1]*University of Pittsburgh*
[2]*Carnegie Mellon University*

ABSTRACT

Thermal field prediction of laser powder bed fusion (L-PBF) via physics-based numerical simulation can help optimize the process while avoiding the cost of experimental techniques. However, the widely-used finite element method (FEM) for obtaining layer- and part-scale predictions requires the abstraction of critical physics into an effective heat source model, which invokes a tedious calibration process and provides inaccurate thermal fields compared to computational fluid dynamics (CFD) simulations. Models based on CFD have much higher fidelity but are extremely limited in scale due to the computational expense associated with including relevant physics. Accordingly, the driving force behind multi-track melt pool size variation has remained enigmatic up to this point. In this work, the authors extend the CFD-imposed FEM (CIFEM) to multi-track scenarios for Inconel 718 L-PBF to help address these issues. In this methodology, the thermal fields from the CFD simulation and predicted by a dimensionality reduction-based deep learning framework are imposed on the corresponding FEM solution domain rather than applying any analytically-calculated heat source values. These fields are enforced only within a relatively small computational region encompassing the melt pool, while heat diffusion effects elsewhere are solved via the FEM. To extend to multi-track, CIFEM's data-driven heat source model is trained on multi-track CFD simulations with different scan lengths to establish the role of a local thermal environment metric. The local heat accumulation effect is captured by including this metric: the CIFEM-simulated multi-track thermal fields for different scan lengths possess less than 10% error regarding the high-fidelity CFD simulations, and the simulated melt pool sizes are within 10% error regarding experimental measurements up to five consecutive tracks. The CIFEM model thus provides substantially more accurate thermal process predictions compared to using an effective heat source model and also provides a significant efficiency increase compared to CFD by running on a GPU-based, matrix-free FEM solver that can feasibly be extended to the part scale. These advancements help elucidate the role of local heat accumulation on multi-track melt pool size variation and ultimately can be used to help better identify possible sources of defect formation and improve process-structure-property predictions.

A STUDY ON LOCKING EFFECTS WITHIN THE SOLUTION OF STRUCTURAL MECHANICS PROBLEMS USING PHYSICS INFORMED NEURAL NETWORKS

Lukas Striefler[1], Till Weithoff*[2], Josef Kiendl[2] and Bastian Oesterle[1]*

[1]Hamburg University of Technology
[2]University of the Bundeswehr Munich

ABSTRACT

Key Words: physics informed neural networks, locking effects, collocation

Artificial intelligence (AI) applications have recently gained widespread attention due to their capabilities in the domains of speech and image recognition as well as large language models. This has drawn research attention towards AI and artificial neural networks (ANNs) in particular within numerous branches of applied mathematics and computational mechanics. The challenge of generating extensive training data for supervised learning of ANNs can be addressed by incorporating laws of physics into ANNs. Most of so-called physics informed neural network (PINN) [1] frameworks for structural mechanics applications incorporate the partial differential equations (PDEs) governing a specific problem within the loss function in the form of energy methods or collocation methods.
Many structural mechanics problems are governed by stiff PDEs resulting in locking effects which have already been recognized in the early days of finite element analysis. Locking effects are present for all known discretization schemes, not only for finite elements, independent of the polynomial order or smoothness of the shape functions. This applies to both Galerkin-type solution methods and collocation methods based on the Euler-Lagrange equations of the specific boundary value problem [4].
In this contribution, we examine the impact of stiff PDEs and corresponding locking effects on the accuracy and efficiency of PINN-based solutions of problems in structural mechanics. As a test case, PINN-based solutions of beam problems using shear deformable beam formulations are investigated. Different types of beam formulations are compared with respect to accuracy and efficiency.

REDUCED-ORDER MODELING OF STOCHASTIC CHEMICAL KINETICS UNDER THE LINEAR NOISE APPROXIMATION

Justin Eilertsen[1] *and Wylie Stroberg**[2]

[1]*Mathematical Reviews*
[2]*University of Alberta*

ABSTRACT

Many chemical reaction networks in biology and industrial chemistry involve processes that occur at disparate timescales. This timescale separation permits the systematic reduction of deterministic chemical kinetic models, facilitating parameter estimation and model exploration. In particular, geometric singular perturbation theory provides a coordinate-free framework for deriving reduced mass action models in the deterministic realm. However, for systems of relatively low numbers of molecules, the variance of populations may be important, requiring stochastic models. Interestingly, several studies indicate that timescale separation does not always guarantee the accuracy of reduced stochastic models. In this work, we examine the roles of timescale separation and coordinate transformations in the reduction of the Linear Noise Approximation (LNA) and, unlike previous studies, we do not require the system to be comprised of distinct fast and slow variables. We demonstrate that eigenvalue disparity does not guarantee the accuracy of the reduced LNA. However, through proper coordinate transformation, we are able to recover a reduced model that accurately captures the mean and variance of the LNA. This works demonstrates the need for caution when transferring heuristic model reduction techniques from deterministic problems to stochastic settings.

DECA: DISCRETE EVENT INSPIRED CELLULAR AUTOMATA FOR GRAIN STRUCTURE PREDICTION IN ADDITIVE MANUFACTURING

Benjamin Stump[1], Alex Plotkowski[1] and James Nutaro[1]*

[1]*Oak Ridge National Laboratory*

ABSTRACT

The Cellular automata (CA) approach has been a commonly used method for simulating the microstructure evolution in response to the thermal fields seen in additive manufacturing (AM). The CA approach is computationally cheaper than most other approaches while still maintaining some degree of physical fidelity due to both the decentered octahedral algorithm alongside a calibrated interface response function (IRF). The most common CA approach uses a time-stepped framework which, although it is the easiest to implement while being amenable to parallelization, faces load-balancing challenges when applied to AM problems across multiple compute nodes. This talk introduces a new methodology, inspired by the field of discrete-event simulations, for CA simulations. This new technique, titled DECA, steps in events while also ignoring the global causality constraint (meaning events can happen out of order); however, due to the received events at any cell still following a local causality constraint, the end state of a DECA simulation will still be identical to the end state of a conventional, time-stepped CA simulation (provided the time-step is small enough that the solution is converged). The benefit to using DECA or conventional, time-stepped CA for AM simulations is that it is still relatively easy to implement and amenable to parallelization while also alleviating the load-balancing problem inherent in AM processes (due to the local nature of the process).

IMPACT OF PARTICLE MORPHOLOGY ON PHYSICAL AND MECHANICAL FEATURES OF GRANULAR MATERIALS VIA DEM INVESTIGATION

Dong Su[*1]

[1]*Shenzhen University*

ABSTRACT

Granular materials are commonly encountered in nature, industry, and civil engineering practice, and their mechanical responses are intricately linked to the morphology of the individual particles. As a result, it holds significant theoretical and engineering value to systematically study the inherent connection between the geometric morphology at the particle scale and the macroscopic mechanical behavior characteristics. In this regard, the generation and DEM investigation of physical and mechanical properties of morphological controllable particles are introduced. Firstly, the theories and techniques of geometric reconstruction, and morphological characterization of irregular particles are presented. Secondly, methods for generating virtual particles with controllable multi-level morphological features, including form, angularity and roughness, are introduced. Building upon this, DEM investigations on the particle shape effects on the packing structures and shear behaviors of granular materials are further discussed. The relevant research was financially supported by the National Natural Science Foundation of China (No. 52278364).

ABSTRACT

CoCrNi medium-entropy alloy (MEA) possesses an FCC crystal structure with multiple slip systems and low stacking fault energy [1]; a substantial amount of nanoscale deformation twins can be generated under low-temperature and high-speed deformation. Consequently, this CoCrNi medium-entropy alloy demonstrates exceptional mechanical performance in extreme environments such as space or high-velocity impact scenarios. Adding a proper amount of Si can not only reduce the manufacturing cost and mass density but also enhance ballistic resistance by further lowering the stacking fault energy. Previous studies [2] utilized small-scale vacuum arc remelting techniques to investigate the solid solution or secondary phase strengthening of CoCrNi-based MEAs with Al or Si additions. However, to extend the application of lightweight, high-entropy alloys to industrial-grade impact-resistant plate manufacturing, especially for low-temperature environments, it is necessary to study the solidification and heat treatment characteristics of CoCrNiSix castings. This study employs finite element analysis at the macroscopic scale to investigate the solidification phase transformation and heat transfer characteristics of CoCrNiSix under precision-cast conditions. Additionally, at the mesoscopic scale, the phase-field method [3] is used to simulate the dendritic solidification microstructure and element segregation of CoCrNiSix. Thermodynamic parameters required for simulations are calculated using Thermo-Calc high-entropy alloy databases TCHEA6 and MOBHEA2. This research also utilizes electron microscopy to analyze the microstructures of chemically complex CoCrNiSix ingots, focusing on measuring the secondary dendrite arm spacing and elemental segregation profiles. Collecting these microstructure-related features allows us to reasonably infer the cooling rate corresponding to the precision casting process of CoCrNiSix and design rational parameter combinations for homogenization heat treatment of the cast ingots in terms of temperature and isothermal holding time. By validating macroscopic and mesoscopic simulation results through CoCrNiSix microstructure analysis experiments, the multiscale kinetic computational techniques included in this study can be further applied to cost-saving and process optimization practices in the manufacturing of various lightweight high-entropy alloys.

ABSTRACT

Designing complex multiscale materials requires a comprehensive understanding of their relationships between mechanical behaviors and varying microstructures, leading to extensive research in multiscale materials modeling. In recent years, machine learning methods have emerged as a promising way to accelerate computational multiscale modeling and its time-to-solution predictions of materials behaviors. Among these machine-learning-based multiscale materials modeling methods, the deep material network (DMN) [1] has gained significant attention due to its ability to be used for fast and accurate nonlinear multiscale modeling while only trained on linear elastic data. However, the DMN model can only be confidently used for the specific microstructure it was fitted on, implying that different microstructures need to train other DMN models.

In this work, we adopted a data-driven point of view to tackle the limitation of DMN to a single microstructure. We cleared this roadblock by introducing a graph neural network (GNN) to learn the microscopic informatics of materials through their graph representation. This learned information can be used to generate an appropriate DMN for each microstructure and predict homogenized nonlinear material behaviors. This entire process is integrated under a single umbrella, a hybrid GNN-DMN model. This newly proposed GNN-DMN model [2] can single-handedly treat multiple microstructures and derive their DMN representations for online prediction of structure-property relationships. Examples demonstrate the validity and reliability of the approach, even when it comes to predicting material responses for new microstructures.

CENTRAL-MOMENT-BASED DISCRETE BOLTZMANN MODELLING OF COMPRESSIBLE REACTIVE FLOWS

Xianli Su[*1] and Chuandong Lin*[12]

[1]*Sun Yat-sen University*

[2]*Key Laboratory for Thermal Science and Power Engineering of Ministry of Education, Tsinghua University*

ABSTRACT

Compressible flows, especially the highly compressible reactive flows, have been widely used in modern industry and engineering, for example, in the fields of jet engines and rocket motors. Therefore, understanding compressible reactive flows is crucial to improve the design and performance of modern aircraft, rockets, engines, and other advanced technologies. In fact, the compressible reactive flows generally encompass a wide variety of nonlinear, unsteady, and nonequilibrium processes. Besides, both hydrodynamic and thermodynamic nonequilibrium influences are usually prominent, and the range of timescales involves several orders of magnitude. To probe the dynamic process, a central-moment-based discrete Boltzmann model (CDBM) is developed for highly compressible reactive flows. Via the Chapman-Enskog analysis, the CDBM is demonstrated to recover the Navier-Stokes (NS) equations in the hydrodynamic limit. Moreover, it provides quantification of thermodynamic nonequilibrium effects beyond the NS equations. The capability of the CDBM is demonstrated through simulations of the sound wave, thermal Couette flow, sod shock tube, shock reflection, and detonation wave. It should be mentioned that, compared with the previous discrete Boltzmann models, the CDBM can provide the nonequilibrium effects of highly compressible reactive flows which related to the thermal fluctuation directly. This work is helpful to have a better understanding of highly compressible reactive flows, and provide reliable numerical data for further improving the technologies of aeronautics and astronautics, energy and power engineering.

STUDY OF FAILURE EVOLUTION IN SHOCKED POROUS SOLIDS BY COMPARING MATERIAL POINT METHOD AND MOLECULAR DYNAMICS SIMULATIONS

Yu-Chen Su[1], Mohammed H. Saffarini[2] and Zhen Chen[2]*

[1]*National Central University*
[2]*University of Missouri*

ABSTRACT

Understanding the failure evolution in porous solids (or architected materials) under impact loading has become an important research topic over the past decade because their well-designed porous structures can result in high energy dissipation to weight ratios as compared with non-porous solids. Especially, multiscale failure evolution in shocked porous solids plays an important role in optimizing blast/impact-resistant design scenarios. Material Point Method (MPM) and molecular dynamics (MD) share significant similarity in the sense that both are particle methods. The MPM is a continuum-based particle method that displays great potential in simulating large deformation and multi-phase interaction problems beyond the nanoscale. The MD is a discrete particle method in which an appropriate potential function is utilized to calculate the interatomic forces and to describe the motion of an atomic or molecular system. However, it is still a challenging task to validate MD responses against the experimental data due to the spatial and temporal limitations in impact and/or shock tests. Therefore, this study mainly aims to conduct a series of impact simulations of porous solids by using the MPM and MD to understand the differences and similarities between these two spatial discretization approaches. Since both MD potential function and MPM constitutive modeling are well-formulated for metallic solids, we establish a computational model with 40 nm×40 nm×40 nm porous and non-porous gold cubic targets impacted by full density non-porous gold cubic flyers with an extreme high speed for the comparative study. The overall deformation patterns and particle-velocity histories are analyzed and illustrated with the use of the two particle methods. It appears that the MPM and MD can capture consistent physical responses, which shows the potential of using the MPM for multiscale simulations of extreme events with available verification and validation capabilities.

ABSTRACT

This study introduces a robust pipeline for converting medical images into computational domains, addressing a significant gap in the current integration of these images into computational simulation frameworks. Standard medical image formats, such as those from computed tomography (CT), are not inherently structured for direct application in computational simulations. Thus, preprocessing is essential to delineate shapes and interfaces within the Region Of Interest (ROI), enabling an accurate computational representation of the physical domain.

The proposed methodology is crucial in computational biomechanics, where medical images serve as a primary source for simulating various physical phenomena, providing the necessary geometric foundation. The transition from CT scans and similar modalities to operational computational domains is complex, especially with open-source tools.
Common commercial software, like Avizo from ThermoFisher Scientific, often involves subjective choices impacting the reliability of computational domains. Our methodology offers a systematic approach for the automatic preprocessing of structures and microstructures (from micro-CT), ensuring high-fidelity representations while maintaining resolutions compatible with the capabilities of contemporary computer simulation technologies in terms of memory and computational time.

To demonstrate the applicability of such a methodology, two example cases are considered : i) the analysis of a porous microstructure obtained from a human meniscus sample, and ii) the analysis of a multi-body system considering the digitization of a tumor embedded inside a human brain. In both cases, the entire computational process is considered, from the medical image to the simulation and post-processing of the results to verify the reliability of the computed discretized domains, either tetrahedral distributions for finite element (FEM) applications or point clouds representation for the discretization corrected particle strength exchange method (DC-PSE)

ADAPTIVE COUPLING OF BULK AND THIN FILM FLOW MODELS USING MESHFREE METHODS

Pratik Suchde[*1]*

[1]*University of Luxembourg*

ABSTRACT

Various thin film flow models have been proposed in literature to study the flow of fluids in thin layers. These models have been widely used when the thin fluid film is only object of interest. However, these models are not applicable when a bulk flowing fluid hits a curved surface and forms a thin layer of fluid over it. Such scenarios commonly occur, for example, in cleaning processes in the food industry. Simulations of such flow typically rely on bulk (3D) fluid models, with excessively fine resolutions in the thin flow regions, which make them prohibitively expensive.

In this talk, we present a novel adaptive fluid modelling framework to simulate coupled bulk-surface fluid flow. The proposed framework uses a traditional 3D Navier--Stokes model for bulk fluid flow, and switches to a pseudo 2D thin film flow model when appropriate. The bulk and thin film flow both involve free surfaces and can undergo significant deformations. Thus, the bulk fluid and thin film fluid layers are both modelled using meshfree methods. Thus, this forms a meshfree-meshfree coupling.

The framework proposed automatically identifies regions where the thin film model is applicable, and adaptively changes the fluid model used. In this talk, we will discuss how the models are coupled, and how mass conservation is ensured when switching between the two meshless models. Numerical results are verified against fine bulk simulations, and applications to cleaning simulations in the food industry, and automotive water crossing simulations are presented.

A STRUCTURAL TOPOLOGY OPTIMIZATION METHOD USING PHYSICS-INFORMED NEURAL NETWORKS BASED-ON KL EXPANSION

Koutarou Suetake[*1], Kazuhiro Izui[1], Kozo Furuta[1] and Shinji Nishiwaki[1]*

[1]*Kyoto University*

ABSTRACT

Topology optimization is a widely utilized method in engineering design for optimizing the material distribution within a given design domain to achieve optimal performance under specified constraints. In recent years, Physics-Informed Neural Networks (PINNs) have emerged as a noteworthy alternative to the Finite Element Analysis (FEA) conventionally employed in topology optimization. However, with the increase in the number of parameters in a neural network, there is a corresponding rise in computational requirements.
The approach of topology optimization using Karhunen-Loève (KL) expansion, as proposed by Y. Tsukuda, K. Furuta, K. Izui, S. Nishiwaki, and S. Watanabe [1], stands out for significantly reducing the number of parameters. This reduction serves to effectively mitigate the associated computational costs. This study proposes a novel approach to topology optimization integrating PINNs and KL expansion. The method comprises a neural network representing the displacement field and a neural network representing the density field. The displacement field is solved using a PINN introduced in [2], employing a Fourier Features neural network architecture with boundary conditions implemented as hard constraints. The neural network for the density field using KL expansion can learn weights by the loss gradient in the neural network for the displacement field. Applying KL expansion to the density field neural network has result in a substantial reduction in design variables has been achieved.

DIFFUSIVE-DISCRETE CRACK TRANSITION SCHEME REALIZED BY EXTENDED B-SPLINE-BASED IMPLICIT MATERIAL POINT METHOD

*Riichi Sugai**[1], Jike Han[1], Shuji Moriguchi[1] and Kenjiro Terada[1]*

[1]*Tohoku University*

ABSTRACT

A novel procedure is proposed to realize transition from a diffusive crack to discrete crack topology within the framework of the extended B-spline-based implicit material point method (EBSMPM) [1]. After the formulation is explained in detail, the specific manner of how the EBS basis functions are constructed is explained. At the end, several representative numerical examples, one of which includes a large rotation problem, are presented to demonstrate the performance of the proposed method.

The crack initiation and propagation are determined by the crack phase-field model, and the damage distribution is obtained as the diffusive crack that is continuously distributed in the body. Based on the damage distribution, we determine the location of the discrete crack surface and generate a new physical boundary to represent separation of the body. Specifically, on the basis of the idea that the damage gradients are supposed to be normal to the potential crack surface, the discrete crack surface is identified as the location where the damage gradients are inverted [2]. Once the location of the discrete crack surface is identified, the transition from the diffusive crack to discrete crack is performed by applying the extended B-spline (EBS) basis functions [3]. To date, in the mesh-based methods and even in the MPM, additional degrees of freedom (DOFs) and remeshing are required to represent the strong discontinuity. On the other hand, in the proposed transition scheme, the EBS basis functions are constructed so that the support domain of the basis function contains only a single physical domain separated by the discrete crack surface, which is the novel concept presented in our study. Thus, the proposed scheme does not need the additional DOFs and remeshing with reconfiguration of connectivity and reconstruction of tangent stiffness matrices.

CRACK PROPAGATION SIMULATION USING DAMAGE MODEL AND FINITE COVER METHOD

Hirofumi Sugiyama[*1] and Shigenobu Okazawa*[1]

[1]*University of Yamanashi*

ABSTRACT

In this work, we examined the crack propagation simulation using the finite cover method regardless of the mesh. The present method uses a damage model to estimate the initial crack and crack propagation. Recently, multi-material structures have been widely used in many engineering fields; thus, crack propagation simulation needs to estimate crossing different types of materials, such as steel and plastics. In particular, the adhesion area between different materials is important to predict the structural behavior that affects the accuracy of the products. In previous work, the authors have presented the crack propagation simulation using a damage model for ductile fracture. Ductile failure is one of the unsolved problems in computational mechanics. The continuum damage mechanics has been developed for predicting material behavior. These assume that the microscopic voids govern the ductile failures and that their mechanisms consist of a few major steps. In this work, we adopt this concept to deal with the crack propagation simulation for multi-materials. The so-called damage parameters are major state variables, and their evolution laws are the main interests in these mathematical models. However, these models can clearly describe the discontinuities because these modeling approaches treat the ductile fracture as a parameter, and the discontinuities describe immersed boundaries. On the other hand, we focus on the simulation methods. The conventional finite element simulation(FEM) is not good at handling the discontinuities, especially in crack propagation analysis because the FEM describes the discontinuities by themselves elements boundaries. Moreover, generalized finite element methods have been developed mainly in fracture mechanics. The extended finite element method(X-FEM) is well-known for simulating crack propagation, mainly in linear elastic bodies. This method can easily simulate the nucleation and growth of discontinuities (cracks) by the character of enhanced approximation function.
By contrast, the finite cover method(FCM)is also proposed as one of the generalized finite element methods. The FCM can describe the discontinuities by multiple covers, which is based on the concept of this method. Consequently, some numerical examples show that FCM with the damage model simulates the crack propagation for simple multi-material structures.

PRACTICALITY INVESTIGATION OF THREE-DIMENSIONAL LIMIT EQUILIBRIUM METHODS FOR WIDE-AREA LANDSLIDE PREDICTION

[2]*Hachinohe Institute of Technology*

ABSTRACT

For wide-area landslide risk assessment, numerous approaches have been proposed, but most rely on statistical or simple physics-based models. To elevate the landslide risk assessment with reasonable accuracy and reliability, the advanced physics-based models should be examined for practical applications.

This study investigates the performance and practicality of a variety of the 3D Limit Equilibrium Methods (LEMs) based models by comparing their results with actual landslide events. Specifically, the Hovland method [1], 3D simplified Bishop method [2], and 3D simplified Janbu method [2] are targeted. These methods compute normal and shear forces on soil column surfaces using local equilibrium equations, then integrate them into global equilibrium equations for moment, vertical force, or horizontal force equilibrium equations to determine the factor of safety.

To discuss the accuracy of each method, a comprehensive slope stability analysis targeting Marumori Town, Miyagi, Japan, where numerous slope failures resulted from heavy rainfall induced by Typhoon Hagibis in 2019, is conducted for the comparative study. Both the geological maps and borehole data repositories determine the soil parameters used in the analyses. Considering the landslides during intense rainfall are typically shallow, the slip surface depth is constrained between 0.5 to 5.0 meters in the iterative calculations.

Using a factor of safety threshold value of 1.0, the True Skill Statistics (TSS) revealed a tendency of the Hovland method to overestimate the hazardous areas relative to the other methods. In contrast, Area Under the Curve (AUC) results suggested a consistent level of accuracy across all methods when no specific threshold was imposed. In other words, the Hovland method can yield similar hazardous areas and TSS values to other methods by employing different factor of safety thresholds. Thus, while variations exist in the calculated factor of safety, it is confirmed that the Hovland method can produce results comparable to more advanced methods by adjusting the factor of safety threshold.

QUANTUM ANNEALING FOR STRUCTURAL DESIGN

Naruethep Sukulthanasorn[*1], Koya Wagatsuma[1], Xiao Junsen[1], Shuji Moriguchi[1] and Kenjiro Terada[1]*

[1]Tohoku University

ABSTRACT

Abstract
Solving optimization problems using quantum computing has recently received significant attention due to its advantages in quantum mechanics and the extensive development of quantum machines. One promising algorithm is known as quantum annealing [1], building upon the simulated annealing algorithm used in classical computers. However, quantum annealing exploits the quantum tunneling effect to accelerate the search for the optimal solution, enabling it to outperform in various aspects, especially in the speed of searching for the solution [1, 2]. To date, quantum annealing has been applied in various applications, demonstrating its robust performance [3]. However, based on existing literature, only a few studies have investigated the use of quantum annealing for structural optimization. In fact, a unified structural design framework using quantum annealing, applicable to both truss and continuum structures, has yet to be developed.

In this study, a structural design framework has been developed from the perspective of using quantum annealing as one of the heuristic optimizers. A hybrid approach is adopted, utilizing a classical computer for structural analysis and quantum annealing for topology updating as gradient-free topology optimization. The minimization of the compliance problem with a volume constraint is selected as the objective function and then transformed into a quadratic unconstrained binary optimization (QUBO) format, incorporating the penalty method and slack variable for the constraint. In addition, the encoding process for the design variable is implemented and then updated in each design iteration. To demonstrate its performance, the developed method is applied to the design of both truss and continuum structures. The results indicate that the proposed framework demonstrates promising performance in converging to an optimal topology.

SOLVING PARTIAL DIFFERENTIAL EQUATIONS WITH PHYSICS-INFORMED NEURAL NETWORKS BASED ON A DUAL VARIATIONAL PRINCIPLE

N. Sukumar[1] and Amit Acharya*[2]

[1]*University of California, Davis*
[2]*Carnegie Mellon University*

ABSTRACT

In recent work [1], an approach to devise a variational principle for linear and nonlinear PDEs such as Navier--Stokes equations, nonlinear elasticity, and time-dependent heat equation was proposed. In [1], the essential idea is to treat the primal PDE as a constraint and to invoke an arbitrarily chosen (lends flexibility) auxiliary potential with strong convexity properties to be optimized. This leads to requiring a convex dual functional to be minimized subject to Dirichlet boundary conditions on dual variables, with the guarantee that even PDEs that do not possess a variational structure (in primal form) can be solved via a variational principle.

In this presentation, we explore a new route to solve PDEs that require the imposition of Dirichlet and/or Neumann conditions in physics-informed neural networks (PINNs) [2]. To this end, we adopt ideas from [1] to tackle linear and nonlinear problems using PINNs. In standard PINNs [2], different terms that meet boundary conditions have to be weighted as loss terms in the objective function, which adversely affects training of deep neural networks and the accuracy that it can deliver. Improvements such as using approximate distance fields to impose Dirichlet boundary conditions have been proposed [3], but further advances are needed. Herein, we leverage the dual variational principle, which provides greater flexibility---since the Dirichlet boundary conditions on dual variables can be arbitrarily chosen. The parametric dependence of the dual solution on the choice of Dirichlet boundary conditions (and the auxiliary potential) appears to offer practical advantages in training and optimization of neural networks, and the fact that the dual-to-primal map always yields the unique primal solution, when such uniqueness is a property of the primal problem. To illustrate this new approach, we assess the use of the dual variational principle on several boundary-value problems in heat conduction and solid mechanics, and compare its performance to standard PINNs.

QUANTUM SOLVER OF STOCHASTIC DIFFERENTIAL EQUATIONS

Jinhwan Sul[1] and Yan Wang*[1]

[1]*Georgia Institute of Technology*

ABSTRACT

Stochastic differential equations (SDEs) model the random behaviors of systems and can be applied in various fields such as natural sciences, engineering, and finances. In many cases, SDEs do not have analytical solutions, and the numerical solving process requires exhaustive Monte Carlo sampling, which is computationally expensive. Recently, quantum computing arises as a new paradigm for scientific computing [1,2]. In this work, we propose a new approach to simulate the stochastic dynamics of SDEs on quantum computers. The stochastic behavior is embedded into quantum states. Probability distributions are encoded with computational basis. The proposed approach is demonstrated with several SDE examples. To verify the accuracy, the simulated results are compared with the classical Monte Carlo simulation. The statistical moments are compared quantitatively.

[5]*Rensselaer Polytechnic Institute*

ABSTRACT

We provide an overview and describe progress for the MPAS-SI-MPM project [https://mpas-si-mpm.unm.edu]. The purpose of MPAS-SI-MPM is to enhance the representation of sea-ice mechanics in DOE's Energy Exascale Earth System Model (E3SM) using an elastic-decohesive constitutive model for the ice. The ultimate goal is improving coupled climate simulations and predictions. The more descriptive physics contained in the constitutive model provides a mechanism to model leads explicitly, and to account for frazil ice and dense water formation in leads, for example. The improved representation is expected to generate more realistic coupling fluxes to the atmosphere and ocean.

The model is implemented using the material-point method (MPM). MPM provides a Lagrangian representation of sea ice which allows transport of state variables and tracers without numerical diffusion, as well as history along trajectories for constitutive models. Platform portable GPU acceleration is achieved through the polyMPO library which supports material point operations on spherical centroidal Voronoi tessellation/unstructured meshes and is built using the Kokkos library and the PUMIPic library from the SciDAC FASTMath Institute. To assess model performance, techniques for parameter calibration and model validation (especially for leads) are being developed. These techniques depend on new metrics for analyzing spatiotemporal data with discontinuities, and/or lower dimensional features.

SELF-STABILIZED 3D VIRTUAL ELEMENTS FOR LINEAR ELASTOSTATICS: HU-WASHIZU VARIATIONAL FORMULATION FOR POLYHEDRA WITH LINEAR TRIANGULAR FACES

ABSTRACT

Abstract
The traditional finite element method (FEM) is severely limited by the quality of the elements and highly distorted or concave elements are not allowed. The Virtual Element Method (VEM), originally proposed by Beirão da Veiga et al. [1], can be viewed as a development of the traditional FEM. The VEM does not require isoparametric mapping and does not exhibit distortion sensitivity, so it is very flexible and versatile, allowing for arbitrary polyhedral meshes, not necessarily convex. However, the stiffness matrix of the virtual element requires stabilization in most cases [2], which is one of the main limitations of the VEM. This paper proposes a new type of 3D self-stabilized virtual elements, without needing a stabilization process, based on a Hu-Washizu variational approach for 3D linear elastostatics [3]. Since the external surface of this new 3D element is composed of an arbitrary number of triangles looking like the capital Delta (Δ), we named it Deltahedron element. The advantage of triangles over faces of arbitrary polygonal shapes is that the displacement model on a triangular face is completely defined by nodal values. The numerical tests conducted on these Deltahedral elements, including non-convex shapes, showed good accuracy and the expected convergence rate. Deltahedral virtual elements can be effectively used to discretize 3D structures, including those with curved surfaces.

HYDRAULIC FRACTURE SIMULATION OF MESO-CONCRETE USING THE SBFEM-FVM MODEL

Liguo Sun[*1], Chengbin Du[1] and Shouyan Jiang[1]*

[1]*Hohai University*

ABSTRACT

This paper explores the simulation of the coupled interaction between mesoscale crack water pressure and the process of mesoscopic crack initiation and propagation in concrete, treating it as a three-phase material consisting of aggregates, mortar, and interfaces. A hybrid approach, combining the scaled boundary finite element method (SBFEM) and finite volume method (FVM), is employed at the microscale to model the interplay between crack water pressure and mesoscopic crack evolution. The cohesive crack model is applied to analyze the non-linear fracture transition zone. When multiphase materials are present within the crack tip element, the crack propagation direction is determined by generalized stress intensity factors and the fracture toughness of each phase material. Comparisons of numerical results with experimental data reveal a close correspondence between F-CMOD curves and water pressure variations under different loading conditions. The impact of crack water pressure on the mesoscopic concrete crack propagation direction is emphasized. This coupled model provides valuable insights into the interrelation of mesoscale phenomena and macroscopic behavior in brittle concrete materials. The findings contribute to an enhanced understanding of fracture processes in concrete structures, particularly under varying environmental and loading conditions.

A MPM LAGRANGIAN-EULERIAN HYDROCODE FOR SIMULATING BURIED EXPLOSIONS IN TRANSVERSELY ISOTROPIC GEOMATERIALS

Mian Xiao[1] and WaiChing Sun[1]*

[1]Columbia University

ABSTRACT

Shock waves in geological materials are characterized by a sudden release of rapidly expanding gas, liquid, and solid particles. These shock waves may occur due to explosive volcanic eruptions or be artificially triggered. In fact, underground explosions have often been used as an engineering solution for large-scale excavation, stimulating oil and gas recovery, creating cavities for underground waste storage, and even extinguishing gas field fires. As such, hydrocodes capable of simulating the rapid and significant deformation under extreme conditions can be a valuable tool for ensuring the safety of the explosions. Nevertheless, as most of the hydrocodes are often formulated in an Eulerian grid, this setting makes it non-trivial to track the deformation configuration of the materials without a level set. The objective of this presentation is to propose the use of the material point method equipped with appropriate equation of state (EOS) models as a hydrocode suitable to simulate underground explosions of transverse isotropic geomaterials. To capture the anisotropic effect of the common layered soil deposits, we introduce a new MPM hydrocode where an anisotropic version of the Mie-Gruneisen EOS is coupled with a frictional Drucker-Prager plasticity model to replicate the high-strain-rate constitutive responses of soil. By leveraging the Lagrangian nature of material points to capture the historical dependence and the Eulerian calculation of internal force, the resultant model is capable of simulating the rapid evolution of geometry of the soil as well as the high-strain-rate soil mechanics of anisotropic materials.

SUPERPOSITION-BASED CONCURRENT MULTISCALE APPROACHES FOR PORODYNAMICS

Wei Sun[*1]

[1]*Sun Yat-sen University*

ABSTRACT

Superposition-based concurrent multiscale approaches for porodynamics problems aimed at resolving localized fluid flow and deformation of a solid skeleton including its possible fracture or strain localization are developed. The main departure of the proposed formulation is that the primary unknowns in the coupling zone, the solid displacement u and pore pressure p, are discretized by possibly different numerical models. Two discretization schemes are studied: (i) superposition of two or more finite element (FE) discretizations of the Biot's u-p model of a porous medium, and (ii) superposition of the peridynamics (PD) discretization of the fractured solid phase on the FE discretization of the Biot's u-p model of a porous medium. In the latter case, the total stress of the fluid–solid mixture in the coupling domain is derived from the effective stress obtained from the combined PD and finite element method solutions while the pore pressure is obtained from the FE solution. The accuracy of the superposition-based concurrent multiscale method is studied on several benchmark problems including the classical Terzaghi's one-dimensional dynamic consolidation problem, the two-dimensional strip footing dynamic problem, the sand liquefaction induced strain localization and the fluid-driven fracture propagation problem in saturated porous media. The main strain localization phenonmenon and hydraulic fracture characteristics have been found to be reasonably well reproduced by the proposed method.

SEISMIC DAMAGE ANALYSIS OF UNDERGROUND FRAME STRUCTURES WITH PERIDYNAMICS

Wei Sun[*1]

[1]*Sun Yat-sen University*

ABSTRACT

Strong earthquake poses a significant threat to the structural integrity of underground frame structures. This paper presents an innovative seismic damage analysis method for underground frame structures based on superposition-based coupling of Peridynamics (PD) and Finite Element Method (FEM). In the numerical model, peridynamics (PD) is employed to simulate underground structures, effectively capturing the initiation and propagation of cracks within the structures, while the surrounding soil is simulated using FEM. The efficacy of the proposed numerical methods is assessed through comparison with dynamic centrifuge tests. The nonlinear collapse and failure mechanism of the Daikai Subway station during the 1995 Kobe earthquake are elucidated. Numerical results demonstrate that this approach facilitates the replication of damage patterns in underground frame structures subjected to seismic effects, with an explicit representation of cracks. A parametric study is conducted to explore the influence of key factors on the damage patterns of underground frame structures.

MODELING AND SIMULATION OF HYDROGEN-DEFECT INTERACTIONS IN NANOSTRUCTURED METALLIC MATERIALS ACROSS MULTIPLE TIME SCALES

Xingsheng Sun[*1]*

[1]*University of Kentucky*

ABSTRACT

Hydrogen (H), the lightest and most abundant element in the universe, plays a pivotal role in shaping the future landscape of energy and sustainability. Its significance lies in its extraordinary versatility as an energy carrier, capable of efficiently storing and transporting energy derived from diverse sources. However, as H-based energy systems become more prevalent, material challenges associated with H detection, storage, and transport remain a bottleneck to be addressed. For example, crystalline defects such as dislocations and grain boundaries are commonly found in metallic materials. Therefore, the interactions between H atoms and lattice defects are of paramount importance, as they profoundly influence the mechanical, electrical, and chemical properties of materials. In this talk, we will employ two numerical methods to unravel H-defect interactions in nanostructured metals across multiple time scales. The first method, referred to as Diffusive Molecular Dynamics (DMD), focuses on capturing hydride phase transformation and the evolution of H-induced lattice defects over a diffusive time scale. The second method, Molecular Dynamics (MD), provides more detailed insights into atomic movements and lattice relaxation over the time scale of thermal vibrations. These two methods are connected with MD simulations initialized using statistical measures of microscopic variables obtained from DMD at different H concentrations. Our focus will be on the palladium-hydrogen (Pd-H) systems. Our study demonstrates that DMD can effectively capture the H diffusion mechanisms over an extended time scale as well as the dynamics of solute-induced misfit dislocations and stacking faults. While the H-concentrated phase leads to a reduction in the vibrational energy, the presence of stacking faults locally increases the vibrational energy of both Pd and H atoms. Furthermore, the MD simulation results align with DMD in terms of equilibrium potential energy, the preservation of hydride phase boundary, and the spatial distribution of stacking faults. We thoroughly characterize the lattice crystalline structures in four key regions of the particle. We observe a preference for H atoms to occupy tetrahedral interstitial sites near stacking faults due to the lower stacking fault energies provided by these sites within the H-concentrated phase.

PORE EFFECTS ON THE PROPERTIES OF TRIPLY PERIODIC MINIMAL SURFACE BONE SCAFFOLDS

Yadi Sun[*1], Jianxiong Ma[1], Xinlong Ma[1] and Yan Wang[1]*

[1]*Tianjin University (Tianjin Hospital)*

ABSTRACT

As an important strategy in the field of bone tissue engineering to deal with necrosis of the femoral head, the triply periodic minimal surface bone scaffold has become a promising candidate for bone repair due to its excellent structural properties, including excellent mechanical properties, biocompatibility, and promotion of tissue regeneration. A strong candidate that has received much attention in the field. In this context, the pore structure plays a crucial role in the construction of triply periodic minimal surface bone scaffolds. How to properly select and regulate the properties of triply periodic minimal surface bone scaffolds to make them compatible with the repair of the target bone area The matching of requirements has become a problem that needs to be solved urgently. The purpose of this review is to summarize the significant impact of pore structure on the properties of triply periodic minimal surface bone scaffolds, and to provide guidance and inspiration for the development and manufacture of such bone scaffolds. In the process, the effects of factors such as pore shape, porosity, pore size, curvature, and specific surface area on the properties of triply periodic minimal surface bone scaffolds were briefly outlined and discussed, in order to provide useful reference for future research and practice.

TRANSLATING BIOLOGY TO ENGINEERING THROUGH MULTIPHYSICS COMPUTATIONAL MECHANICS

Adamya Singh Dhaker[1], Yuchen Sun[1], Francesco Regazzoni[2], Luca Dede'[2], Cecilia Laschi[1] and Gianmarco Mengaldo[1]*

[1]National University of Singapore
[2]Politecnico di Milano

ABSTRACT

Life's key to survive in nature is the smart adaptation to its complex surrounding environments. Cephalopods muscular hydrostats, which consist only of muscle tissues and preserve volume during deformation, are a well-known example of biological entities which exhibit infinite degree-of-freedom motion and manipulation to perform complex environment-oriented tasks. One such muscular hydrostat of interest is the octopus arm, which has exceptional flexibility and dexterity to achieve complex motion. Several experimental studies from a biological and neuromuscular control perspective, as well as soft-bodied robotics perspective have been conducted to understand and exploit octopus morphology, which lacks a rigid skeleton, for a multitude of engineering applications. However, there are very few computational simulation frameworks which accurately model and capture the precise activation sequences and resultant motion in octopus arms. Here, we present a high-fidelity, 3-D computational model of octopus arm biomechanics, replete with muscular fiber arrangements and muscle activation strategies which mirror those of a biological counterpart (Octopus vulgaris). An octopus arm geometry is modelled in the multiphysics solver life-x, with a
biologically similar implementation of longitudinal and transversal muscle fibers. The material properties of the arm follow the Neo-Hookean constitutive law, with an isovolumetric constraint applied to the geometry and Dirichlet, Robin and Neumann boundary conditions at the base, curved surface and tip respectively to mimic a fixed arm immersed in a fluid environment. Three primary movements shown by octopus arms are elongation or shortening, bending and reaching. All three movements are elicited through different activation profiles on the same muscle fiber segments by applying stresses which follow the sequential nature of muscle activation found in real octopus. The most characteristic octopus arm motion is the reaching motion, which involves the propagation of a bend from the base to the tip in order for the octopus to grasp an object. Our model is able to mimic and capture the biomechanics of the reaching motion with significant accuracy. The analysis shows that the simulated bend follows the same fundamental kinematic profiles for displacement and bendpoint tangential velocity, which are invariant across specimen, as physical experiments. The simulation framework provides a biologically accurate platform for creating digital twins of biological entities, which can be leveraged to extract valuable physics as a benchmark to the field of modeling and fabrication in soft robotics community.

IMAGE-BASED VASCULAR FLUID-STRUCTURE INTERACTION WITH ANISOTROPIC FIBER-REINFORCED ARTERIAL WALL MODELS

Yujie Sun[*1], Ju Liu[1], Jiayi Huang[1], Qingshuang Lu[1], Xinhai Yue[1] and Xuanming Huang[1]*

[1]*Southern University of Science and Technology*

ABSTRACT

In this study, we present a computational framework for vascular fluid-structure interaction (FSI), which enables image-based geometric modeling for anisotropic arterial walls. This framework employs the unified continuum formulation for monolithic FSI coupling [1]. In particular, the variational multiscale formulation is invoked to handle the incompressibility constraint. The arterial walls are constructed using segmentation techniques as well as physiological knowledge of the arterial wall thickness. The modeling of the multi-layer arterial walls can be conveniently realized through the same vein. The Holzapfel-Gasser-Ogden (HGO) constitutive material model is employed here for the arterial walls. This material model features the exponential form of the strain energy and takes fiber dispersion into account. It characterizes the mechanical behavior of vascular tissues to high accuracy. Furthermore, we also develop a technology for fiber direction definition of the arterial wall model. It leverages the vascular centerline to define the local basis, which can be conveniently utilized to determine fiber direction at each quadrature point.

The developed fiber generation method is evaluated by comparing with a strategy from a previous study [2]. It is shown that our approach yields satisfactory fiber definitions in patient-specific models. Additionally, through two numerical examples, we investigate the impact of anisotropic arterial wall models on the vascular FSI. The first case involves a simulation of an idealized curved geometry, and the second case investigates an image-based abdominal aorta model. The numerical results reveal that under physiologically realistic conditions, the transmural stress distribution within anisotropic arterial walls is significantly different from that of isotropic models. Lastly, we consider a two-layer model for the abdominal aorta, and each layer is treated as the HGO model with different fiber orientations and material parameters. Compared to the single-layer model, significant differences are again observed in a variety of biomechanical quantities of interest. Our work suggests that the arterial wall model has a non-negligible impact on the computational modeling of vascular problems.

A NONLOCAL MANIFOLD FRACTURE MODEL FOR MULTIFIELD-DISCOTINUOUS PROBLEMS IN GEOMECHANICS

Yuqi Sun[1] and HaiTao Yu*[1]

[1]*Tongji University*

ABSTRACT

Multifield-discontinuous problems play a pivotal role in geomechanics, where understanding and predicting crack propagation in geomaterials under multiphysical fields, such as fluid flow and heat transfer, is essential for practical guidance. This study focuses on the development of a novel nonlocal model that quantitatively describes the continuous-discontinuous deformation of geomaterials and its interaction with fluid and heat fields in a unified and objectively geometric manner.

Our model involves the formulation of nonlocal momentum balance laws for a continuum manifold. The resulting governing equations are established within the fiber bundles of the continuum manifold, emphasizing the intrinsic geometric characteristics of discontinuous deformation. This geometric approach renders the model suitable for constructing nonlocal transport equations for fluid and heat when voids and cracks appear in geomaterials.

Theoretical and computational results demonstrate that our proposed model is asymptotically compatible with classical continuum mechanics as the characteristic length of the nonlocal interaction domain approaches zero. This study underscores the significance of nonlocal and geometric characteristics in describing the balance laws of discontinuous deformation in geomaterials involving multifields. Our findings are validated through comparisons with experimental data and existing theoretical models, showcasing the accuracy and applicability of the proposed model.

This study significantly contributes to the comprehension of continuous-discontinuous deformation in geomaterials under multiphysical fields. The insights gained can provide valuable guidance for optimizing productivity in real-world applications.

OPTIMIZATION METHOD OF FIBER REINFORCED PLASTIC (FRP) COMPOSITE STRUCTURES

Zhi Sun[*1] and Xu Guo*[1]

[1]*Dalian University of Technology*

ABSTRACT

Fiber reinforced plastic (FRP) composite structures are made from fiber fabrics or tapes. Tape-laying and overwrapping process, by which the fiber angle and thickness would change with the radius of structure, are two common manufacturing methods for the FRP composite structures. Therefore, the curvature radius and geometry are coupled with fiber plying parameters during the optimized design of the FRP composite structures. In this study, Moving Morphable Components (MMC) method, which is able to explicitly describe the geometry of structures, is used to perform topology optimization for FRP composite sandwich and stiffiened structures. The FRP composite structures are considered to be manufactured based on geodesic winding, with fiber plying angle and thickness calculated according to the curvature radius of each beam. The stiffness and deformation of FRP composite structures are then analyzed by Finite Element Method. The numerical and experimental results indicate the validity of the proposed optimization method.

PARTICLE DYNAMICS IN A LOW-REYNOLDS-NUMBER FLUID BETWEEN TWO SPHERICAL SHELLS

Zhuang Sun[*1]*

[1]*Chinese Academy of Sciences*

ABSTRACT

Dynamics of a particle and the suspending low-Reynolds-number fluid confined between two spherical shells were studied numerically. We calculated the particle's hydrodynamic mobilities at various locations in the confined space. The mobility is largest near the middle of confined space along radial direction and decays as the particle becomes closer to no-slip walls. Fluid vortices in the confined space induced by the particle motion were observed and analyzed. We also found that the particle can exhibit a drift motion perpendicular to the external force. Magnitude of the drift velocity normalized by the velocity along the direction of the external force depends on particle location and particle-to-cavity sizes ratio. This work forms the basis to understand more complex dynamics in microfluidic applications such as intracellular transport and encapsulation technologies.

AN IMMERSED BOUNDARY MMALE PARTICLE METHOD FOR EFFICIENT MODELING FSI PROBLEMS WITH STRUCTURAL DAMAGE

Zixian Sun[*1] and Xiong Zhang*[1]

[1]*Tsinghua University*

ABSTRACT

Fluid-structure-interaction (FSI) phenomena with multi-phase flow dynamics and structural damage commonly exist in engineering practice, which however bring great challenges to nowadays numerical FSI algorithms. A novel localized subdomain smoothing MMALE particle method (ls-ALEPM) is proposed in this paper for efficient and accurate simulations of large scale FSI problems. The MMALE method and the MPM are strongly coupled by immersing the MPM particles into the MMALE grid. In order to avoid the spurious strain induced by the mixed FSI velocity field, a decoupled stress updating scheme is proposed to update the stress of solid particles by introducing a virtual velocity field in the vicinity of FSI interface. And specifically, the highly accurate polyhedron intersection based method is employed for its remapping phase, which however is time-consuming. Thus, the localized subdomain smoothing method (LSSM) is put forward to accelerate the remapping phase which only involves the distorted regions of computational grid. The LSSM is composed of a distorted subdomain determination step and a combinated mesh smoothing step. Each iteration of the combinated mesh smoothing step consists of the modified GETMe and the weighted average method, and the transfinite interpolation method is adopted if the quality criteria is still not satisfied after prescribed maximum number of iterations. The validity and efficiency of ls-ALEPM is verified by several benchmark numerical examples and practical engineering simulations.

TACKLING TEMPORAL DOMAIN COMPLEXITY TO EFFECTIVELY TRAIN PINNS FOR UNSTEADY FLOWS PAST MOVING BODIES

Rahul Sundar[*1], Didier Lucor[2] and Sunetra Sarkar[1]*

[1]*Indian Institute of Technology Madras*
[2]*Université Paris-Saclay, CNRS*

ABSTRACT

Physics-informed neural networks are a class of neural networks that embed physics-based constraints into the loss function, proving viable for solving inverse problems when data is limited. Recently, for unsteady flows past moving bodies, motivated by the benefits of PINNs and the immersed boundary method, an immersed boundary-aware (IBA) surrogate modeling framework has been proposed[1]. This framework removes the limitations of case-specific computational domain transformations to the body-attached frame of reference. Under this framework, two variants of PINN models have been proposed, one suitable for scenarios where body position and velocity are known apriori and another for scenarios where those need to be estimated along with the flow-field variables.

In either setting, one might encounter temporal domain complexities in terms of temporal sparsity, a large temporal domain, or rich spectral content in the flow field data. The present study explores temporal domain decomposition strategies[2] to tackle such scenarios. Assuming the body position and velocity are known, the moving boundary-enabled PINN (MB-PINN) variant under the IBA framework is chosen for velocity flow-field reconstruction and pressure recovery. Specifically, the sequential and backward-compatible extensions of MB-PINN are explored for temporal domain decomposition. Flow past a plunging elliptic airfoil at a low Reynolds number is considered an example.

For a periodic flow case, when velocity data snapshots are temporally sparse, a backward-compatible version performs better than standard MB-PINN in both pressure recovery and velocity reconstruction. Moreover, this version only requires a single network at inference. However, in the case of a large time domain, where, breaking the temporal domain into relatively smaller segments is necessary to reduce problem complexity, having multiple small sub-networks is beneficial to avoid training large networks. Currently, it is also being investigated if these sequential training methods are beneficial when the flow-field data has richer spectral content in the temporal domain as in the case of flow-field aperiodicity.

A COMPARATIVE STUDY OF DIFFUSION-BASED AND RATE-FORM MODELS IN BONE REMODELLING

Prudhvi Sunil[1] and Ravi Sastri Ayyagari*[1]

[1]*Indian Institute of Technology Gandhinagar*

ABSTRACT

Dynamic evolution of cells, viz. osteoclasts and osteoblasts, is pivotal to bone remodelling. The present study comprehensively compares diffusion-based models and phenomenological rate forms that predict the dynamic evolution of osteoblasts and osteoclasts. Primarily, our work focuses on the influence of messenger substances with the aim of decrypting the intricate mechanisms governing the evolution of these cells, shedding light on dominant timescales affecting their progression. Diffusion-based models in our study account for the complex inter-connected processes governing remodelling and include a) osteocyte evolution mediated by flexoelectric signalling [1] as opposed to models depending on mechanical stimuli [2], b) coupled diffusion equations with cell evolution dependent on messenger substance evolution unlike other works in literature, c) accounting for anisotropic diffusivity under thermodynamic constraints, and d) accommodating osteocyte apoptosis, a critical precursor to osteoclast and osteoblast evolution [3]. We demonstrate the numerical implementation of diffusion-based and phenomenological models within the Finite Element framework and highlight the advantages of coupled diffusion-based approaches. In addition, we also validate the coupled diffusion-based models with clinical data to emphasise the sensitivity of various parameters to cellular mechanotransduction and anisotropic growth.

DESIGNING ARCHITECTED MATERIALS USING NEURAL NETWORKS

Krishnan Suresh[*1] and Akshay Kumar*[1]

[1]*University of Wisconsin, Madison*

ABSTRACT

Design of architected materials, i.e., microstructural optimization, is a special case of topology optimization where the objective is to find the optimal distribution of material within a representative unit cell, to result in a desired homogenized behavior. A popular strategy for designing architected materials, i.e., microstructures, is the density field method where a pseudo-density field is defined and optimized over an underlying mesh to achieve a desired objective. Typically, the density field is represented using an underlying finite element mesh.

In this talk, we propose a neural network (NN) framework where the density field is represented using the NN's activation functions, weights, and biases. The decoupling (1) avoids manual sensitivity analysis derivation through automatic differentiation, (2) prevents checkerboard patterns without additional filters, (3) supports recovery of high-resolution microstructural topology via a simple post-processing step, and (4) supports easy extension to multiple materials.

In the proposed framework, any of the microstructural quantities, namely, bulk, shear, Poisson ratio, or volume, can serve as the objective, while the remaining can be subject to constraints. The framework is illustrated through a variety of microstructural optimization problems.

AN IMPROVED BOX ALGORITHM FOR SOLVING LINEAR SYSTEMS OF EQUATIONS ON QUANTUM-ANNEALING MACHINES

Sanjay Suresh[1] and Krishnan Suresh*[1]

[1]*University of Wisconsin, Madison*

ABSTRACT

A typical strategy for solving linear systems of equations on quantum annealing machines is to pose them as quadratic unconstrained binary optimization (QUBO) problems. The underlying principle is to represent the unknowns (i.e., real numbers) in a radix-2 qubit form and iteratively converge to the desired solution by minimizing the underlying potential energy. The box algorithm [1] is a robust iterative implementation of this strategy.

However, the box algorithm suffers from two main problems. Firstly, it faces convergence issues when the potential energy is relatively flat. Secondly, it fails to recycle the computed solution in successive iterations.

In this talk, we will present an improved box algorithm that addresses both these deficiencies. This is illustrated through several numerical experiments. We then apply the improved box algorithm to compute sparse approximate preconditioners for large matrices, arising from partial differential equations [2].

[1]*University of Tennessee, Knoxville*
[2]*University of Wisconsin-Madison*

ABSTRACT

The demand for poroelastic soft materials in biomedical and engineering applications is increasing exponentially due to their remarkable resemblance to biological soft tissues and unique mechanical properties. The study of mechanical responses of poroelastic soft material under contact scenarios is one of the active areas of research which is essential for reliable performance of the parts made with these materials. The characteristics of poroelastic multiphasic soft swollen materials rely on the behavior of the solid matrix and the interstitial fluid. Soft multiphasic materials undergo large deformations and exhibit mechanical response that is both dependent on the rate of deformation and characterized by nonlinearity. However, the existing computational models often overlook the influence of adhesion in the contact formulation, neglecting its significance in representing real-world scenarios. The purpose of this study is to bridge this gap by incorporating the rate-dependent adhesion effects for poroelastic material contact into an open-source nonlinear finite element analysis code FEBio.

Indentation is a commonly used technique to identify the dependency of contact phenomenon on a broad range of loading and unloading rate, relaxation time, and coupling of adhesion and friction. The main obstacle of contact formulations is to precisely determine the active contact zone within the interface by solving a constrained optimization problem with an appropriate set of Karush-Kuhn-Tucker (KKT) conditions. This research aims to explore the mechanics of rate-dependent adhesion and the associated suction effect within a poroelastic contact model. Our primary objective is the modification of the FEBio source code to incorporate effective traction-based contact formulation with nuanced intricacies of adhesion at interface. In addition, the comprehensive capture of rate-dependent adhesion characteristics is focused on the identification of the active contact zone through the KKT condition. The simulation results following the compilation of the modified source code are validated against experimental results. The adaptation of the FEBio source code to include a rate-dependent adhesion, coupled with the precise determination of the active contact zone through the KKT condition, not only sets out to enrich our understanding of material behavior but also improves the capabilities of computational tools towards more authentic simulations of intricate biological interactions.

ABSTRACT

Integration of numerically stiff chemical reaction systems is a challenging problem that can significantly restrict the temporal scale of achievable Computational Fluid Dynamics (CFD) simulations of chemically reacting flows. Sufficiently resolved integration of stiff chemical systems reduces the allowable timestep of a CFD simulation such that even massive parallelization of the spatial domain cannot enable tractable simulations as the temporal evolution is not as efficiently aided by distributed domain parallelization. Other mitigation strategies like using unconditionally stable solvers for the chemical systems, tabulation procedures, or reduced-order kinetics models have been used successfully, but each approach manifests different inaccuracies that affects CFD simulation credibility. We present recent work of applying Deep Operator Networks (DeepONet) with an Autoencoder-Decoder framework to learn the temporal evolution of stiff chemical systems within the context of a CFD simulation. The purpose is to investigate an alternative approach to conventional mitigation methods employed by CFD practitioners. Recently published results [1] have demonstrated that an autoencoder-based DeepONet can predict temporal evolution of a stiff ordinary differential equation system with acceptable accuracy while relegating the costly temporal integration to offline training. This is particularly suitable for CFD simulations because a single learned model with more complex chemical kinetics can support many simulations without as much cost for in-situ chemical source term evaluation, and with improved chemical species evolution. The presented method does not address sub-grid scale localization of reactions, nor turbulent mixing; therefore, error is invariably introduced during the presented DeepONet approach. The motivation of this presented work is to investigate whether the access to greater temporal range and more complex reaction mechanisms is advantageous for select applications relative to the impact of incurred error.

ABSTRACT

Energy storage materials exhibit strong electro-chemo-mechanical coupling and highly anisotropic material properties, contributing to the formation and propagation of micro-cracking during charge/discharge cycling and resulting in reduced performance and service life. A coupled electro-chemo-mechanical reproducing kernel particle method (RKPM) formulation has been developed to analyze this system. With microstructural images supplied by the National Renewable Energy Laboratory (NREL), pixel-based model construction by RKPM is used to represent the complex material microstructures that dictate the coupled physics of these systems. Traditional electro-chemo-mechanical models rely on mesh-based finite element methods, which can lead to difficulties in meshing such complex geometries and capturing crack propagation due to mesh dependency. Here, a neural network-enhanced reproducing kernel particle method (NN-RKPM) [1, 2] is introduced to effectively model damage and crack propagation in the material microstructures; the location, orientation, and solution transition near a localization are automatically captured by superimposed block-level NN optimizations. This NN enrichment approach allows for effective modeling of localizations via a fixed background discretization, relieving tedious efforts for adaptive refinement in traditional mesh-based methods. Applications to the heterogeneous microstructures of Li-ion battery cathodes will be presented to demonstrate the effectiveness of the proposed methods. NN-RKPM is additionally used to inform how crack opening and closure in turn affect the coupled chemical equations and material microstructure.

FRACTURE SIMULATION OF FEMTOSECOND LASER-INDUCED DAMAGE IN MULTI-LAYER DIELECTRIC COATINGS

Fariha Haque[1], Tareq Zobaer[1] and Alok Sutradhar[1]*

[1]The Ohio State University

ABSTRACT

We present a dynamic fracture simulation to study the femtosecond laser-induced damage in multi-layer optical coatings. We modeled the formation and propagation of cracks in an expanded hafnia layer in a blister created through laser-induced damage using finite element analysis. The extended finite element method (XFEM) is used to simulate the propagating crack. We validate our mechanical modeling and crack propagation with experimental results supported by X-TEM measurements.

EVALUATION OF MECHANICAL PROPERTIES OF THREE-DIMENSIONAL POLYCRYSTALLINE MICROSTRUCTURES OF DUAL-PHASE STEEL USING MACHINE LEARNING MODEL BASED ON PHASE-FIELD METHOD AND CRYSTAL PLASTICITY FINITE ELEMENT METHOD

Misato Suzuki[*1], Kazuyuki Shizawa[1] and Mayu Muramatsu[1]*

[1]*Keio University*

ABSTRACT

In this study, mechanical properties of three-dimensional polycrystalline microstructures of dual-phase (DP) steel are evaluated using a machine learning model. DP steel is composed of a soft phase (ferrite) and a hard phase (martensite). The mechanical properties of DP steel depend on the spatial distribution of martensite, which contributes to strength, and ferrite, which contributes to ductility.

In the material development of DP steel, there is a need to improve the trade-off relationship between strength and ductility. However, material development requires repeated experiments through trial and error. To reduce experimental costs, numerical simulations are used. The crystal plasticity finite element method (CPFEM) is used to take the effect of crystal orientation and grains size into account. However, CPFEM is computationally expensive, especially in three-dimensional analysis. Therefore, convolutional neural network (CNN) is utilized to replace CPFEM in this study.
Microstructures of DP steel are generated in two steps in this study. For the first step, polycrystalline microstructures are generated using the multi-phase-field method. The multi-phase-field method predicts whether each grid point is within a crystal grain or grain boundary. Next, the results of the multi-phase-field method are used as initial states of the phase-field method that predicts martensitic transformation. By extracting the results before martensitic transformation has fully developed, microstructures with various volume fraction of martensite can be obtained.
CPFEM is used to evaluate the mechanical properties. Using CPFEM, the stress-strain relationship for each microstructure is obtained. We employ the maximum stress and the working limit strain obtained from the stress-strain relationship as mechanical properties. The maximum stress is the indicator for strength, and the working limit strain is the indicator for ductility, respectively.
CNN is trained by setting the DP steel microstructure generated by the multi-phase-field method and the phase-field method as input, and the maximum stress and the working limit strain as output. By replacing CPFEM with the trained CNN, a framework is constructed to rapidly repeat the generation of DP steel microstructures and the evaluation of the mechanical properties of the generated microstructures. Using the framework, the effects of grain size and the volume fraction of martensitic phase on strength and ductility in three-dimensional polycrystalline microstructures of DP steel are evaluated.

EXPLICIT FEATURE SIZE CONTROL IN PARAMETER-FREE SHAPE OPTIMIZATION

Kenneth Swartz[1], Jorge-Luis Barrera[1], Mathias Schmidt[1] and Daniel Tortorelli[1]*

[1]*Lawrence Livermore National Laboratory*

ABSTRACT

Parameter-free shape optimization [1] is a powerful tool for designing structures when an exact boundary description is required. This technique, arguably a misnomer, directly parameterizes nodal coordinates of a finite element mesh, allowing a design to be optimized directly from a nonlinear programming solver. The lack of a mesh-independent parameterization allows great design flexibility; however, feature size control remains a challenge. Namely, limiting the smallest allowable feature of an optimized design is almost always required in practice, but is a non-trivial constraint to enforce in parameter-free shape optimization.

Here we present a differentiable constraint that enables explicit feature size control, allowing users to set minimum feature sizes in optimized designs. The constraint works by computing the distance between relevant boundary integration points and computing a smooth minimum of these distances. Determining which boundary integration point distances are relevant for computing a feature size is a focus of this research. Further, the constraint formulation is used to compute both positive and negative features of a design, which a user may wish to limit depending on the manufacturing process utilized. Feature size control is demonstrated using this constraint on both 2D and 3D shape optimization problems.

A MACHINE LEARNING APPROACH FOR TOPOLOGY OPTIMIZATION OF SELF-SUPPORTING STRUCTURES USING GRAPH NEURAL NETWORKS

Alireza Tabarraei[*1], Saquib Ahmad[1] and Alireza Mohan Elapolu[1]*

[1]*University of North Carolina, Charlotte*

ABSTRACT

Additive manufacturing (AM), also known as 3D printing, has revolutionized the landscape of manufacturing, offering unprecedented design freedom and customization capabilities. Unlike traditional subtractive manufacturing methods, which involve cutting away material from a solid block, additive manufacturing builds objects layer by layer from digital designs. This layer-by-layer approach enables the fabrication of highly complex geometries with intricate internal structures. In tandem with this technological leap, the significance of topology optimization has surged. Topology optimization aims to determine the optimal distribution of material to achieve desired performance objectives while satisfying various constraints. Traditionally employed in engineering disciplines such as aerospace, automotive, and mechanical engineering, it minimizes weight, maximizes stiffness, or enhances other performance metrics of structural components. The synergy between topology optimization and AM presents a compelling opportunity to push the boundaries of design and manufacturing, offering novel designs unattainable with conventional manufacturing techniques.

As the demand for optimized designs continues to grow, the challenge of computational expense in topology optimization remains a significant hurdle to overcome. The intricate nature of topology optimization problems, with their vast array of design variables and iterative optimization processes, often requires substantial computational resources. Machine learning approaches can be used as a tool to expedite the topology optimization process. In this paper, we use a graph neural network to propose a framework specifically for the topology optimization of overhang-free parts. In this paper, we propose a framework specifically for the topology optimization of overhang-free parts using a graph neural network. Eliminating overhangs is crucial because they require support structures, which are laborious to remove and add to manufacturing costs. Our approach integrates automatic differentiation (AD), streamlining sensitivity analysis and reducing computational overhead. This method enhances computational efficiency and facilitates the seamless integration of sensitivity analysis into the optimization pipeline, addressing both 2D and 3D problems under mechanical and thermomechanical loading. By leveraging AD, our framework eliminates the need for explicitly coding sensitivity calculations, enabling efficient optimization even with complex overhang filters.

LARGE DEFORMATION MESHFREE ANALYSIS USING HIGHER-ORDER GRADIENT CRYSTAL PLASTICITY

Yuichi Tadano[*1]*

[1]*Saga University*

ABSTRACT

Mechanical behavior of metallic materials is strongly influenced by the size effect at the micrometer scale. The conventional crystal plasticity theories, which are widely used for the meso-scale modeling of polycrystalline metals, do not represent the size effect because these theories cannot consider the accumulation of dislocations. Therefore, the higher-order gradient crystal plasticity models have been proposed for taking the dislocation information into account to describe the size effect. In this model, geometrically necessary dislocations (GND) are introduced into a hardening function of the slip system. In this model, the following governing equations for displacement and GND density fields should be simultaneously solved.
The finite element method, which is the most popular method to solve a problem in the solid mechanics, sometimes provides an improper solution in the higher-order gradient crystal plasticity analysis. Therefore, the development of a numerical method to solve the higher-order gradient plasticity is essential. In this study, the reproducing kernel particle method (RKPM), which is a kind of meshfree method, is introduced into the higher-order gradient crystal plasticity analysis. In order to improve the accuracy and stability of the analysis, the stabilized conforming nodal integration is adopted as the numerical integration scheme. Several numerical examples are demonstrated, and an advantage of the RKPM for solving the large deformation problem with the higher-order gradient plasticity model is discussed.

ABSTRACT

Failure due to fatigue is a key concern in the aerospace industry. While plasticity in general is understood to govern failure in aerospace-grade titanium alloys, various experimental and modeling studies over the past few decades have revealed the role of the underlying microstructure in controlling plastic deformation and subsequent failure. Numerous multiscale modeling approaches have evolved to delineate the role of these key factors. The development of a continuum-scale plasticity framework that can model plasticity at structural length scales while explicitly accounting for the microstructural features and predicting fatigue crack nucleation has posed a consistent challenge to the modeling community. This work discusses the development of a unique class of novel modeling approach referred to as Parametrically Upscaled Constitutive Models (PUCM) and Parametrically Upscaled Crack Nucleation Models (PUCNM) framework for prediction of structural-scale fatigue crack nucleation in α/β Ti-6Al-4V alloys, whose polycrystalline microstructures contain micro-texture regions (MTRs). This approach provides a thermodynamically consistent upscaled constitutive framework to bridge spatial scales through the explicit representation of microstructural descriptors in the constitutive equations in the form of Representative Aggregated Microstructural Parameters (RAMPs). The coefficients of model parameters in the PUCM are functions of the RAMPs. The fatigue life of a specimen has shown strong dependence on the presence of MTRs. A novel MTR intensity measure is formulated in this work to quantify the effect of its presence. This is incorporated in the PUCNM framework as a RAMP. A database of probability of crack nucleation and the corresponding RAMPs are developed using the Crystal Plasticity Finite Element (CPFE) model [1]. Using this database, a functional form of the macroscopic indicator for crack nucleation probability (R) is identified using Genetic Programming based symbolic regression (GPSR). The capabilities of the PUCM/PUCNM are demonstrated by simulating two different types of specimens, a structural scale compressor disk from an aircraft engine, and a Double Edge Notched Tensile (DENT) coupon specimen. The microstructural features represented by RAMPS obtained from EBSD micrographs are distributed on these specimens while preserving the spatial correlation based on 2-point statistics. This location-specific distribution of RAMPs allows the investigation of the effect of microstructural as well as geometric features on crack nucleation. Uncertainty in the fatigue life due to variability in microstructure is also quantified this way.

MICRO-SCALE TOPOLOGY OPTIMIZATION FOR THERMAL-FLUID PROBLEMS USING FTT-BASED HOMOGENIZATION METHOD

Keisuke Takaara[*1], Hiroya Hoshiba[1], Koji Nishiguchi[1] and Junji Kato[1]*

[1]*Nagoya University*

ABSTRACT

The demand for miniaturization and higher performance in electronic devices continues to increase. Consequently, the increase in the heat generation density inside electronic devices has made thermal countermeasures even more challenging. Therefore, research and development of new cooling technologies to maintain electronic devices at appropriate temperatures is being actively pursued. For example, porous metal materials and micro lattice structures have been proposed as heat dissipating structures. These structures with fine voids are expected to increase the heat transfer area between solids and fluids and improve the cooling performance. However, narrow flow paths increase flow resistance. In other words, there is a trade-off between pressure loss and cooling performance, making satisfactory design difficult. Furthermore, theoretical methods to design such materials or structures do not exist yet.

In this study, topology optimization based on the homogenization method is developed as a microstructure design method for heat exchange structures. Topology optimization based on the homogenization method is an effective method for designing materials and structures with hierarchical or multi-scale structures. The characteristic feature of the homogenization method is the separation of the governing equations into a micro boundary value problem and a homogeneous (average) governing equation. In this study, the Stokes equations and the heat advection and diffusion equations are assumed as the governing equations on the micro scale.

To solve the micro boundary value problem, the Fast Fourier Transform (FFT)-based homogenization method is utilized. Conventionally, the finite element method (FEM) is used as a numerical analysis method for homogenization problems. On the other hand, the FFT-based homogenization method has been proposed as a more efficient method than FEM for solving homogenization problems [1].

The proposed method is applied to the maximum heat transfer coefficient problem and the results are discussed.

DISLOCATION DYNAMICS ANALYSIS OF BASAL PLANE DISLOCATION NEAR THE SURFACE IN 4H-SIC

Noboru Takahashi[*1], Atsuo Hirano[1] and Akiyuki Takahashi[1]*

[1]*Tokyo University of Science*

ABSTRACT

4H-SiC has recently become a focus of attention as a new power semiconductor material that could replace silicon. One of the challenges for its practical application is the reduction of basal plane dislocations (BPD) in the epitaxial layer. In devices utilizing SiC, it is known that device performance deteriorates due to the expansion of stacking faults that accompany the movement of BPD [1]. BPD typically dissociates into partial dislocations, which exist as pairs of 30°-30° and 30°-90° partial dislocations based on the angle made between the dislocation line and the Burgers vector. During the growth of the epitaxial layer, almost 30°-30° partial dislocation pairs are converted to threading edge dislocations [2], but the conversion mechanism has not been clear yet. On the other hand, 30°-90° partial dislocation pairs do not remain in the epitaxial layer [3], and the reason is not clear. Therefore, it is essential to elucidate the behavior of BPD partial dislocation pairs. Molecular dynamics analyses have been conducted, but an interatomic potential that accurately reproduces dislocations near surfaces has not yet been developed.
In this study, 2D dislocation dynamics analysis was performed to clarify the behavior of BPD partial dislocation pairs near the surface of 4H-SiC. Based on the dislocation theory, the forces acting on the dislocation were calculated by the stress field around the dislocation near the surface obtained by the finite element method (FEM), and the equilibrium distance between two partial dislocations was calculated. The results indicated that the equilibrium distance of BPD partial dislocation pairs decreases as they approach the surface. Meanwhile, the translational force exerted on the dislocation pairs was found to be inactive for the 30°-30° partial dislocation pairs, whereas it significantly increased for the 30°-90° partial dislocation pairs as they approached the surface. This result suggests that a potential explanation for the exclusive persistence of 30°-30° partial dislocation pairs within the epitaxial layer. This result suggests that only 30°-30° partial dislocation pairs remain in the epitaxial layer.

A BOUNDARY-INTEGRAL-EQUATIONS-FRIENDLY SHAPE OPTIMISATION FOR PERFECTLY ELECTRIC CONDUCTORS

Toru Takahashi[*1]*

[1]*Nagoya University*

ABSTRACT

This study establishes an adjoint-variable-method-based shape optimization for 3D electromagnetic scattering problems regarding PECs. The main contributions of this study are to derive (i) the new expression of the shape derivative on the basis of the surface current density, which is usually solved with boundary integral equations (e.g. EFIE, MFIE, CFIE) and (ii) the explicit form of the EFIE and MFIE for the adjoint problem. Some numerical examples verify the correctness and applicability of the proposed shape optimisation.

ABSTRACT

Aortic dissections and ruptures are the most fatal conditions of aortic aneurysms which is said to have caused over 170,000 deaths around the world in 2019[1]. This work aims to present the potential of utilizing an opensource software (OSS) based platform as clinical tool for risk assessment of acute aortic dissections and ruptures. First, three-dimensional surface aorta models are created from chest CT DICOM image files of patients. Image segmentation is implemented through active contours and thresholding of CT values. Then, CAD is used to construct the analysis model which consists of the ascending(AAo) and descending aorta(DAo) as the inlet and outlet respectively. Boundary conditions mimicking a human pulsation[2] was applied to these inlet and outlets by flow pressure and flowrate. The aortas used in this work were classified into three different types: healthy (no dissection or aneurysms), Stanford type A (dissection at AAo) and Stanford type-B (dissection at DAo). Finally, an OSS OpenFOAM was used to calculate the pressure distribution, flow velocity and wall shear stress (WSS) within the three different types of aorta models. The simulation method showed that points of high WSS, concentrated in the areas where the aorta was torn into the true and false lumen. This indicated that these areas are at high risk being damaged from pulsatile flow from the heart. Therefore, the proposed OSS platform has the potential of locating high risk rupture areas that could assist in selecting proper treatment methods in the clinical field.

ADJOINT SENSITIVITY ANALYSIS AND DESIGN OPTIMIZATION FOR LAGRANGIAN SHOCK HYDRODYNAMICS

Brandon Talamini[*1], Robert Rieben[1], Daniel Tortorelli[1] and William Schill[1]*

[1]*Lawrence Livermore National Laboratory*

ABSTRACT

Numerical methods for the Euler equations of compressible fluid flow are widely used in the study of shock physics. While these methods yield predictions of the flow given fixed problem parameters, one often additionally desires sensitivities of these solutions to the problem parameters, say to enable design optimization or for inverse identification of unmeasurable experimental conditions. This talk describes a discrete adjoint method for efficiently computing sensitivities in shock hydrodynamics problems. For the discretization, we use a Lagrangian-description, high-order finite element method, which has been shown to confer several advantages, such as exact mass conservation, perfect resolution of material interfaces, and amenability to efficient implementation on modern supercomputer architectures [1,2]. Time integration is accomplished with high-order explicit finite difference schemes, and shocks are captured with a suitable artificial viscosity approach.

We discuss the formulation and implementation of the discrete transient adjoint (that is, the “discretize-then-differentiate” approach) [3], including appropriate smoothing of the discrete problem to ensure differentiability, and the judicious use of automatic differentiation tools to simultaneously obtain ease of implementation and good computational efficiency. Finally, we demonstrate the method with highly nonlinear design optimization problems inspired by inertial confinement fusion research and illustrate its potential to help advance this field.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

PHYSICS-INFORMED MACHINE LEARNING OF THE THERMODYNAMICS AND KINETICS OF POINT DEFECTS IN ALLOYS

*Anjana Talapatra**[1]

[1]*Los Alamos National Laboratory*

ABSTRACT

Desirable properties of multi-component alloys, such as corrosion, high-temperature oxidation and irradiation resistance, are highly sensitive to the formation and migration of point defects such as vacancies and interstitials. Point defect formation, diffusion and the associated energy barriers are governed by the interactions between individual and/or groups of atoms. In this work, we use Machine learning (ML) algorithms in tandem with molecular dynamics based Nudged Elastic Band (NEB) calculations to learn the composition- and configuration-dependent formation energies and migration barriers for vacancies. Specifically, we train deep neural network models using numerical representations of the local configurational environment and also implement a physics-informed approach ensuring that the detailed balance criteria are obeyed. We discuss various scenarios including i) comparison of results using relaxed as well as unrelaxed geometries, ii) multiple methods to implement the detailed balance criteria and iii) compositional complexity by comparing vacancy energetics in Cu-Ni and Cu-Au and Fe-Co-Ni_Ti alloys and iv) configurational complexity by comparing vacancy and interstitial defects in Cu-Ni.

HOW TO USE STATISTICAL FRACTOGRAPHY AND COMPUTATIONAL FRACTURE MECHANICS TO UNDERSTAND AND MODEL SIMPLY AND EFFICIENTLY IN-SERVICE FAILURES

Wassim Taleb[*1] and Laurent Ponson*[1]

[1]*Tortoise*

ABSTRACT

Failure during service often results from a mismatch between the assumptions made by design engineers during the development phase and the realities of in-service conditions. Typically, either the applied load has been underestimated, or the actual material resistance has been overestimated. Despite the critical importance of this information, no current technique can measure material resistance and applied load simply and directly after an in-service mechanical failure.
We propose a disruptive method of failure analysis based on the statistical analysis of the fracture surfaces of components that have failed in service. This method, known as statistical fractography, extracts the material failure properties and the loads applied to the component at failure from the roughness features of the fracture surface. It provides a simple and rapid experimental methodology to measure the input data required to simulate an in service failure. In practice, the material failure properties and failure load measured from the scan of the fracture surface are used as inputs for fracture mechanics models, which then create numerical twins of the in-service failure.

This innovative approach is used to understand and describe failure scenarios in complex mechanical systems, offering a powerful tool to rationally redesign structures with enhanced failure resistance and longevity. Ultimately, this technique opens new perspectives for mastering the durability and reliability of mechanical components with unprecedented performance. In my talk, I will illustrate these methods through several examples of failure analysis.

PENETRATION RESISTANCE OF GRAPHENE COATED CERAMIC MATERIALS UNDER PROJECTILE IMPACTS

Mohammad Reza Talebi Bidhendi[*1] and Kamran Behdinan*[1]

[1]*University of Toronto*

ABSTRACT

Extreme conditions including impact can result in material degradation, permanent damages, and occasionally property/life loss. Therefore, investigation of materials and structures under projectile impact has been a canonical field of research over the past decades. Such studies have led to the development of hybrid materials with high performance and durability under the aforementioned loading. As an emerging hybrid material, graphene oxide (GO)-silicon carbide (SiC) provides promising thermo-chemo-mechanical properties with various applications in defense, energy, and aerospace engineering. Nevertheless, penetration resistance of such composites under impact received less attention due to experimental and computational difficulties. Here, ReaxFF molecular dynamics is leveraged to address the aforesaid problem. Accordingly, the response of 4H-SiC thin films coated by GO samples under indentation and high-velocity projectile impact is studied. It is observed that (a) ceramic substrates coated by GO samples with higher oxidation degree demonstrate softer behavior under indentation, and (b) fracture pattern and penetration resistance under high-velocity impact are dependent on the oxidation degree of the coating layers. In essence, impact-induced complete perforation is more localized to the impacted region as oxidation degree of the coating layers increases. Therefore, oxidation content can be deemed as a novel tuning factor for the fracture behavior of the GO-SiC thin films subjected to projectile impacts. The influence of oxygen functional groups on the adhesion energy between GO and SiC layers is also investigated. It is found that adhesion energy between SiC and the coating can be modified by the oxidation degree of the graphene samples. Eventually, the findings of this study reveal some insights into the bottom-up design pathways for developing novel ceramic-based protective barriers in which GO is used as a coating layer or reinforcement.

ON THE CROWDSENSING-BASED OPERATIONAL MODAL ANALYSIS OF BRIDGE STRUCTURES USING PREDICTED RESPONSES WITH MISSING VALUES

Mohammad Talebi-Kalaleh[*1] and Qipei Mei*[1]

[1]*University of Alberta*

ABSTRACT

The development of intelligent solutions for condition monitoring of infrastructures represents a pivotal stride toward realizing smart cities. Bridges, critical components of public transportation systems, are deteriorating due to various factors. This underscores the critical importance of vigilant monitoring and maintenance practices to ensure their structural stability and long-term performance.
Current indirect bridge monitoring techniques, relying on single or multiple passages of a sensing vehicle, have shown promising results as a low-cost alternative to traditional methods using fixed accelerometers. However, these methods face challenges in eliminating road roughness effects and continuously monitoring bridges due to limited interaction time between the sensing vehicle and the bridge, resulting in insufficient vibration data collection.
This research introduces an innovative crowdsensing-based method to identify the mode shapes and natural frequencies of bridges by applying the frequency domain decomposition technique on the vibrational data with missing values, considering road roughness and measurement noise effects. The proposed method employs a random selection approach among a network of sensing vehicles. Leveraging vertical and rotational acceleration data, along with GPS location data, enables predicting the bridge's sparse responses at virtual fixed sensing nodes. A primary innovation lies in using randomly selected sensing vehicles at each timestamp, overcoming data length limitations with a multi-agent approach for real-time data collection. Moreover, the method is robust to road roughness and operational effects, known to impact indirect bridge health monitoring techniques, by utilizing residual responses from the selected agents' rear and front axles.
Comprehensive numerical studies evaluated the method's performance, simulating a 2D bridge subjected to random traffic flow with two-axle vehicles. Numerical analyses, considering vehicle-bridge interaction, demonstrate the proposed method's efficacy in accurately identifying the first three mode shapes and natural frequencies of bridges. Notably, the method achieves over 95% accuracy in identifying the bridge's first three mode shapes and less than 5% error in identifying its natural frequencies.

MODEL FORM SELECTION IN THE INDENTATION PLASTOMETRY INVERSE PROBLEM

Emmanuel Michalakis[1], Matthew Priddy[1] and Aaron Tallman[2]*

[1]Mississippi State University
[2]Florida International University

ABSTRACT

Can the performance reliability of additively manufactured metal components be predicted? Fatigue and fracture are highly sensitive to sample microstructure and the distribution of plastic deformation. Typical microstructure-sensitive models of metal deformation require microstructure generating statistics and instantiation of an ensemble of statistically representative volume elements. The common approach is difficult to apply to additive manufacturing processes due to two additional complications: (1) microstructure can vary spatially in a component due to process variations, and (2) property variations and geometric features are often on the same length-scale and are not separable as in the traditional problem formulation. What data can be used to select a model of heterogeneous plasticity between the single crystal and the homogenized length scales?

To capture the complexity of these new microstructures, local data sources will be crucial. Indentation plastometry can provide a local, physical homogenization of material properties with a flexible length scale of observation. Due to the challenge of interpreting material properties from the non-homogeneous loading conditions in indentation tests, material heterogeneity is often neglected in micro-indentation. However, nano-indentation of single crystals has been used to calibrate parameters of crystal plasticity constitutive models [1]. In all cases that use finite element simulations to aid the interpretation of experimental observations (of indentation profilometry and/or load-displacement curve), an inverse simulation problem is used. I.e., the unknown parameters of the material model are evaluated by minimizing error between the simulated data and the experimental data.

In this work, the process of selecting a plasticity model form from alternatives is determined. Data from 84 profilometry-based indentation plastometry tests of Al 7075 plate are used. Three macroscale plasticity model forms are used to replicate the data via finite element simulations. Bayesian ensemble approach [2] is used to determine parametric uncertainty in different model forms. A model selection procedure is developed that operates in model output space, such that the model selection can be performed in like-terms. A surrogate model is employed to accelerate the analysis. This new model selection will enable the development of new plasticity models for advanced processing applications.

ABSTRACT

We present an efficient approach to quantify the uncertainties associated with the numerical simulations of the laser-based powder bed fusion of metal processes. Our study focuses on a thermomechanical model of an Inconel 625 cantilever beam, based on the AMBench2018-01 benchmark proposed by the National Institute of Standards and Technology (NIST). The proposed approach consists of a forward uncertainty quantification (UQ) analysis of the residual strain of the cantilever beam given the uncertainty on some of the parameters of the numerical simulation, namely the powder convection coefficient and the activation temperature. The uncertainty on such parameters is modeled by a data-informed probability density function (PDF) obtained by a Bayesian inversion procedure, based on the displacement experimental data provided by NIST. To overcome the computational challenges of both the Bayesian inversion and the forward UQ analysis we employ a multi-fidelity surrogate modeling technique, specifically the multi-index stochastic collocation method. The proposed approach allows us to achieve a 33% reduction in the uncertainties on the prediction of residual strains compared with what we would get basing the forward UQ analysis on a-priori ranges for the uncertain parameters, and in particular the mode of the PDF of such quantities (i.e., its "most likely value"', roughly speaking) results to be in good agreement with the experimental data provided by NIST, even though only displacement data were used for the Bayesian inversion procedure.

A NOVEL DAE-ROM FRAMEWORK INTEGRATING ARBITRARY SPATIAL AND TIME DISCRETIZATION METHODS IN MULTIPLE SUBDOMAINS WITHIN A SINGLE ANALYSIS

Kumar Tamma[1] and David Tae*[2]

[1]*University of Minnesota, Twin Cities*
[2]*University of Minnesota, Twin Cites*

ABSTRACT

Over the years, the development of numerical simulation computational framework has grown. Various space discretization methods such as finite element method, meshless methods, and particle methods and so on have been built. Concurrently, many researchers have upon worked numerous space and time discretization methods. Zhou and Tamma developed Generalized Single Step Single Solve (GSSSS) family of time integration algorithm[1] to embrace well known time integration algorithms as well as more new and novel schemes with improved physics such as energy-momentum conservation and numerical dissipation control while maintaining second order accuracy in time. They, later, extended the algorithm to first of system with the development of isochronous time integrators [i-Integrators].

There also has been a high interest in coupling subdomains which allows local control of analysis for computation efficiency. Here, we provide a novel representation of particle methods named, generalized particle system (GPS) method, and the FEM in a generalized setting for space; and for the time, we also propose integration of a novel subdomain DAE-ROM framework and the well-known GSSSS time family of algorithms for dynamic systems[2]. A variety of spatial and time-discretized methods and algorithms can be employed within a single analysis. The versatility of the GSSSS family of algorithms and its improved physics proves extremely useful to the subdomain framework. Coupling of different spatial and different time integration methods will allow for the selection of an appropriate method exploiting its advantages for localized subdomain areas. The flexibility, robustness, and reduced order modeling of the presented DAE-ROM framework is not possible with existing technologies that show limitations such as reduced order accuracy, limitations of flexibility, robustness, versatility and the like, including preserving a consistent second-order time accuracy in all variables such as displacement, velocity, acceleration and Lagrange variables.

A BOND-BASED PERIDYNAMICS MODELING OF POLYMERIC MATERIAL FRACTURE UNDER FINITE DEFORMATION

Caglar Tamur[*1] and Shaofan Li*[1]

[1]*University of California, Berkeley*

ABSTRACT

We have developed a bond-based peridynamics model to study the fracture of polymer networks under finite deformation. Our approach is based on the Kuhn-Grün model of randomly jointed polymers with extensible chains, which allows the rupture of polymers through the chain scission mechanism. We introduced a novel mesoscale potential function into a nonlocal continuum framework with the purpose of modeling the mechanical response and fracture of polymers. We have demonstrated through a series of numerical examples, both two-dimensional and three-dimensional, that the proposed model is robust and efficient in modeling crack growth in polymeric materials. The model is carefully validated with experimental data and numerical results obtained on the basis of existing continuum mechanics polymer models. We have shown that the proposed peridynamics model is accurate and stable in various configurations and loading modes, such as mode-I and shear crack opening. In comparison to existing continuum polymer models and fracture modeling methods, our technique has the advantages of being theoretically simple, rigorous, and computationally fast. The numerical results show that the nonlocal polymer model can easily capture the fracture process in polymeric materials without complex ad hoc modeling parameters under finite deformation, and it has the potential to become a convenient simulation tool for modeling the polymer failure process in the design and optimization of polymeric materials.

PHYSICS-CONSTRAINED LEARNING FOR PDE SYSTEMS WITH UNCERTAINTY QUANTIFIED PORT-HAMILTONIAN MODELS

Kaiyuan Tan[*1], Peilun Li[1] and Thomas Beckers[1]*

[1]*Vanderbilt University*

ABSTRACT

Modeling the dynamics of partial differential equation (PDE) systems plays a pivotal role in making safe and efficient control decisions as it allows us to forecast the future state of the systems. The applicability of such models extends across various domains. In particular, soft robots have gained popularity due to their ability to navigate complex and dynamic environments with greater adaptability and safety compared to traditional rigid robots. Their flexible and deformable structures make them well-suited for tasks such as medical procedures, search and rescue missions, and collaborative interactions with humans. However, finding accurate PDE models of these robots is challenging because of the materials involved with highly nonlinear properties. Data-driven approaches seem promising for modeling soft robots as PDE systems but often neglect basic physical principles, which consequently makes them untrustworthy and limits generalization. In this scenario, predictive models learned only from the data might be able to provide reliable forecasts. Previously, physics-informed learning methods such as PINNs[1] have been introduced, but typically lack uncertainty quantification to indicate the reliability of the learned models. Recently, we introduced a physics-informed Bayesian learning framework[2] which, however, was limited to learning rigid body dynamics.

In this talk, we present a physics-constrained learning method that combines powerful learning tools and reliable physical models. Our method leverages the data collected from observations by sending them into a Gaussian process that is physically constrained by a distributed Port-Hamiltonian model. Based on the Bayesian nature of the Gaussian process, we not only learn the dynamics of the system, but also enable uncertainty quantification. Furthermore, the proposed approach preserves the compositional nature of Port-Hamiltonian systems which allows us to easily connect the model with models of the environment while maintaining physical correctness and uncertainty quantification.

[3]*Tongji University*

ABSTRACT

Together with the rapid development in manufacturing technology, multiscale structural topology optimization presents opportunities for the design of components at both the structural and sub-structural scales. A few works on topological optimization based on FE2 computational homogenization to concurrently evolve the structure and sub-structure have been reported. However, significant expertise and coding are required in the conventional implementation of FE2. It is shown that multiscale FE2 optimization can be readily implemented on commercial finite element codes using the Direct FE2 approach. The multiscale analysis is carried out as a single topology optimization job on commercial FE software after 2 simple pre-processing steps with no coding required. Numerical example problems are solved using ABAQUS to demonstrate the proposed method for stiffness optimization. It is shown that Direct FE2 optimization takes only a fraction of the computational time required for optimization with a fine mesh and yet gives comparable optimized stiffness.

[1]Queen Mary University of London
[2]University of Oxford

ABSTRACT

Composite materials find increasing applications in aerospace and offshore wind energy sectors owing to their outstanding specific mechanical properties. Nonetheless, these materials face susceptibility to demanding conditions, including dynamic impact loading and environmental degradation. Notably, the high-velocity impact of liquid droplets can induce significant erosion damage to the leading edges of wind turbine blades. Phase Field (PF) fracture models emerge as promising solutions for anticipating such challenges. These PF methods adeptly capture diverse crack paths and evolving interfaces, seamlessly integrating with multiphysics phenomena. Moreover, the PF interface approach plays a crucial role in replicating the flow behaviour of two distinct, immiscible fluids, with a specific emphasis on accurately determining their interface position. This study aims to explore the influence of factors such as microstructure, moisture content, and dynamic liquid-solid impact on the material's macroscopic performance.

In this research, we introduce a numerical framework that integrates phase-field fracture modelling with moisture diffusion and hygroscopic expansion to forecast environment-induced failures in composite materials. Our model undergoes rigorous validation against experimental data, demonstrating proficiency in replicating moisture dispersion, fibre and matrix swelling, and fibre-matrix debonding. Expanding our computational framework, we proceed to simulate liquid-solid interactions, leveraging the Arbitrary Lagrangian-Eulerian (ALE) technique in conjunction with a predefined multiphysics interface for Two-Phase Flow and Phase Field. Comparative analyses of displacement, strain distribution, and historical strain waves affirm the model's accuracy in alignment with experimental findings. The computational architecture provides a virtual platform to explore microstructural features, material properties, environmental-induced degradation, and dynamic liquid-solid impacts. Such advancements are pivotal in optimizing designs, propelling the evolution of next-generation transport and offshore energy innovations

AN AI ASSISTED WALL HEAT FLUX MODEL FOR FLAME-WALL INTERACTION IN TURBULENCE

Takuki Kaminaga[1], Yamato Shiotsuki[1], Ye Wang[1] and Mamoru Tanahashi[1]*

[1]Tokyo Institute of Technology

ABSTRACT

Flame-wall interaction (FWI) is a widely encountered phenomenon in combustion devices where the combustion occurs in an enclosed chamber. It is typically characterized by a pronounced decrease in flame reactivity (near-wall flame quenching) and a substantial level of quenching-induced wall heat flux which critically impacts the thermal efficiency of combustion devices. Currently, despite active research into FWI through Direct Numerical Simulations (DNSs) and experimental approaches, the highly localized and reaction-coupled nature of FWI presents ongoing challenges for its accurate modeling.

In response to these challenges, this study introduces a machine-learning-based Large Eddy Simulation (LES) model designed to predict wall heat flux resulting from FWI. The model is trained on a DNS dataset of premixed methane-air combustion in constant volume vessels across various flow conditions, including 1D laminar, 2D laminar, and 2D turbulent flows. It is trained with the neural network, considering the time-integrated value of the wall heat flux as the output quantity and the flame-wall distance, integration time, and other wall-heat-transfer-related thermochemical quantities (e.g. mean pressure and the ratio of preheat temperature to wall temperature) as the input quantities. Additionally, the model incorporates flame-wall geometric features by including the angle between the flame and the wall in the input layer. All input and output quantities are appropriately non-dimensionalised and scaled numerically based on the maximum of their absolute values. The Adam optimization method and mean squared error loss function are utilized in the model training process.

The current results from the DNSs of current combustion scenarios indicate a strong dependence of FWI-induced wall heat flux on the flame-wall distance, as well as on thermodynamic states including preheat temperature, wall temperature, equivalence ratio, and initial pressure. Correspondingly, the AI-trained model demonstrates robust predictive performance for wall heat flux during near-wall combustion under various flow conditions, as evidenced by a notable decrease in the loss function value during machine learning training and a correlation coefficient exceeding 0.9 when comparing model-predicted to original DNS wall heat flux values. The current study underscores the potential and promise of employing machine learning methodologies to develop advanced models for wall heat transfer in combustion systems.

SPECTRAL DECOMPOSITION BASED NATURAL STABILIZED NODAL INTEGRATION FOR HIGHLY ORTHOTROPIC AND NEARLY INCOMPRESSIBLE MATERIALS

Huy Nguyen[1] *and Satoyuki Tanaka**[1]

[1]*Hiroshima University*

ABSTRACT

Nodal integration (NI) methods are of great interest in meshfree methods because they are simple and require less computation to integrate the weak form. However, a naive application of NI such as direct NI (DNI) usually results in an unstable and inaccurate formulation due to spurious singular modes. Recently, naturally stabilized nodal integration (NSNI) has been proposed by Hillman and Chen [1] to eliminate the unstable modes with a minimally additional cost compared to DNI. Overall, NSNI is a highly efficient and accurate integration scheme widely used in various problems. However, when we applied NSNI to applications related to highly orthotropic and nearly incompressible materials, we realized that the displacements were usually underestimated by large factors, especially for small nodal support sizes. Hence, an improved NSNI is introduced to overcome the locking issues encountered by the standard counterpart. The elasticity matrix is known to have stiff modes associated with high eigenvalues for highly orthotropic and nearly incompressible materials. Since the standard NSNI contains the full elasticity matrix, it may provide improper stabilized energy, which causes locking. Therefore, the proposed method utilizes spectral decomposition [2] to identify stiff modes in the elasticity matrix. Then, terms associated with stiff modes in the weak form are integrated by NI without stabilization, whereas NSNI is introduced for the other terms. Several two- and three-dimensional numerical examples are tested to demonstrate that the proposed approach enhances the capability of NSNI to deal with displacement locking.

ABSTRACT

This study introduces a framework for assessing the seismic risk of urban buildings, specifically in Sendai City, Japan. It integrates city-scale numerical simulations with sensor data to evaluate earthquake responses of buildings. The methodology focuses on developing and refining building-specific fragility functions using numerical simulations, enhanced by sensor data integration. The Proper Orthogonal Decomposition (POD) technique plays a crucial role in optimizing sensor placement for maximum efficiency and minimal quantity, to circumvent practical constraints in urban environments.

A critical part of the research is applying POD to analyze numerical simulation data. POD is a method that identifies principal components from numerical simulation data, enabling effective data decomposition and reconstruction. This approach helps represent large-scale simulation results in a more compact and meaningful way, a crucial step in comprehending seismic impacts. Besides, the framework also highlights the importance of sparse sensor distribution [1]. The study strategically places sensors to maximize data collection efficiency while minimizing the number of sensors. This optimization is vital for practical use in urban areas, where large sensor networks may be impractical.

Also, the study uses cloud analysis [2] and Bayesian updating [3] in a novel manner. It first creates fragility functions for all buildings together based on cloud analysis using numerical simulation data, Cloud analysis uses the linear regression in the logarithmic scale by least squares to establish the relationship between engineering demand parameter (EDP) and intensity measure (IM), and then progressively refines them by incorporating sensor data through Bayesian inference. This dual-stage approach allows for a rapid safety assessment of all buildings in a given area, with continuous improvements to the fragility functions by the accumulating sensor data.

This research offers valuable insights into seismic impacts and mitigation strategies, particularly relevant for earthquake-prone area such as Sendai city. It contributes to urban seismic risk management, providing methodologies that strengthen earthquake preparedness and resilience in urban areas worldwide.

MODEL SELECTION AND DIMENSION REDUCTION OF CHEMICAL KINETICS MODELS FOR TURBULENT COMBUSTION

Kunkun Tang[*1], Tulio Ricciardi[1] and Jonathan Freund[1]*

[1]*University of Illinois Urbana-Champaign*

ABSTRACT

Our ultimate goal is to simulate the interaction between supersonic turbulent combustion and composite materials in complex geometries. Validation of such simulation models is particularly challenging in part due to the many sources of uncertainty present in the integrated model. This work focuses on combustion kinetics models, whose uncertainty has a significant impact due to the nonlinearity of Arrhenius models.

A set of candidate kinetics models is shortlisted based on their efficiency and anticipated accuracy. A probability distribution is assigned to Arrhenius parameters, which represents the primary source of uncertainty in a kinetics model. We then develop a model selection approach to select the best available mechanism for our particular combustion applications. There is a challenging balance between model complexity and model prediction power. More calibrated parameters will typically allow a model to better reproduce data. However, a model that is 'overfitted' will not extrapolate well. Formal model selection statistical analysis provides a route to balancing these two factors to suggest a model that is justified based on the available data for calibration but still not slavishly linked to it so much that the underlying physics of the model become secondary to the goodness of fit. We demonstrate our model selection approach and select the most plausible mechanism using the standard combustion software tool Cantera for a case of axisymmetric flames stabilized at a stagnation point.

Once the most plausible kinetics model is selected, a remaining significant challenge is the curse of dimensionality when uncertainty quantification and validation are performed for large-scale turbulent combustion simulations. Global sensitivity analysis is a standard approach to focus on the most influential reactions. One drawback is that an arbitrary threshold is often required. When reactions are comparable between each other, threshold-based selection is not always viable. We propose a novel method for dimension reduction, which considers the number of uncertain parameters as model classes, as in a model selection approach. This method takes advantage of experimental data for selecting the most important reactions and avoids a user-given threshold. We will use an axisymmetric configuration of ethylene-hydrogen-air flat flame on a McKenna burner to assess our dimension reduction approach. The simulation is performed using the in-house developed multiphysics software framework MIRGE-Com.

A MICRO-MESO COUPLED MODEL FOR CORAL REEF ROCKS BASED ON CT SCANNING

Dengfeng Sang[12], Shoulong Zhang[2], Peijun Xie[2] and Liqun Tang[1]*

[1]South China University of Technology
[2]CCCC Harbour Engineering Research Institute Co.Ltd

ABSTRACT

The coral reef rock has a rich porous structure, and establishing a entity model with a realistic porous structure will do great good to study the mechanical behavior and its mechanisms. However, the pore's characterized size of coral rocks span four orders of magnitude from micro to meso scales (1μm to 10mm). Large pores require the size of a specimen to be sufficiently large, while small pores request the element size in the model to be very small. The selfconflict sizes of specimen and element result in an enormous number of elements in the entity model to lead to extremely high computational costs. To overcome this fundamental challenge, this paper uses CT to scan a macro coral specimen to obtain an entity model and establishes a dual scale coupled model: (1) retaining pore's equivalent diameter larger than 1mm in the overall CT entity, and regarding the rest part as a uniformly dense matrix material with unknown material's properties, which is called the meso model; (2) extracting a small entity containing pore's equivalent diameter less than 1mm from the CT entity, which is called the micro-scale model also with unknown matrix material properties; (3) the unknown matrix material parameters in meso model are derived from mechanical response of the micro model, and the unknown matrix material parameters in micro model are confined by that meso model's mechanical responses should be coincident with that of a resl coral specimen. This micro-meso dual scale coupled model retains the influence of pores at various scales, and a computational result shows that it can reduce the computational complexity of a single CT entity model by four orders of magnitude. It provides a new approach for studying similar materials' mechanical behavior and mechanisms under complex loading conditions.

DATA DRIVEN POLYMER CONSTITUTIVE MODEL BASED ON PRIOR KNOWLEDGE OF MECHANICS

Shan Tang[*1], Xu Guo[1], Zefeng Yu[1] and Yicheng Lu[1]*

[1]*Dalian University of Technology*

ABSTRACT

Traditional constitutive models for polymers have achieved remarkable results over the years, with the advantages of fewer control parameters and clearer physical meanings of the parameters. However, the building of these models is complex and time-consuming, relies on a large amount of experience, and is difficult to keep pace with the development of new materials. Data-driven constitutive modeling methods based on data processing and analysis have developed rapidly. However, existing research in this field usually treats methods such as machine learning as a black box for data processing, ignoring the prior knowledge of mechanics accumulated over a long period of research. Thus requires the support of a huge amount of data in order to obtain an accurate material constitutive model. This report presents our recent research work that enables viscoelastic/viscoplastic constitutive modeling and computational methods for polymers using less data requirements driven by combining solid mechanics mechanisms with data-driven computational methods. Our method has several advantages: (1) it eliminates the interference of human experience by automating the establishment of constitutive relationships through data, which greatly improves the efficiency of establishing new material constitutive; (2) it effectively combines mechanistic mechanisms, and the amount of data required is much smaller than that of a purely data-driven method, which improves the practicability of the method; (3) it can be conveniently integrated into Abaqus, which is easy to use. These advantages give our method a wide range of applications in the field of material constitutive modeling.

ONLINE UPDATE OF DIGITAL TWIN AND ITS APPLICATION TO METAL ADDITIVE MANUFACTURING

Yifan Tang[1], Mostafa Rahmani Dehaghani[1], Pouyan Sajadi[1] and Gary Wang[1]*

[1]*Simon Fraser University*

ABSTRACT

Digital twin (DT) refers to any model with capabilities to predict responses of physical systems and update online based on measured sensor data from physical systems. Depending on the type of DT models, online update methods could be classified into several categories. 1) The data-driven artificial intelligence models could be updated by changing model architectures and hyperparameters, whose relevant topics include lifelong learning, meta learning, and incremental learning. However, those methods suffer from the catastrophic forgetting problem, where the updated model would lose information about previous data. 2) The unknown system parameters of partial differential equations (PDEs) (i.e., dynamic systems) could be updated online by optimization, inverse engineering, statistics, or Kalman filters. Although those methods have been studied widely in hybrid simulations and data assimilation tasks, they are designed based on PDE functions which are not always accessible in all engineering tasks. 3) The proper orthogonal decomposition based reduced order models (POD-ROM) can adjust the number of reduced modes and update corresponding mode coefficients by incremental computation, which keeps prediction accuracies of previous data and new sensor data simultaneously. However, the accuracy of previous data is less important during applications, as the online sensor data may differ from the previous data even on the same input conditions.

Given the fact that PDEs of physical systems are not always available, and the update is based on an existing DT which is supposedly representing the current physical system, it seems the third category of update approaches is most promising for online DT updating. This work thus focuses on developing DT update methods based on POD-ROM. By fixing the first n modes and mode coefficients, the update of remaining modes and relevant coefficients are defined as a pseudo dynamic system which is extracted from the POD process and incremental computation process. Kalman filter series are then applied to update the remaining modes and coefficients to increase the online prediction accuracy with increasing online sensor data.

The proposed method is tested in metal additive manufacturing, where the temperature field of the yet-to-print layer is reconstructed by POD-ROM. As simplifications (e.g., no geometry deviation) are applied during modeling, POD-ROM would fail to provide accurate feedback to support the process control for the current layer. Based on the proposed online update method, the offline POD-ROM is tuned with the sensor data of same points during printing, improving the prediction accuracy for the layer at future timesteps.

A VC/NON-VC COUPLED MATERIAL POINT METHOD FOR STRUCTURAL FRAGMENTATION PROBLEMS WITH PHASE FIELD METHOD

Harshal Tangade[*1], Cameron Rodriguez[1] and Tsung-Hui Huang[1]*

[1]*National Tsing Hua University*

ABSTRACT

Meshfree methods, such as the material point method (MPM), can effectively handle material fragmentation problems, bypassing mesh distortion and separation that is deleterious to the conventional mesh-based formulation like finite element method. In addition, by incorporating proper fracture mechanics into Galerkin formulation, such as phase field method, one can easily track the fracture domain under variational principle. The well-known cell-crossing instability and loss of Galerkin exactness can be mitigated by our recently developed VC-RK material point enhancement [1], where the cell-crossing is overcome by using a smooth reproducing kernel (RK) approximation and the loss of Galerkin exactness is remedied by introducing the variationally consistent (VC) correction. However, during material fragmentation, dealing with the boundary integral within the VC framework becomes challenging due to the presence of newly generated surfaces. To achieve a robust simulation in fragmentation problems, the deformation-based coupling scheme [2] is introduced in the Galerkin MPM to couple VC (for continuum bodies) and non-VC (for discrete bodies), and proper stabilization is introduced to ensure the stability in the non-VC portion of the problem. The stabilized MPM framework is proven effective through benchmark examples with extreme deformations, assessing its consistency and stability.

ABSTRACT

Nonlinear homogenization, as explored in [1], has proven to be a dependable approach for deriving macroscopic constitutive relations and field statistics in two-phase composite materials. The method is based on an optimal linearization of the nonlinear composite, leading to the best linear comparison composite with identical field statitics than the nonlinear material and which properties can be estimated with standard linear homogenization methods. However, as the fidelity of the physical representation of the material improves, the associated calculation time increases, thereby limiting the practical implementation of nonlinear homogenization methods in commercial finite element software for larger scale structure calculation.

To address this challenge while maintaining both precision and efficiency, machine learning can be leveraged to construct a digital twin of the composite constitutive law. This approach allows predicting macroscopic material behavior in real time, while ensuring accurate results.
The robustness of this method has been demonstrated for two-phase composites with nonlinear power-law constitutive relation, and it has been successfully extended to model the more intricate three-dimensional behavior of viscoplastic polycrystals. In the latter case, there is a substantial reduction in computational time without compromising the precision of nonlinear homogenization methods.

ABSTRACT

We studied ion evaporation from a planar interface between the room-temperature ionic liquid (RTIL) and vacuum under external electric fields by using molecular dynamics (MD) simulations. We calculated the ion evaporation rate (je) as a function of the electric field normal to the RTIL surface (En), and results under Langevin, dissipative particle dynamics (DPD), and Berendsen thermostats were compared. It was found that DPD thermostat is more suitable for simulating the ion evaporation phenomenon. We also compared results under different methods for applying the electric field (constant potential, constant charge, and constant field methods) and found that je-En curves from the three methods agree with each other. Temporal evolution of electric fields in vacuum was further analyzed, and variations of electric fields over time were traced to the induced electric field between the evaporated ion and RTIL film. This work could guide the selection of proper methods for MD simulations of electrospray in the pure ion regime and lays the foundation to study more complex electrospray phenomena using MD simulations.

A CALIBRATION STRATEGY FOR PROGRESSIVE INTEGRATION OF NEW CREEP EXPERIMENTS FOR SALT ROCKS

Herminio Tasinafo Honorio[1], Lambertus J. Sluys[1] and Hadi Hajibeygi[1]*

[1]*TU Delft*

ABSTRACT

The storage of green hydrogen in salt caverns requires fast injection and production rates to cope with the imbalance between energy production and consumption. This raises concerns about the mechanical stability of salt caverns under such operational conditions, which requires careful planning, often using numerical simulations. However, the accuracy of simulations is strongly dependent on the choice of a suitable and appropriately calibrated constitutive model. Salt rocks present a complex mechanical behavior, with different time-dependent deformation mechanisms simultaneously taking place [1]. As a result, constitutive models for salt rocks tend to depend on many material parameters, for which automated calibration strategies are often employed. Moreover, as pointed out in [2], inherent differences between samples of the same batch and difficulties in experimental controls constitute additional challenges to the calibration process, as a large set of experimental results should be employed to obtain a single set of representative material parameters. However, creep experiments are usually time-consuming, implying that the size of experimental datasets increases at a low pace. Therefore, it would be convenient to perform partial calibrations with the experimental data currently available and incorporate new experiments as they become available. During this process, the quality of the model results should increase as more experiments are used for calibration, and it should stabilize when a sufficient number of experiments is reached.

In this context, we present a progressive calibration procedure that incorporates one experiment at a time by properly adjusting an objective function and solving it as a multi-objective function optimization problem. Moreover, a regularization term is added to the loss function to roughly favor the same fitting quality for all experiments. The Particle Swarm Optimization (PSO) algorithm is employed to solve the optimization problems. Additionally, we investigate a situation where each experiment is performed on salt samples with slightly different material properties, for which the goal is to find a single set of representative material parameters. The results show that the proposed calibration strategy is robust and provides increasingly better predictions as more experiments are available for calibration.

DEEP LEARNING FOR MODEL CORRECTION

Caroline Tatsuoka[*1] and Dongbin Xiu*[1]

[1]*The Ohio State University*

ABSTRACT

Despite many recent advances and new deep learning technologies, training of the Deep Neural Networks (DNNs) for modeling of unknown systems generally requires large amounts of high-fidelity training data. Such large quantities of data may not be available in many practical applications, hence it is of importance to develop methodologies that can accurately correct imperfect prior models given scarce amounts of high-fidelity data. Hence, utilizing the Flow-Map DNN methodology and transfer learning, we present a model correcting framework and demonstrate its effectiveness on several numerical examples.

NUMERICAL STUDY ON MODELING OF ICE CRYSTAL ICING WITH CONSIDERATION OF ICE EROSION PHENOMENON.

Wakana Tatsuta[1], Koji Fukudome*[2], Soichiro Fujimura[1] and Makoto Yamamoto[1]*

[1]*Tokyo University of Science*
[2]*Kanazawa Institute of Technology*

ABSTRACT

Many experiments and numerical simulations have been conducted to predict ice accretion, as its occurrence on an aircraft poses a threat to the safety and stability of the aircraft during operation. Ice crystal icing is a phenomenon of ice accretion that occurs in aircraft engines. It leads to engine power loss due to the ice layer formation by impinging ice particles on the fan and compressor walls. However, as the mechanism behind ice crystal icing is not yet fully understood, modeling of ice crystal icing remains an urgent issue. Recent experiments on ice crystal icing have unveiled phenomena such as sticking, bouncing, and erosion by the conditions of the impinging ice particles. Understanding the behavior of ice particles during impingement is crucial for accurately predicting the ice shape in ice crystal icing. While ice crystal icing models incorporating the effects of sticking and bouncing have been developed in recent years, only a limited number of models account for ice erosion.

This study introduces a novel ice crystal icing model by incorporating an ice erosion model. The icing simulation comprises four steps: flow field computation, ice particle trajectory computation, thermodynamic computation, and grid modification. The proposed ice erosion model is integrated into the thermodynamic model based on the extended Messinger model [1]. The erosion model for the accreated ice was derived from a semi-empirical model employed in predicting sand erosion based on classic solid/solid collision theory [2][3]. The parameters for this semi-empirical model were selected based on the impacts of ice particles on the ice layer and the melting ratio of the impacting ice particles. Numerical simulations of ice crystal icing were conducted under various conditions using the ice erosion model. The results revealed a significant discrepancy in the predicted icing shape depending on the presence or absence of the erosion model. In addition, the model was also validated through comparison with experimental data.

A FLUID-STRUCTURE INTERACTION MODEL USING MOVING PARTICLE SEMI-IMPLICIT (MPS) METHOD

Saeed Tavakoli[*1], Najib Bouaanani[1] and Ahmad Shakibaeinia[1]*

[1]*Polytechnique Montreal*

ABSTRACT

Fluid-structure interactions (FSI) play a crucial role in civil engineering, shaping the resilience and optimal design of structures facing intricate forces. This paper presents an accurate and efficient fully-Lagrangian FSI model based on the Moving Particle Semi-Implicit (MPS) method. The simulation algorithm solves the governing equations of fluid and solid mechanics using separate two-way coupled MPS models. The coupling scheme is streamlined by adopting the mesh-free method (MPS), eliminating challenges associated with meshes while maintaining accuracy comparable to conventional mesh-based models. The solid model accounts for nonlinear structural dynamics and a failure mechanism in solid materials. Computational efficiency is achieved through parallelization as well as an innovative neighbor search strategy. Modified particle-shifting and interface detection methods enhance the simulator's capability to capture complex interactions.

To validate and evaluate the model's performance, we conduct comprehensive benchmark comparisons for various conditions, including solid-only models (e.g., free vibration of a cantilever thin plate), fluid-only models (e.g., dam break flow), and different FSI scenarios such as dam break flow against an elastic wall. Stability, computational efficiency, and accuracy of the results are evaluated against the available analytical and experimental data, proving the capability of the developed model.

A HYBRID LATTICE BOLTZMANN APPROACH FOR PARTICLE-LADEN FLOWS WITH THE PRESENCE OF FOULING LAYERS

Hugo Tavares[*1], Luca Moriconi[1] and Juliana Loureiro[1]*

[1]*Federal University of Rio de Janeiro*

ABSTRACT

We this study, we focus on exploring hybrid lattice Boltzmann methods for simulating particle-laden flows, particularly to model calcium carbonate scale formation in high Reynolds number environments. Accurately modeling these particle-laden flows with fouling layers is challenging due to the need to balance model complexity and computational feasibility. Factors such as particle size, shape, density, and chemical composition significantly influence flow dynamics and fouling layer formation. Developing comprehensive models that encompass all relevant physical effects is impractical, necessitating the proposal of more manageable yet effective models. Correlating these models with experimental data presents its own set of challenges, highlighting the need for precise calibration tools. Such tools require a significant number of simulations to ensure accuracy in the results. To balance computational efficiency and accuracy, we propose an improved combination of phase-field models with Eulerian-Eulerian descriptions of particle motions. Additionally, for the proposed set of equations, we introduce a numerical solution based on a hybrid formulation of the lattice-Boltzmann method. We also discuss comparisons with Eulerian-Lagrangian schemes, and when possible, we compare the results with experimental data, using data assimilation enhanced by Bayesian inference tools.

ENERGY AND ENTROPY STABLE HIGH-ORDER CUT DISCONTINUOUS GALERKIN METHODS

Christina Taylor[1], Jesse Chan[1], Lucas Wilcox[2] and Akil Narayan[3]*

[1]*Rice University*
[2]*Naval Postgraduate School*
[3]*The University of Utah*

ABSTRACT

We present results on energy and entropy stable frameworks for high-order discontinuous Galerkin methods on cut meshes. Cut meshes provide the ability to represent complex geometries while maintaining the simplicity of a Cartesian mesh wherever possible. However, cut elements present two issues due to their arbitrary size and shape: the possibility of a severely restricted CFL condition and difficulty in generating exact quadrature. In the energy stable case, we show that state redistribution can be used to address the small cell problem while maintaining L2 stability. For entropy stability, which requires exactness guarantees on quadrature, we use curvilinear triangulations and Caratheodory pruning to generate sufficiently exact but still computationally efficient quadrature on cut elements. We present initial results applying these frameworks to the acoustic wave and compressible Euler equations, respectively.

TOWARD ESTABLISHING A REDUCED ORDER AND SURROGATE MODEL FOR RESIDUAL STRESS IN ADDITIVE MANUFACTURING

Kirubel Teferra[*1], Lukasz Kuna[2] and Steven Rodriguez[1]*

[1]*U.S. Naval Research Laboratory*
[2]*Pacific Northwest National Laboratory*

ABSTRACT

The high thermal gradients and fast thermal cycles associated with additive manufacturing (AM) lead to residual stress development during solidification, which has a deleterious effect on the long-term structural integrity of AM components. Further, the small length scale of AM components, such as the lattice struts or thin wall features commonly constructed, combined with the epitaxial growth of solidification causing large grain sizes, results in a coupling of length scales between the engineering length scale of the component and the scale of microstructural heterogeneity. This motivates the development of process-structure-property descriptive models resolved at the polycrystalline level to understand the effect of build condition parameters on microstructure features, and in turn, on material properties. Recently, a solidification model for laser powder bed fusion processing based on the cellular automata finite element (CAFE) was developed and validated against experimental electron backscatter diffraction data, and is capable of generating representative volume elements of solidified microstructures. When coupling this model with the crystal plasticity finite element model, the thermomechanical equations associated with laser processing can be solved to predict the mechanical response, which includes the effect of polycrystalline heterogeneity, at the microstructural length scales. While this modeling framework is capable of computing detailed, high fidelity mechanical response fields, it is prohibitively computationally expensive for parametric analysis or for simulations covering very large domains. Therefore, this work studies the applicability of hyper reduced order models (HROM), such as the energy conserving sampling and weighting algorithm, for identifying and constructing the low dimensional manifold over which the solution field resides. A distinct feature of AM solidification for HROM applications is the translating heat source, leading to the potential existence of a steady state solution. It is sought to exploit this feature by developing evolutionary reduced bases functions that are defined with respect to the translating laser source. One factor limiting widespread use of HROMs is that they are inherently intrusive, meaning that solving the online problem requires completely recoding the numerical implementation of the solution to the system of equations. In contrast, neural operator surrogate models are nonintrusive, yet they suffer from the large demand placed on optimization algorithms by searching over a large parameter space. This work studies integrating HROMs with neural operator networks such that neural network optimization is confined to the low dimensional manifold identified by the HROM. The new model will be formulated and its performance tested on example problems.

[4]*The University of Manchester*

ABSTRACT

An ageing population and changes in demographics have brought valvular heart disease to a central focus in cardiovascular medicine. Aortic stenosis, accounting for 42% of valvular heart disease cases, is characterised by calcium deposits that narrow and stiffen the aortic valve, resulting in elevated transvalvular pressure, reduced blood flow, and increased cardiac workload. It is widely recognised that fluid-structure interaction (FSI) simulations offer the most accurate representation of the interaction between the aortic valve and its surrounding flow field, as well as associated pathologies [1]. FSI simulations, however, particularly involving complex, patient-specific geometries, present challenges such as time-consuming image-based anatomy reconstruction, complex meshing, long set-up times, and the difficulty of automation. We present an automated workflow designed to create virtual twins of the aortic root and conduct FSI simulations to analyse blood flow in stenosed aortic valves. While the focus here is on the simulation of native diseased valves, the workflow is designed with subsequent simulation of clinical interventions, such as transcatheter aortic valve implantation (TAVI), in mind.

Using computed tomography angiography (CTA) scans, echocardiography, and Doppler imaging data, patient-specific simulations of the valve haemodynamics are obtained using the workflow detailed below. Detailed models of the aortic root, including the aorta, left ventricle outflow tract, and calcifications, are generated from CTA scans. Valve leaflets, not directly obtained in segmentation due to limitations on imaging spatial and temporal resolutions, are inferred for each patient from detected anatomical landmarks. These steps are performed using SimplewareTM Software (Synopsys Inc, USA), and an in-house code. Fully coupled FSI simulations of the valve haemodynamics are then conducted for each patient. Using Ansys LS-DYNA, augmented with custom Python scripts, this process is applied to several patients to provide performance predictions for comparison with clinical measurements. The simulations provide information on pressure gradients across the valve; stress field and blood velocity, at peak systole and diastole; and calculations for blood flow rate, regurgitant volume, orifice area, and jet time-velocities. Model outputs are validated against Doppler traces.

This automated workflow, incorporating FSI simulations, aims to provide a tool for understanding the physiology of aortic stenosis and the underlying disease mechanisms. With further refinement, it can form a key building block of in-silico trials of cardiac devices and interventions.

MECHANICAL MODELING OF CARDIAC FIBROSIS WITH EXPLICIT SPATIAL REPRESENTATION OF MYOCYTE LOSS AND COLLAGEN ALIGNMENT

Åshild Telle[*1], Mary M. Maleckar[2], Joakim Sundnes[2], Samuel Wall[2] and Patrick Boyle[1]*

[1]*University of Washington*
[2]*Simula Research Laboratory*

ABSTRACT

Cardiac fibrosis is a pathological condition that decreases myocardial contractility and increases stiffness, leading to reduced cardiac function. One form, replacement fibrosis, occurs as damaged myocytes are replaced with stiffer collagenous tissue containing more aligned collagen fibers [1]. It remains unclear how different sub-processes individually contribute to the loss of cardiac function. In this work, we explored the mechanical microscale impact of various factors through a computational framework.

We employed a mechanical model allowing for explicit geometrical representation of individual myocytes embedded in extracellular matrix (ECM), also incorporating spatial representation of the collagen fibers. We assumed all cells to be aligned within the tissue block, while allowing for spatial variation of collagen. An active stress model was used to model cellular contraction.

Previous work [2] indicates that contractility and stress are locally dependent on the directionality of fibrosis progression. Expanding on these findings, we examined myocyte loss of 50% (64 out of 128 cells) progressing longitudinally, transversely, or randomly. We next used our framework to simulate the impact of myocyte loss in combination with other parameter changes, impacting myocyte/matrix stiffness and collagen alignment.

In our simulations, the impact of myocyte loss had the largest effect on resulting strain and stress – with up to 45% loss in strain and up to x7 higher stresses in the extracellular subdomain. Increased myocyte and matrix stiffness further reduced the strain (up to 12%). Meanwhile, collagen alignment in the myofiber direction increased strain, partially restoring the effect of myocyte loss (~5% restoration). Collagen alignment in the myofiber direction also reduced the extracellular stresses caused by myocyte loss (up to 45% and 25% restoration, respectively).

Our modeling framework effectively captures differences in stress and strain resulting from changes in spatial cellular configuration and extracellular collagen alignment. Myocyte loss in all scenarios led to reduced contractility and increased matrix stresses. Meanwhile, increased myofiber direction collagen alignment partially restored contractility and decreased matrix stresses, which may signal this is a compensatory mechanism to the loss of myocytes. Future endeavors integrating modeling frameworks with experimental data could build on this to gain deeper insight into factors of cardiac fibrosis.

ACTIVE LUBRICATION INTERFACES WITH TUNABLE MICRO-TEXTURES

Ilker Temizer[*1] and Sena Pekol*[1]

[1]*Bilkent University*

ABSTRACT

Designing interfaces with the optimal operating conditions for hydrodynamic lubrication has been a vibrant research topic in the context of tribology. Since early studies, there has been an effort to design surface textures towards optimal load carrying capacity or friction behavior. Homogenization is a well-established methodology to account for the oscillatory response due to the micro-texture features of a design. This approach is based on the Reynolds equation that is commonly adopted to capture the physics of the thin film lubrication problems. Given such an approach, most design studies in the field are based on parametric frameworks which limit their ability to capture complex topological features. In this context, topology optimization is a widely invoked approach that may be suitably combined with homogenization to deliver an unrestricted design space. Moreover, the surface design does not need to be fixed in time. Manufacturing of smart surfaces have recently displayed significant development. The materials that such surfaces are composed of are not only tailored spatially but also display temporal changes according to an external excitation, such as for electric field-responsive surfaces. Such smart surfaces offer a potential for further optimizing the lubrication behavior, which is the focus of this work. Specifically, a space-time homogenization-based topology optimization approach will be invoked in order to design active surfaces which target objectives based on flux and traction. A novel unit cell optimization approach is additionally employed in order to remove configurational constraints from the optimization framework. The results obtained from this framework are then heuristically projected to generate 3D realizations of representative surface elements which respond to electric fields, thus morphing their surface textures. The macroscopic response of these preliminary realizations are subsequently compared against the original design predictions. Overall, this study is a first step towards a comprehensive design framework for active interfaces.

A POSITION-BASED FORMULATION OF THE PARTICLE FINITE ELEMENT METHOD FOR MONOLITIC SOLUTION OF FLUID-STRUCTURE INTERACTION CONSIDERING NEWTONIAN AND NON-NEWTONIAN FLOWS

Luiz Teodoro[*1], Giovane Avancini[2], Darcy Moreira[1] and Rodolfo Sanches[1]*

[1]*University of São Paulo*
[2]*State University of Campinas*

ABSTRACT

This work presents the application of a position-based formulation of the Particle Finite Element Method (PFEM) [1] applied to the monolithic solution of fluid-structure interaction problems considering free-surface incompressible Newtonian flows and non-Newtonian Bingham flows. The same motion description is adopted for both, fluid and solid domains, taking as main variable the current position, making the monolithic solution of the coupled problem straight-forward. However, as solids develop only finite strains, its description always takes the initial configuration as reference (total Lagrangian Description), while for the fluid, we allow the reference to be arbitrarily updated to any other configuration of equilibrium of the fluid domain, enabling partially or fully updated Lagrangian descriptions. For the solid, we consider the Saint-Venant-Kirchhoff elastic constitutive model. The principle of stationary energy is employed to get the weak solution for both, fluid and solid domains, so that it is written regarding current nodal positions for the solid and regard current nodal positions and nodal pressures for the incompressible fluid flow. The Newtonian constitutive model, as well as the Papanastasiou regularization that we adopt for the Bingham model, keep stresses independent of the deformation history. This makes updating the reference for the fluid simple, without the need for considering the stress distribution in the past reference. To deal with the undefined distortions that can occur in the fluid domain, as well as to allow topological changes, we adopt for the fluid domain the PFEM technique, that has as main characteristic considering a cloud of particles as nodes of a finite element discretization that is constantly reconstructed, justifying the updated Lagrangian description of the fluid. To circumvent the Ladyzhenskaya-Babuska-Brezzi restrictions, and allow linear interpolation for both, pressure and position, a pressure stabilizing Petrov-Galerkin technique is employed. The implicit α-generalized strategy is chosen to perform the time integration, enabling second order convergence and ensuring good stability due to the numerical dissipation control. A variety of selected 2D and 3D problems, including dam-break problems over elastic structures, flux valves, and concrete casting, are simulated to assess the formulation. The simulations demonstrate the robustness, versatility, and potential applications of the proposed formulation.

NUMERICAL ANALYSIS OF HOT AIR RECIRCULATION PHENOMENON USING MICRO-WEATHER MODEL, A COMPRESSIBLE LARGE EDDY SIMULATION

Takashi Terada[*1], Ryo Onishi[1] and Xidong Hu[12]*

[1]Tokyo Institute of Technology
[2]JGC Corporation

ABSTRACT

Liquified natural gas (LNG) has been growing its demand as a low CO2 emission energy resource. Its production efficiency is strongly affected by the efficiency of heat exchangers in LNG plants. The Hot Air Recirculation (HAR) phenomenon, which occurs under specific weather conditions such as crosswinds, is one of the important factors that deteriorate the heat exchanging efficiency. The fundamental fluid structure of HAR is the Jet In Cross Flow (JICF), which is common in environmental flows, e.g., heat dispersions into the atmosphere. Many numerical analyses have been performed for JICF using incompressible CFD models that rely on the Boussinesq approximation for buoyancy force consideration. For predictions of HAR in actual atmospheric conditions, it is desirable to use meteorological models that compute unsteady compressible flows (Large Eddy Simulation based on compressible fluid equations, compressible LES). This study presents numerical simulations of JICF using a compressible LES, firstly to confirm the reliability of compressible LES and secondly to investigate the validity of the Boussinesq approximation, which is used in incompressible models, in JICF simulations. The present compressible LES results were compared with those from other incompressible CFD models that employed the same equally spaced grid settings. The comparison has confirmed the reliability of the present compressible LES. It has been also confirmed that the present compressible LES model reproduces the typical vortex structures of JICF.

When calculating the transport of heat by using incompressible models, the Boussinesq approximation is usually employed to consider the buoyancy due to hot air. The approximation is not, however, applicable to large temperature differences between hot air and ambient air. The compressible LES model, which is free from such approximation, can provide a reference for the incompressible models. The present compressible LES model was applied to the case of JICF with hot air, i.e., high temperatures. The obtained reference data has revealed the applicability limits of the Bousinessq approximation.

It is expected that the present results will advance the understanding and the prediction of exhaust heat diffusion phenomena under realistic weather conditions with unsteady winds in the future.

A STUDY OF CONTINUUM-SCALE STRESS CALCULATION ON FINITE ELEMENT METHOD INDUCED BY MOLECULAR-SCALE STRUCTURAL TRANSITION

Yuto Terashima[*1], Paul Brumby[1], Varvara Kouznetsova[2] and Mayu Muramatsu[1]*

[1]*Keio University*
[2]*Eindhoven University of Technology*

ABSTRACT

In this study, we develop a methodology to couple molecular-scale thermodynamic properties, derived from molecular dynamics (MD) simulations, with the continuum-scale finite element method (FEM). Typically with the FEM approach, single-phase constitutive equations are determined a priori to define the stress-strain relationship. However, polymers and gas hydrates, which may undergo structural changes and phase transitions, have multiple stress-strain responses that are condition-dependent. In previous research, it has been observed that polycarbonate exhibits a unique drop in structural resistance with increased void generation. Carbon dioxide hydrate has different mechanical resistances for tensile and shear modes. These features can only be examined using MD simulations, which accurately capture the stress-strain relationships at each stage of the deformation process. To capture these properties and, in turn, determine their relation to continuum-scale stress fields, we utilized MD simulations as a replacement for specific constitutive equations in the FEM scheme. To begin with, we propose a fully coupled FEM-MD approach. For the FEM scheme, we utilized a work conjugate of the first Piola Kirchhoff Stress tensor and the deformation gradient. This allows us to incorporate the non-linear region of the stress-strain relationship. The update of the displacement is performed by explicit time integration with the central difference scheme. Then, the deformation gradient tensor is calculated at each integration point and applied to the boundary conditions of the representative unit-cell (r-cell) in the MD simulation. For MD simulations, a certain amount of time is required for equilibration and potential energy minimization. Here, we used a Nose-Hoover thermostat to maintain the r-cell's temperature. From the equilibrated r-cell, we obtain the Cauchy stress tensor and use it as a substitute for the internal force in the FEM scheme. Subsequently, we compare the results of fully coupled FEM-MD with one-way coupled FEM-MD, which we developed previously. Since the one-way coupled approach does not receive feedback from MD, continuum-element deformation is determined only from FEM calculations. On the other hand, in the fully coupled approach, there is an interplay between the continuum and molecular scales which results in relaxing the stress-strain response. In the future, we plan to establish a methodology to fully capture the relationship between molecular-scale structural stability and deformation history at the continuum-scale of the material.

A DIGITAL TWIN FRAMEWORK FOR CIVIL ENGINEERING STRUCTURES

Matteo Torzoni[1], Marco Tezzele[2], Stefano Mariani[1], Andrea Manzoni[1] and Karen Willcox[2]*

[1]Politecnico di Milano
[2]The University of Texas at Austin

ABSTRACT

In this talk, I will present a digital twin (DT) formulation for the structural health monitoring of civil engineering structures [1], with a focus on bridges.
A DT is a virtualization of a physical asset built upon a set of computational models that dynamically update to persistently mirror a unique asset of interest throughout its operational lifespan, enabling informed decisions that realize value.
The talk covers the health monitoring, predictive maintenance, and management planning of civil structures. The asset-twin coupled dynamical system is encoded using a probabilistic graphical model (PGM) [2] which provides a general framework for data assimilation, state estimation, prediction, planning, and learning while accounting for the associated uncertainty. The assimilation of high-dimensional multivariate time series describing the vibration response is carried out by exploiting physics-based reduced order methods and deep learning models. The numerical models allow automated selection and extraction of optimized damage-sensitive features and real-time assessment of the structural state of a bridge.

EXPLORING RIEMANN SOLVERS, MACHINE LEARNING SURROGATES, AND SHOCK TRACKING IN HYPERBOLIC PDE SYSTEMS

Akshay Thakur[*1] and Matthew Zahr*[1]

[1]*University of Notre Dame*

ABSTRACT

In the computational modeling of systems governed by hyperbolic partial differential equations (PDEs), Riemann solvers (RS) assume a pivotal role. The landscape of available Riemann solvers encompasses various options, each characterized by distinct merits and drawbacks related to accuracy, computational efficiency, and cost. Preeminent among these solvers is the exact RS, acknowledged for its superior accuracy; however, its implementation is intricate and computationally demanding. Conversely, the Roe solver and the Harten, Lax, and Van-Leer (HLL) solver offer simplicity and computational efficiency, yet the former falters in addressing strong shocks and contact discontinuities, while the latter tends to yield excessively diffusive solutions and struggles with intricate wave structures. Both solvers also grapple with challenges in handling transonic rarefactions, and the Roe solver lacks positivity preservation. Modifications, such as entropy fixes for Roe or the HLL with Contact solver, may enhance accuracy selectively but lack universality. Concurrently, the application of machine learning, particularly deep learning, has witnessed a notable surge in the field of mechanics. Consequently, the integration of deep neural networks (DNNs) as surrogates for exact RSs has gained attention, offering cost-effective approximations while preserving critical attributes like resilience in the face of strong shocks or transonic rarefactions. This study endeavors to craft a DNN-based surrogate endowed with additional properties, including hyperbolicity, conservation, and consistency, through the assimilation of concepts from the burgeoning field of differentiable programming. Furthermore, our objective is to harness this surrogate in the domain of shock tracking, a field experiencing renewed interest, characterized by frequent encounters with strong shocks and intermittent confrontations with transonic rarefactions.

ABSTRACT

Fatigue is one of the most studied and modeled phenomena in engineering practice due to its practical importance. In this talk, we describe a novel smooth yield rate-independent J2 plasticity-based constitutive theory for modeling plastic deformation in metals [1], and its efficacy is demonstrated by the accurate prediction of low-cycle to high-cycle fatigue life in a variety of metallic alloys (aluminum, steel etc.) even under variable amplitude loading conditions [2]. The key aspect to our theoretical approach is that we are able to accurately track the hysteresis caused by micro-plastic deformation which occurs under fatigue loading, and this is the physical cause for fatigue-accumulated damage in metallic materials. We have also computationally-implemented the smooth yield plasticity-based constitutive model into the implicit-based ABAQUS/Standard finite-element program through a UMAT subroutine interface [3], and the numerical implementation of the constitutive theory into a finite-element framework is shown to be robust.

Traditionally, the material parameters responsible for the estimation of fatigue life are determined through a series of low-cycle to high-cycle fatigue experiments e.g. through a unified Coffin-Manson and Basquin approach. However, in our approach, material parameters in the constitutive theory were calibrated to a single uniaxial and cyclic loading simple compression experiment, and a single low-cycle fatigue experiment (less than a few hundred cycles). With the constitutive parameters calibrated, we are then able to independently and accurately predict a variety of fatigue experiments from low-cycle to high-cycle loading conditions under uniaxial (cyclic tension-compression) and multi-axial loading conditions (axial-torsional under proportional or non-proportional loading) through a series of finite-element simulations [3]. Finally, another main contribution of the present work is that our developed theoretical and computational framework for modeling uniaxial and multi-axial low-cycle and high-cycle fatigue loading in metals is able to provide a better prediction for fatigue life estimation compared to several other popular fatigue life prediction-based models in the literature.

PREDICTION OF PATIENT-SPECIFIC KNEE JOINT DYNAMICS IN TIBIAL FRACTURES

Elin Theilen[*1], Anna Rörich[1], Joachim Georgii[1] and Kaywan Izadpanah[2]*

[1]Fraunhofer MEVIS
[2]University Hospital Freiburg

ABSTRACT

Introduction
The knee joint is one of the most complex human joints and fracture or morphology of the human femur and / or tibia are among the most common in the event of osteoporosis or injuries. Since the tibia supports a great amount of body weight, it plays an important role in maintaining the stability and functionality of the knee joint. Understanding the importance of tibia fractures in knee dynamic analysis is crucial not only for assessing the extent of the injury but also for predicting critical dynamical motion and making informed decisions about the necessity of surgery. Models that take into account the patient-specific knee joint motion are supposed to largely improve surgery planning and outcome. State-of-the-art finite element (FE) knee joint models are highly complex, computationally demanding and time-intensive.

Methods and results
We propose a simplified knee joint model based on position-based dynamics (PBD) for real-time prediction of patient-individual knee joint motion [1]. The PBD-model was successfully verified against to the state-of-the-art FE model [2] in dynamic knee motion. Magnetic resonance (MR) images of human knees were obtained in a study of eleven healthy volunteers, which was approved by the ethics committee of the Albert-Ludwigs University Freiburg (Nr. 91/19 – 210696, 19 August 2021). We compared two motion sequences going from 0° knee flexion to 20° flexion and adding 1) internal or 2) external rotation torque [3]. The PBD model predicts similar motion while being approximately 150-times faster.

To analyse fracture defects, we additionally consider different artificial tibial fractures in the dynamic analysis to understand critical impacts on knee joint motions and derive whether treatment is necessary. We believe that PBD prediction yields a good trade-off between accuracy and time constraints and thus, is able to efficiently support the clinical workflow.

ABSTRACT

In Part 1 we demonstrated that Hammerstein-Wiener (HW) models are an effective tool for modeling a circuit's behavior, especially when the behavior can be easily separated into a nonlinear, DC, portion and a linear, AC, portion, such as in, e.g., amplifier circuits. In this talk we shall focus on the development of such models for a simple differential amplifier with particular emphasis on effects that depend on the frequency of the input signal. Specifically, differential amplifiers exhibit gain degradation and phase shift as this frequency increases. Capturing this behavior in the time domain requires training data spanning a wide range of frequencies and can lead to very large training datasets.

In this talk we show that training the linear time invariant (LTI) block of the HW model in the frequency domain is an effective alternative to training in the time-domain data that leads to significant reduction in the size of the necessary data sets. In particular, the training process reduces to a regression of a rational function (the transfer function) from frequency domain data. Once this function is fitted, it is trivial to convert the model back to the time domain thereby enabling conventional Spice time-domain simulations.

Lastly, for the HW model to be useful in numerous situations, it has to be generalized to operate for different loads at its output. To that end we fix the structure of the rational function representing the transfer function and treat its coefficients as functions of the load. Given a desired load range for the circuit simulation we then sample this range at a finite set of loads and learn the coefficients corresponding to each load value. To simulate the circuit at a specific load value in the desired range we use interpolation between these predetermined coefficients to construct a transfer function corresponding to the specified load value. Again, this function can be easily converted from the frequency domain to the time domain to perform conventional Spice simulations.

INVERSE DESIGN OF PERIODIC MICROSTRUCTURES WITH TARGETED NONLINEAR MECHANICAL BEHAVIOUR

Dilaksan Thillaithevan[*1], Ryan Murphy[1], Robert Hewson[1] and Matthew Santer[1]*

[1]*Imperial College London*

ABSTRACT

Structural metamaterials derive their mechanical properties from the distribution of material on the microscale, typically in the form of discrete microstructure geometries, rather than the properties given by the bulk material. Interest in structural metamaterials has greatly accelerated with the increased adoption of additive manufacturing (AM) technologies. Metamaterials offer the possibility of designing materials with highly tailored, application specific properties. This work introduces an inverse design framework for the precise tailoring of desired nonlinear mechanical responses in periodic microstructures, with particular focus on prescribed nonlinear stress-strain relationships. The topology optimization hinges on minimizing the error between the target and realized properties of the microstructures, using a deformation-driven homogenization framework. The periodic constraints needed for the microscale equilibrium equation are imposed through strongly enforced periodic boundary conditions and the removal of the translational nullspace, avoiding the need for Lagrange multipliers, greatly simplifying the implementation. To further aid the design of discrete designs an intermediate density penalty constraint is proposed.

Two main contributions are made to the state-of-art in this field:
1) A effective framework for designing periodic microstructures with targeted nonlinear stress-strain relationships is developed;
2) An intermediate density penalty constraint formulation is presented to encourage the formation of discrete microstructure designs and further aid the optimization convergence.

Using a materially linear but geometrically nonlinear hyperelastic model, a deformation-driven homogenization approach is utilised to derive the homogenized quantities required for the optimization. Several numerical examples are tackled to demonstrate the efficacy of the framework. We demonstrate that the framework is able to design microstructures that accurately replicate the targeted stress-strain relationships with less than 10% errors. The IDP constraint is also shown to encourage the formation of discrete microstructure topologies with less than 2% grey material in all designs. As discrete designs better promote nonlinear behaviours, the IDP constraint further aids the optimization convergence. Finally, the effect of initialisation is also studied.

This framework lays the foundation for multiscale nonlinear optimization, where nonlinear structures are optimized on the microscale (either concurrently or in a offline manner) to design nonlinear macroscale structures with highly nonlinear structural responses. For example, the design of deployable nonlinear structures which exhibit bi-stable behaviours and or deploy at targeted loads.

A NOVEL DIFFUSION TENSOR BASED MYOCARDIAL MATERIAL MODEL: FORM DETERMINATION USING NEURAL NETWORKS

Benjamin Thomas[*1], Christian Goodbrake[2] and Michael Sacks[1]*

[1]*Oden Institute for Computational Sciences and Engineering*
[2]*The University of Texas at Austin*

ABSTRACT

Cardiac tissue has a very complex structure that induces substantial local mechanical anisotropy that varies with anatomical location and in various pathologies. Structural information for cardiac tissue is readily available using Diffusion Tensor Magnetic Resonance Imaging. Interestingly, to date only the eigenvectors of the diffusion tensor D have been used to determine the local fiber direction in myocardial material models. Yet, D contains much more tissue structural information. In the present study, we developed a novel method to directly incorporate D into the material model, allowing for locally heterogenous anisotropic mechanical behaviors within each test specimen. To quantify the unknown form of the material model, we introduced a neural network to represent the strain energy function following [1]. In this approach automatic differentiation tools are utilized to streamline computations. This approach allows for generalized model form determination directly from the experimental data. This is a very important step as form determination for hyperelastic biological tissues remains a major hurdle in accurate simulation of disease and surgical planning.

The inverse model framework starts by acquiring force-displacement pairs from the experimental data. A generic form was provided to the inverse model containing the pseudo-invariants I4 and I5. A JAX-FEM solution was found where the material is modeled as nearly incompressible. The parameters are then trained by minimizing the error between the force data and the prediction of the model. The gradients were obtained from the JAX-FEM solver through automatic differentiation. During training, if parameters fall to zero, it shows terms disappearing from the final form.

The method was first tested on the Li model [2], which was used to fit highly anisotropic myocardial data using the eigenvectors of D. This dataset contains 5 specimens tested under various protocols. Based on the results of the new form, we developed form for the directional strain energy using exponential forms of I4 and I5. To allow for local heterogeneity, D was incorporated as a weighting distribution. We note that tension/compression differentiation was also required, unique to modeling. The final form obtained an excellent fit to the data with only three material constants. The incorporation of D gives the material model more structural information making the final form much simpler, as well as allowing for regional heterogeneity. Next steps include incorporation into full 3D cardiac models.

ABSTRACT

This work presents a comprehensive exploration of the implementation of smooth spline shape functions and the immersed finite cell method for the simulation of high deformation Lagrangian mechanics in blast scenarios. The focus is on demonstrating computational efficiency and robustness through the utilization of these techniques. The implementation of the finite cell method is discussed in detail, supported by specific examples showcasing its effectiveness.

The study incorporates Cook's membrane to elucidate how the integration of smooth spline shape functions, finite cell method, and reduced quadrature methods can mitigate material locking issues. Plastic deformation is analyzed through Taylor impact simulations, providing insights into the behavior of materials under high-deformation conditions.

To assess the capability of the proposed methods in wave propagation, the Hopkinson bar is employed. The results illustrate that smooth splines and an immersed mesh can accurately approximate the mechanics of waves propagation.

Furthermore, the study explores diverse scenarios, including example penetrators, self-contact situations, and the buckling of a square tube. Each scenario serves to highlight the versatility and applicability of the implemented techniques in a number of common situations.

In conclusion, the presented work not only details the implementation of smooth spline shape functions and the finite cell method but also demonstrates their efficacy through a series of simulations. The findings in this work contribute to the advancement of automated computational methods for accurately and efficiently modeling complex high-deformation scenarios in Lagrangian mechanics.

ABSTRACT

The modified Immersed Finite Element Method (mIFEM) [1] is an overlapping mesh method that couples a Lagrangian foreground solution with an Eulerian background solution. Coupled analysis techniques like the mIFEM can be used to model crash or impact/penetration scenarios, combining a Lagrangian mechanical system model with an Eulerian model of the material being impacted. These classes of problems often involve extensive contact, and the mechanics between material surfaces (e.g., bonding, frictionless sliding, Coulomb friction, nonlinear pressure dependent friction) can strongly influence the response of systems. We explore formulations of interface mechanics between Lagrangian surfaces and Eulerian materials using the mIFEM. We present the mIFEM coupling method and numerically investigate contact formulations on a set of exemplar problems. Accuracy will be assessed against canonical contact and impact cases, and the favored formulation is demonstrated with a realistic example problem.

SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

ADIABATIC SHEAR BAND MODELLING IN TI6AL4V USING FINITE ELEMENT APPROACHES

*Ben Thorington-Jones**[1]

[1]*Atomic Weapons Establishment*

ABSTRACT

Ti6Al4V is an alloy which is widely used in industry due to it having a number of desirable properties, including its high strength to density ratio. However, the material is highly susceptible to failure via the adiabatic shear banding mechanism. Whilst there exists a large sum of simulation work in the literature on the topic, appropriate methods for the meshing and treatment of the material heterogeneity, which influences the processes of shear band initiation and development, remains an active area of research.

The present study utilises 3D finite element hydrocodes to assess the modelling sensitivities in simulations of spontaneous shear band formation, using the thick-walled cylinder experimental geometry. To capture the effect of material heterogeneity, a Lagrangian perturbation field is applied to the yield strength, inducing localisation in the target material.

CHALLENGES AND APPROACHES FOR REINTEGRATING REDUCED-ORDER MODELS IN CIRCUIT SIMULATION

Heidi Thornquist[*1] and Ting Mei*[1]

[1]*Sandia National Laboratories*

ABSTRACT

Reduced-order modeling has been an active area of research for several decades, focusing on the creation of efficient and accurate approximations for computationally expensive mathematical models. For circuit simulation, reduced-order models have been extensively studied for large interconnect networks that are often embedded in larger VLSI (Very Large Scale Integrated) circuit designs. For nonlinear and linear time-varying circuits, methods have also been considerably explored, but to a lesser extent than their linear time-invariant (LTI) counterparts. This presentation will focus on what is rarely addressed in literature, the practical aspects of reintegrating reduced-order models into a larger circuit design. The discussion will illustrate challenges and demonstrate viable approaches for implementing a modular design flow that includes reduced-order models using Xyce [1].

Xyce is an open source, SPICE-compatible, high-performance analog circuit simulator that provides both time and frequency domain analysis capabilities. Internal to Xyce there are methods for reducing LTI circuits based on moment-matching approaches, like the Passive Reduced-Order Interconnect Macromodeling Algorithm (PRIMA) [2]. This algorithm will be used as an exemplar to explore the challenges of reintegrating reduced-order models into a modular design flow and illustrate approaches, like sparsification [3], that can help reduce total simulation time. Approaches for reintegrating reduced-order models developed external to Xyce will also be discussed.

IGA-BASED MODELLING OF WET GRINDING PROCESSES WITH SPECIAL FOCUS ON HYDRODYNAMIC PROPERTIES

Paul Thunich[*1], Yan Tong[1], Michael Müller[1], Oliver Schömig[12], Robar Arafat[12] and Christoph Herrmann[12]*

[1]*Technical University of Braunschweig*
[2]*Fraunhofer Institute of Surface Engineering and Thin Films (IST)*

ABSTRACT

In grinding processes, process parameters are usually set based on experience or empirical trial-and-error tests, as there is limited knowledge about basic interactions. Especially in the development of new cutting fluids, a conflict arises between cooling effects and hydrodynamic load-bearing effects. Therefore, a model should be developed, in order to investigate interactions and optimize wet grinding processes.

Besides this hydrodynamic conflict, further processes and properties determine the wet grinding process. These include the contact mechanics of the grain-workpiece interface, the temperature distribution, the temperature rise due to friction and fluidic friction and the associated viscosity decrease, the grinding wheel structure, as well as abrasion and deformation effects and even the cutting fluid supply strategy, all of which more or less influence the grinding performance. Therefore, it is generally challenging to develop a model which considers all subprocesses and properties to a satisfactory level for wet grinding.

With a special focus on the cutting fluids in grinding, this paper presents a hydrodynamic analysis of the process, which is done by using the Reynolds equation and NURBS-based isogeometric analysis (NURBS-IGA). In combination with a mortar-based cavitation algorithm and the heat equation, a model within the NURBS-IGA framework is built that enables the contact properties to be modelled within reasonable time. The results generated by the model correspond to modelling results from commercial CFD tools such as Ansys Fluent with good accuracy. In this context, the necessary stabilization techniques need to be mentioned, necessitated by the convection-dominated governing equations and the small number of computational nodes in the NURBS-IGA. Additionally, it can be shown to what extent the consideration of dependencies of the material properties of the fluids is necessary and in which cases they can be neglected to decrease the computational cost. The resulting model is a performant description of the hydrodynamic effects, which is easily applicable to other cases like lubricated journal bearing calculations and that is also validated via experimental measurements.

Finally, to model the entire wet grinding process, the model is combined with other influencing factors in the further course. These include the consideration of the grinding wheel porosity, which reduces the maximum hydrodynamic pressure generated, the material removal and further influences, all within the framework of NURBS-IGA.

In this way, the model is a valuable basic approach and has a large potential for construction of complex models and even iterative optimizations in the field of wet grinding.

FRACTURE PATTERNS AND DYNAMICS OF SOFT MATERIALS□PHASE FIELD MODELING

*Fucheng Tian**[1]

[1]*Hokkaido University*

ABSTRACT

Soft materials possess unique traits of withstanding large strains and exhibiting high recoverability, rendering them irreplaceable in cutting-edge fields such as life sciences and soft robotics. Understanding the complicated fracture behavior of such materials is not only of urgent application demands but also a longstanding pursuit in interdisciplinary fundamental research, spanning the realms of materials science, physics, and nonlinear mechanics. A well-grounded theoretical framework has been established to date for fracture in linear elastic regimes. However, the fracture in soft materials typically involves nonlinearities associated with large strains, exhibits diverse dynamic morphologies, involving straight, oscillation, branching, and supershear fracture. These intricate crack dynamics are believed to be associated with nonlinearity. Using the latest developed dynamic phase-field model, we successfully reproduce various crack morphologies and establish crack stability phase diagrams for three distinct soft materials. The contrasting phase diagrams highlight the crucial role of nonlinearity in regulating crack dynamics. In strain-softening materials, crack branching prevails, limiting the cracks to sub-Rayleigh states. Yet strain-stiffening stabilizes crack propagation, allowing for the presence of supershear fracture. Of particular interest is the large-strain linear elastic materials, where crack oscillation is readily triggered. Moreover, our findings suggest that the increase in characteristic wave speed due to strain-stiffening can account for the observed transition of cracks from sub-Rayleigh to supershear regimes.

EXPLORING MECHANICS AND PIEZOELECTRIC PROPERTIES VIA MULTI-SCALE SIMULATIONS IN DEFECT-ENGINEERED ZINC INDIUM SULFIDE (ZIS) FOR PHOTOCATALYTIC WATER SPLITTING

Ming-Yuan Hung[1], Yen-Ting Kuo[1], Jih-Jen Wu[1] and Hong-Kang Tian[1]*

[1]National Cheng Kung University

ABSTRACT

This study delves into the realm of chemically complex materials, focusing on Zinc Indium Sulfide (ZnIn2S4, ZIS) for efficient photocatalytic water splitting into hydrogen (H2) and oxygen (H2). Recognizing the pivotal role of microstructures in chemically complex materials, our research emphasizes the impact of defects in ZIS, a material with multiple principal chemical components, on its H2 production efficiency. We explore the optimization of material defects, particularly sulfur (S) and indium (In) vacancies, under external stress to enhance H2 production through dipole and piezoelectric effects. To unravel the intricate process-structure-property relationships in ZIS, we utilize a multi-scale computational approach. Density Functional Theory (DFT) is employed to calculate dipole moment, dielectric, elastic, and piezoelectric properties under varying defect compositions. These properties are then integrated into a continuum model developed through Finite Element Analysis (FEA), bridging mechanical and electrical phenomena to simulate the electric potential distribution (voltage) in both pristine and defective ZIS. Our simulations demonstrate a marked increase in voltage, induced by internal dipole moments and piezoelectric effects, especially pronounced along the (100) and (010) crystal orientations in defective ZIS. This enhanced voltage leads to improved charge separation, substantially increasing the H2 production rate upon electron excitation and generation of electron/hole pairs. Our findings contribute vital insights into the microstructural influences on the photocatalytic performance of ZIS, offering design principles for advanced materials in renewable energy applications. This study exemplifies the power of computational techniques in elucidating the complex interplay between microstructure and properties in chemically complex materials, aligning with the core focus of this symposium.

DIGITAL TWIN FOR STRUCTURAL LOAD-CARRYING CAPACITY MONITORING AND PREDICTION

Kuo Tian[1]*

[1]*Dalian University of Technology*

ABSTRACT

The digital twin method is proposed for the structural load-carrying capacity monitoring and prediction of complex shells. Firstly, a multi-source data fusion approach is introduced to integrate simulation data with sensor readings, enabling the construction of a high-accuracy and robust digital twin. Secondly, an optimal sensor placement strategy is established for complex curved structures, enhancing the monitoring efficiency of sparse sensors. Thirdly, a dynamic update method for the digital twin is developed based on a reduced order model, ensuring the accuracy and reliability of the digital twin in practical strength assessment scenarios that account for deviations. Finally, the proposed method's effectiveness is validated through structural strength tests on open hole panels, hierarchical stiffened plates, and cargo spacecraft cabins. The results demonstrate that the method can achieve real-time and high-accuracy structural load-carrying capacity monitoring and prediction of complex shells.

PERIODIC LAGRANGIAN ANALYSIS WITH MESH RECONSTRUCTION FOR OFFSHORE GEOTECHNICAL LARGE DEFORMATION PROBLEMS

Ran Tu[1], Huan Zhao[2], Shubhrajit Maitra[1] and Yinghui Tian[*1]*

[1]The University of Melbourne
[2]Tianjin University

ABSTRACT

Large deformation process is commonly encountered in offshore geotechnical applications, with typical examples including penetrometer penetration, anchor installation (keying), spudcan preloading and pipeline laying and buckling. Numerical large deformation modelling still remains one of the most challenging aspects of computational geomechanics. Offshore engineers require reliable and accessible numerical approaches to simulate large deformation processes. The traditional Lagrangian finite element analysis is inadequate due to excessive mesh distortion. An efficient approach, Periodic Lagrangian Analysis with Mesh Reconstruction, is proposed to overcome the numerical difficulties. This paper first offers a narrative of currently available large deformation modelling approaches within the space of offshore geotechnics. Periodic Lagrangian Analysis with Mesh Reconstruction is then proposed with clear demonstration of concept and implementation. The performance of the proposed approach is demonstrated by showcasing some of its applications to model: (a) anchor trajectory during installation of plate anchor; (b) penetration of conical footings; and (c) spudcan penetration next to an existing footprint.

[3]*University of California, Berkeley*

ABSTRACT

Ever since the successful isolation of graphene in 2004, two-dimensional (2D) materials have garnered much attention due to their vast possibilities of property tuning, making them promising candidates for various applications in next-generation electronics. Employing first-principles calculations, we perform a series of studies examining the nuances of tuning the structural and electronic properties of 2D materials, providing insights into the novel design of related devices.

A prevalent approach to property modulation is strain engineering. However, rippling—a consequence of the intrinsic instability in free-standing 2D sheets—becomes prominent, especially during in-plane compression. In the literature, this rippling phenomenon has been proven to have a contrasting, remarkable impact on the properties of different 2D materials. Using antimonene as a case study, we demonstrate a systematic way of examining the effects of rippling by comparing the flat and rippled structures under uniaxial in-plane compression, and the underlying mechanism is scrutinized. Rippled antimonene is shown to exhibit highly stable properties like the work function and band gap upon structural relaxation at a range of compression levels, closely resembling its pristine state. Conversely, various changes are observed in its flat counterparts. The identification of optimal ripple amplitudes under strain for which the electronic properties of the pristine condition can be recovered will be highly significant in guiding the rational design of antimonene-based devices.

Further, we delve into the impact of out-of-plane compression. Fermi level pinning (FLP) at metal–2D semiconductor contact can hinder the tuning efficacy. We perform a detailed investigation of contact systems formed by common electrode materials and 2D tin monoxide (SnO), a promising transistor channel material. By analyzing the geometry, bonding strength, charge transfer and tunnel barriers of charges, and electronic properties, we unearth the mechanisms behind FLP. We also propose the insertion of a graphene buffer layer at the contact, which efficiently alleviates the metal-induced gap states and enhances the tunning efficiency of out-of-plane compression. This work scrutinizes the possibilities of employing monolayer SnO in field effect transistors by systematically examining its contact with various electrode materials and methods of property tuning. The established model can be modified in the future to accommodate other factors to assess their impacts on the contact performance.

[2]*Georgia Institute of Technology*

ABSTRACT

Particle-reinforced metal matrix composites (MMCs) are composed of ceramic particles in a metal alloy matrix. The toughness and light weight of the ductile metal matrix in concert with the stiffness and strength of the ceramic reinforcement are exploited to enhance properties—such as the tensile strength, fatigue strength, high-temperature stability, wear resistance, thermal shock resistance, and general functionality—relative to the individual constituents. Conventional manufacturing of MMCs by casting or powder metallurgy has limited production to parts with simple geometries that are expensive with high lead and machining times. However, the use of additive manufacturing (AM) has enabled components to be made with high geometric complexity and customization, and rapid prototyping with a lower cost. Specifically, laser powder bed fusion (LPBF) produces geometrically complex MMC structures with easily adjustable amounts of reinforcement particles, attractive strength and weight characteristics, and desirable microstructure characteristics such as small grain sizes and more equiaxed grain shapes, all influenced by manufacturing parameters and composition. Optimization of MMC properties and parameters done experimentally requires large amounts of time and resources to produce powders of varying compositions, print high quality parts using LPBF, and analyze the physical and mechanical properties. Thereby, to achieve tailorable designs of MMCs that efficiently meet specific mechanical performance targets requires high-fidelity models that accurately capture the effects on the hardening and damage evolution of the MMC.

In this work, we propose a modeling framework based on a large-strain elasto-viscoplastic fast Fourier transform (FFT) code, in which we incorporate a work-hardening formulation coupled with triaxiality-based continuum damage mechanics to model the hardening and damage evolution of MMC material as a function of particle reinforcement composition. While most models of MMCs focus on one or two hardening mechanisms for a specific composition, our proposed model considers several hardening mechanisms specific to both MMCs and the AM process while accounting for the effects of reinforcement particle composition. The main hardening mechanisms considered are geometrical differences between the metal matrix and the spherical particle, differences in thermal expansion exasperated by the AM process, differences in hardness between the metal matrix and the ceramic particles and increases in grain boundary abundance compared to the pure matrix material. The superposition of hardening mechanisms, efficacy of the framework, and inspection of fracture-initiation-to-microstructure-neighborhood relationships will be presented. The framework will make the task of exploring the high-dimensional design space for polycrystalline MMCs by AM tractable.

ABSTRACT

Molecular dynamics simulations use detailed models based on atomistic or near-atomistic resolution to simulate the properties of biomolecular systems. Lipid nanoparticles are the technology used to deliver mRNA vaccines and have broad potential for drug and gene delivery in general. A key ingredient in these formulations is cationic lipids that change protonation state during processing in endosomes inside the cell before their cargo is released. We have simulated the properties of these cationic lipids in several contexts relevant for drug uptake and release through local remodeling of lipid nanoparticles and endosomal membranes. We are attempting to link these to the efficacy of mRNA release.

THERMODYNAMICS INFORMED GRAPH NEURAL NETWORKS FOR DOMAIN DEPENDENT PROBLEMS

Alicia Tierz[1], Icíar Alfaro[1], David González[1], Francisco Chinesta[2] and Elías Cueto[1]*

[1]*University of Zaragoza*
[2]*ENSAM Institute of Technology*

ABSTRACT

Currently, Computational Fluid Dynamics (CFD) and Solid Mechanics (CSM) tools deliver precise simulations, enabling companies to save substantial resources in comparison to traditional methods. However, a significant drawback lies in the extensive CPU time required for a single simulation. This computational cost escalation is due to the complex physics inherent in these models and the necessity for a large mesh size to analyze intricate geometries. To mitigate this prolonged processing time, Deep Learning (DL) is being harnessed to address the issue, yielding real-time results with minimal compromise on accuracy.

Presented here is a DL approach aimed at predicting various scenario specifics within specific domains, such as fluid movement in a glass or the behavior of a viscoelastic beam. We advocate for the incorporation of both geometric and thermodynamic data to refine the precision and adaptability of the resulting integration approach. To harness information derived from the Lagrangian portrayal of movement, we will employ graph neural networks (GNNs) [1]. The application of geometric deep learning reduces data consumption due to inherent symmetries in the problem.

The architecture is meticulously designed to learn the GENERIC (General Equation for Non-Equilibrium Reversible Irreversible Coupling) [2] structure of the problem, an extension of the Hamiltonian formalism used for modeling broader non-conservative dynamics.

The employed architecture is rooted in Thermodynamics Informed graph neural networks [3]. A comprehensive database is constructed using a CFD tool, utilized to train the graph-based structure. The network undergoes testing across various geometries and materials. In addition, the model will be tested with never-before-seen physical conditions to verify that it is capable of generalizing physical behavior well.

A MODIFIED INHERENT STRAIN MODELING FRAMEWORK FOR PREDICTING RECOATER INTERFERENCE IN LASER POWDER BED FUSION

Wen Dong[1], Shawn Hinnebusch[1] and Albert To[1]*

[1]University of Pittsburgh

ABSTRACT

Preventing recoater interference and crash is essential in laser powder bed fusion (L-PBF) process for printing parts with overhangs. These issues may compromise product quality by increasing surface roughness, reducing dimensional accuracy, and introducing defects into the parts. This work proposes an integrated simulation and experimental framework to predict potential recoater interference for a given part designed for L-PBF fabrication. In this framework, the criterion for recoater interference is defined to occur when the deformation of the part in the build direction exceeds the thickness of a newly spread powder layer after recoating. The largest deformation in the build direction is assumed to occur at the edge of a part and is postulated to be the sum of two contributions: global thermal deformation and local edge deformation. The global thermal deformation, generated by relaxation of the thermal stresses induced by the rapid laser melting and solidification over the entire part, is predicted using the modified inherent strain (MIS) method. A key novelty in this work lies in employing location-dependent inherent strains (ISs) in the MIS method to simulate the global thermal deformation of overhangs, which shows 60% improvement in prediction accuracy compared with that using constant ISs. On the other hand, the local edge deformation, associated with the melt pool dynamics and deformation near the edge, is estimated by reconciling the MIS simulated and experimentally measured deformation on several overhang wedges. The validity of the proposed framework for predicting recoater interference is confirmed by experiments on different part geometries with overhangs.

COMPUTATIONAL MODELLING AND OPTIMIZATION OF LEPTOMENINGEAL ANASTOMOSES CONFIGURATION: A PATIENT-SPECIFIC APPROACH USING 4D FLOW MRI AND SPECT

Chi Hang To[1], Shigeki Yamada[2] and Marie Oshima[1]*

[1]*The University of Tokyo*
[2]*Nagoya City University*

ABSTRACT

Leptomeningeal anastomoses (LMAs) are arteries connecting otherwise terminal vasculature territories on the cerebral cortex. They aid ischemic stroke recovery by restoring blood flow to inadequately perfused regions. Quantitative assessment is challenging due to their small size and inter-individual variability not captured by MRI scans. Various models have been created to simulate LMAs [1], differing in interpretation of sparsity and scale of LMAs.

The study aims to depict the probabilistic location of LMAs patient-specifically, understanding collateral flow ramifications. As objectives, we develop a two-part peripheral artery model for explicit LMA placement and optimize LMA configurations using measured flow rate data.

We introduce a peripheral artery model with inlet radii derived from measuring outlets of a reconstructed Circle of Willis model from medical images. The number, location and size of the cortical branch roots are stochastically generated in the proximal portion according to anatomical data [2]. The distal network follows Murray’s law for physiological consistency. The model's structure and peripheral resistances align with medical observations and literature values [3] respectively.

The optimization uses 4D-flow MRI data for proximal blood flow and Single Photon Emission Computed Tomography (SPECT) data for distal perfusion in six vascular territories. Using genetic algorithm, spatial arrangement of LMA becomes the decision variable, while the cost function compares SPECT-derived perfusion rates with computed distal flow rates. Iteratively adjusting LMA location, we alter blood flow redistribution across territories, such that computed flow rates satisfy measured SPECT data in each perfusion region.

Moving forward, the authors aim to compare the optimization effectiveness and computational efficiency of genetic algorithm and binary particle swarm optimization algorithm. The latter method represents each potential LMA connection as a dimension in the particles’ positions within the search space, enabling management of individual LMAs within an arrangement.

The case study involves patients with a stenosed internal carotid artery (ICA). Once the cost function falls below a threshold relative to the SPECT flow rate, indicating recreation of measured blood flow redistribution, the validated arrangement of LMAs is examined. The spatial density, radius, and distribution of LMAs across vascular regions correspond to reported values. The authors plan to further validate the model by comparing it to previous studies, such as models generated using constrained constructive optimization algorithm.

MODELLING OF 3D WOVEN TEXTILE REINFORCED CEMENT COMPOSITES RVES

Christian Toderascu[*12], Thierry J. Massart[1] and Tine Tysmans[2]*

[1]Université libre de Bruxelles
[2]Vrije Universiteit Brussel

ABSTRACT

Textile reinforced cement composites (TRC) use fibre textiles instead of steel reinforcement. Doing so, thinner and more free-form concrete elements can be produced with higher resource efficiency. While 2D textiles are state of the art, the integration of transversal connections to create 3D textiles improves not only the manufacturing process but also the mechanical bending behaviour of TRC elements. 3D woven textiles have shown relevancy in the construction world due to the cross-sectional optimisation they allow [1]. Models have to incorporate the 3D nature of the reinforcement to properly account for the interactions with the (cracking) cementitious matrix. 3D through thickness models with an explicit representation of the through thickness connections are indeed required for this purpose. Yet, no computational model for this type of material architecture has been proposed until now, partly due to the complexity of the woven reinforcement geometry. This contribution will develop a generation procedure to build the geometry of a mesoscale through thickness Representative Volume Element (RVE) model of a 3D woven reinforced TRC. This computational model will aim to assess the mechanical behaviour of the composite material under bending-type loading, determine the internal stress/strain fields, and analyse the interaction of the reinforcement with the cementitious matrix having degrading mechanical properties. To this end, an iterative geometry generation scheme is developed starting from concepts previously used for polymer-based composites. In particular, a geometrical tensioning procedure is applied to a simplified geometrical configuration of reinforcing yarns. This tensioning procedure is further combined with an interpenetration solving procedure to produce 3D woven textiles geometries [2]. A discretisation finite element meshing procedure is subsequently used to create the RVE. It will be illustrated that this modelling procedure can be the basis of future developments and computational prediction for TRC materials with complex textile geometries. Based on RVE simulations under bending loadings using computational homogenisation procedures, the average (macroscopic) behaviour associated with the matrix degradation and the progressive transfer of stresses to the reinforcing textile will be assessed.

A STRUCTURE-PRESERVING MATRIX-FREE FINITE ELEMENT METHOD

Svetlana Tokareva[*1], Steven Walton[1] and Nathaniel Morgan[1]*

[1]*Los Alamos National Laboratory*

ABSTRACT

We present a three-dimensional matrix-free finite element method (MF-FEM) which provides an explicit and arbitrary high order approximation of the smooth solutions of the advection-diffusion partial differential equations both in space and time. The scheme allows for an efficient diagonalization of the mass matrix without any loss of accuracy. This is achieved by coupling the MF-FEM formulation in space with a Deferred Correction (DeC) type method for the discretization in time.

We will first focus on the staggered grid MF-FEM scheme for the Lagrangian hydrodynamics. In Lagrangian formulation, the equations are written in a moving reference frame with respect to velocity and internal energy. We will discuss the structure-preserving properties of our scheme, in particular, local conservation of the total energy by means of simple force correction in the momentum update equation. Next, we will present a high-order MF-FEM scheme for the shallow water equations and show that our scheme is well-balanced with a proper choice of numerical stabilization operators.

The MF-FEM implementation is part of the Fierro computational mechanics code which leverages the immense utility of the MATAR C++ library, providing a seamless integration of the Kokkos Performance Portability EcoSystem with MPI for distributed computing.

MODEL ASSISTED NON-DESTRUCTIVE EVALUATION OF DEFECTS USING TERAHERTZ TIME DOMAIN ANALYSIS

Sushrut Karmarkar[1], Mahavir Singh[2], Andreas Jung[2] and Vikas Tomar[2]*

[1]Purdue University
[2]Purdue University West Lafayette

ABSTRACT

Current and future detectors for high-energy particle physics like those at Large Hadron Collider (CERN) and EIC at Brookhaven National Lab pose high demands for the structural materials in a high-radiation environment where the accumulated radiation dose leads to defects like voids and cracks due to de-gassing and thermal cycling in the polymeric composite materials. In this work, terahertz time-domain spectroscopy (THz-TDS) is used for strain mapping of a polydimethylsiloxane (PDMS) doped with passive highly dielectrostictive strontium titanate (STO). A polarization polarization-dependent analytical model for the correlation of volumetric strain to the measured change in time of arrival for a THz pulse is developed. The model consists of effects due to changes in the dielectrostrictive properties of the composite due to changes in STO particle density and the change in thickness of the sample upon application of strain due to Poisson's effects. The stress relaxation behavior of the composite is studied to avoid change in strain during the measurement window. The analytical model is validated with results using an open hole tensile and a circular edge notch specimen. The THz strain mapping results are compared with a scale-dependent finite element model (FEM) and surface strain measurement using the digital image correlation (DIC) method. The experimental results show sensitivity to material features like particle clumping and edge effects. THz strain map shows good agreement with FEM and DIC results proving the applicability of this technique for surface and sub-surface strain mapping in polymeric composites.

The experimental results for THz-TDS-based volumetric strain maps agree with the results from DIC surface measurements as well as predictions using finite element models. This forms a robust analytical approach for the development of stress mapping and fracture front mapping in multilayer composites. The model inefficiencies at lower strain levels can be understood and mitigated by having better THz sensors and improving the signal-to-noise ratio.

ELASTIC-INELASTIC SHELLS WITH GROWTH: AN EULERIAN FORMULATION

Miles Rubin[1] and Giuseppe Tomassetti[2]*

[1]Technion - Israel Institute of Technology
[2]Roma Tre University

ABSTRACT

This contribution introduces a constrained Cosserat-type shell theory adept at integrating viscoelasticity, inelasticity, remodeling, and growth. The theory is formulated by setting constraints on the director vectors which relate to the position vector. The specific free energy of the system is expressed as a function of various factors including the elastic dilatation, elastic mean curvature, elastic Gaussian curvature, and the elastic distortional deformation invariant.

The elastic dilatation is governed by an evolution equation that involves the symmetric part of the velocity gradient and a mass supply term, which is a function of the elastic dilatation and a scalar field. Similarly, the evolution of the elastic distortional deformation invariant is determined by its relation to the deviatoric part of the unimodular elastic distortional deformation tensor and a symmetric, positive-definite, unimodular tensor.

Furthermore, the evolution equations for the mean and Gaussian curvatures are described, taking into account the time derivatives of these curvatures, material constants, and their homeostatic values. The resultant forces and couples are derived from constitutive equations that are consistent with thermodynamics.

A NOVEL METHOD TO CALCULATE THE LOAD VS. CRACK EXTENSION CURVE AND THE SIMILARITY OF THE LOAD VS. LOAD-LINE DISPLACEMENT CURVE

Guangrui Tong[*1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

The crack growth resistance curve is an important curve in fracture mechanics. In order to obtain the crack growth resistance curve, a typical fracture test must measure the load vs. crack extension (F-Δa) curve. In addition to the basic measurement of the load vs. load-line displacement (F-v_LL) curve, additional devices or complex test operations such as partial unloading are necessary to measure the amount of crack extension. Our research proposes a novel method of calculating the F-Δa curve directly from the F-v_LL curve, in which no additional devices or test operations are required. The proposed method is derived based on the energy balance during crack propagation, which can be easily applicable to these non-standard specimens. Several examples of compact tension (C(T)) and middle crack tension (M(T)) specimens are adopted to verify this method. This method is expected to simplify these available standards for measuring crack length. The similarity of F-v_LL curves and F-Δa curves of specimens that have the same configuration and different geometric parameters is found during the verification calculation of the proposed method. It is found that when specimens are identical except for the initial crack length, the shape of the F-v_LL curves or F-Δa curves are similar, but the positions of the feature points (i.e., the maximum load point) are different. For specimens with the same configuration and different geometric parameters, the crack propagation at the same displacement ratio (or stress ratio) point also has a proportional relationship. The influence of different geometric parameters on the similarity of F-v_LL curves and F-Δa curves is analyzed. The method of mutual transformation between F-v_LL curves or F-Δa curves based on similarity is proposed.

AN EFFICIENT ALGORITHM FOR CALCULATING VIBRATION MODES WITH NON-CLASSICAL DAMPING

Liu Tong[1] and Chen Pu*[1]

[1]*Peking University*

ABSTRACT

With the widespread application of dampers in large structures, how to evaluate vibration modes of large-scale damping systems has become an important issue.
A new computing method for vibration modes of large scale linear non-classical damping systems arising in FEA (Finite element analysis) called quasi-symmetric Lanczos method is proposed. The method can solve complex eigenvalue problems using the quasi-symmetric condition,
The complex quadratic eigenvalue problem (λ^2*M+λ*C+K)u=0 with non-classical damping of order n can be converted into a symmetric eigenvalue problem Av=λ*Bv of order 2n, in which v=[u,λu]^T, A=[-K,0;0,M] and B=[C,M;M,0]. Because matrix A and B are both indefinite matrices, we cannot use conventional method for positive definite matrix to solve it.
The matrix A can be congruently transformed into the J-matrix (J=diag(1 or -1)), while matrix B is still an indefinite symmetric matrix P. We can further convert the eigenvalue problem Jw=λ*Pw into w = λ*inv(J)Pw or w = λ*Dw. The offdiagonals of D=inv(J)P are either symmetric, i.e., d_ij=d_ji, or anti-symmetric, i.e., d_ij=-d_ji. We call D as a quasi-symmetric matrix.
For large scale problems, nonsymmetric Lanczos method is a feasible way to find a few meaningful eigen pairs. It reduces the large-scale eigenvalue problem w = λ*Dw into a small-scale eigenvalue problem w = λ*Tw with T as a tri-diagonal matrix. Conventionally, both left and right Lanczos vectors are computed in nonsymmetric Lanczos method. But when D is a quasi-symmetric matrix, the left Lanczos vectors and right Lanczos vectors also have a quasi-symmetric property. The left Lanczos vectors can be directly assigned via the right Lanczos vectors, so only one side Lanczos vectors are computed. The restarting and the orthogonal operation of the conventional nonsymmetric Lanczos method can also be simplified by the quasi-symmetry.
Finally, we can evaluate the vibration modes of large scale

ACCELERATING STRUCTURAL OPTIMIZATION USING GRADIENT ONLINE LEARNING AND PREDICTION

Yi Xing[1] *and Liyong Tong**[1]

[1]*The University of Sydney*

ABSTRACT

Unconstrained and constrained optimization problems are typically solved via some form of iterative processes in which all the design variables are updated repetitively. The update of the design variables is usually conducted along one search direction with a step size or length. Thus, it is important to determine the search direction. In the gradient-based optimization method, such search direction can be determined in terms of the gradients of both objective and constraint functions. However, for some problems, computing the gradients of both objective and constraint functions can be computationally expensive or even prohibitive. One such an example could be structural optimization problem, as a subset of constrained optimization, in which the geometry and size and the scale and complexity of physics involved could make the gradient determination computationally expensive or even prohibitive. The challenges may come from material and geometrical nonlinearity, time dependency, multiple scale, or even multiple physics. In this study, we propose a method that can accelerate the optimization process via machine learning, specifically via gradient online learning and prediction (GoLap). GoLap provides a straightforward framework of implementing the online training and online prediction of a one-hidden-layer neural network (NN) into routine iterative optimization process. In GoLap, the online training of the NN is performed in routine iterations using the available historical gradients as training samples; and the online prediction of the trained NN is activated in selected iterations to predict the gradients by running a rapid forward calculation. This method substantially can significantly reduce the overall computational time used to solve a structural optimization problem with fixed step size. Furthermore, GoLap has also been implemented into the algorithms based on the steepest and conjugate gradient descent methods to accelerate optimization process. GoLap has been implemented into the solid isotropic material with penalization method, accelerating the topology optimization for solving 2D and 3D minimum compliance designs problems [1], 2D compliant mechanism design problem with design-dependent load [2], and reliability-based minimum compliance and minimum volume design problems [3].

A MORTAR-BASED ISOGEOMETRIC MODEL FOR PARTIALLY LUBRICATED CONTACTS

Yan Tong[*1], Michael Müller[1] and Georg-Peter Ostermeyer[1]*

[1]*Technical University of Braunschweig*

ABSTRACT

Fluidic lubricants are commonly used to reduce friction in tribological systems like bearings and gears. The basic concept is that the lubricant forms a thin film separating the solid surfaces in contact, indirectly transmitting the contact force. Present research primarily focuses on fully lubricated contacts, where lubricants are supplied sufficiently without specific quantity control. However, our research group's experimental results suggest that a significant reduction in the coefficient of friction (COF) can be attained with minimal lubricant application. In such cases, the tribological system is partially lubricated, meaning that the narrow gap between solid bodies is only partially filled with lubricants, whereas air pockets occupy the remaining space. The problem's complexity is further increased when the lubricant cannot withstand the high external load, leading to the coexistence of solid contacts and the fluid film. Modeling this complex contact interface is challenging due to the interaction of multiple mechanisms: the solid deformation, the frictional contact, and the mixture flow of the lubricant and air pockets. In order to address these challenges, this work presents a new model for partially lubricated contacts, integrating the mortar method with NURBS-based isogeometric analysis.

In this model, the Reynolds equation, supplemented by the JFO boundary conditions, is utilized to characterize the multi-phase flow, leading to a complementarity problem with inequality constraints. A cavitation formulation is developed to address this. It employs the Augmented-Lagrangian (AL) method, transforming the complementarity problem into an unconstrained form. Additionally, a frictional contact formulation derived from the AL method is implemented to compute potential solid contacts effectively. The model also accounts for large solid deformations, which could be attributed to asperity contact and high fluid pressure.

A monolithic coupling approach is adopted in this model, allowing for the concurrent solution of all variables from both the fluid and solid components. The resulting formulations are discretized within the NURBS-based IGA (Isogeometric Analysis) framework. Notably, the lubricated contact interface is discretized using the mortar method, facilitating the use of inconsistent NURBS meshes for the solid bodies and the fluid domain. This feature is crucial as the fluid domain often necessitates finer meshes to capture the mixture flow behaviors accurately.

The developed model provides a comprehensive representation of lubricated contact, aiming to enhance the understanding of its fundamental mechanisms and to investigate the impact of the lubricant quantity on the COF.

APPROXIMATE VORONOI DIAGRAMS FOR NODALLY INTEGRATED GALERKIN MESHFREE METHODS

Zhiyuan Tong[*1], Mauricio Ponga[1], Mattia Bacca[1] and Zhiyuan Tong[1]*

[1]*University of British Columbia*

ABSTRACT

The application of approximate Voronoi diagrams [1] to nodally integrated Galerkin meshfree methods is presented. Instead of generating exact Voronoi cells as nodal representative domains, the input geometry is pixelated by uniform background cells, and approximate Voronoi cells are obtained by allocating the background cells to the corresponding nodes. As compared to nodal integration using exact Voronoi cells, the computational cost is significantly reduced, while similar accuracy can be achieved. The accuracy is much higher than that of nodal integration using nonconforming cells. This presentation will first briefly review the three categories of domain integration for Galerkin meshfree methods, which include integration by quadrature, integration by stress points, and nodal integration [2]. This presentation will then explain why nodal integration is used for problems with drastic topological changes such as ballistic impacts and natural disasters [2]. The limitations of the current nodal integration techniques will then be presented, which include the impractically high computational cost if exact Voronoi cells are used, and the poor accuracy if nonconforming cells are used. The construction of approximate Voronoi cells will then be presented, which includes the radius expansion algorithm, and a novel way of identifying background cells inside the input geometry. After that, nodal integration using approximate Voronoi cells will be presented, by reusing the integration results, the number of integration performed is very low compared to the number of background cells. After that, several examples are shown to demonstrate the high accuracy and low computational cost of nodal integration using approximate Voronoi diagrams. This research contributes by making nodal integration using Voronoi diagrams computationally practical, and recovers the meshfree nature. The huge sacrifice in accuracy by using nonconforming cells is no longer necessary. Hence this research can lead to increase in computational efficiency for nodally integrated meshfree methods, therefore improve the capability of simulating solid mechanics problems with drastic topological changes.

GENERALISATION OF THE SPECTRAL DIFFERENCE SCHEME FOR THE DIFFUSED-INTERFACE FIVE EQUATION MODEL

Niccolò Tonicello[*1], Guido Lodato[23] and Matthias Ihme[4]*

[1]*International School of Advanced Studies (SISSA)*
[2]*INSA Rouen*
[3]*Université de Rouen Normandie*
[4]*Stanford University*

ABSTRACT

High-fidelity simulations of multi-phase flows represent a crucially relevant tool in the design process of many different fields of engineering applications. The sudden change of density, viscosity and thermodynamic properties at the interface between two immiscible fluids poses a great challenge in terms of numerical modelisation. The development of reliable, accurate and robust discretisation techniques to deal with these types of problems consequently represents an unavoidable step to uncap the simulation of challenging scenarios as the ones commonly encountered in the aeronautical industry.

In the present work the spectral difference scheme is employed in the discretisation of the five equation model equipped with the additional Allen-Cahn regularisation terms for interface capturing purposes [1,2]. Within the framework of the spectral difference scheme, in order to mitigate pressure oscillations in proximity of material interfaces in two-phase flows, a change of variables (from conservative to primitive) in the extrapolation to the flux points step is used in order to alleviate the non-linearity of the stiffened-gas equation of state.

A series of numerical test of increasing complexity is considered in order to assess the robustness of the solver, including both kinematic and two-phase test cases. From the former group, the Rider-Kothe vortex is studied in order to quantify convergence properties of the scheme and mass conservation errors. In terms of two-phase flows, a series of more complex problems are considered: the Rayleigh-Taylor instability, a shock-droplet interaction and a three-dimensional, two-phase version of the Taylor-Green Vortex problem.

Overall, the proposed approach showed a good robustness in dealing with a large variety of classical test cases in the two-phase simulation community, advocating the advantages in using high-order discretisations.

CELL AGGLOMERATION FOR CUT CELLS IN EXTENDED DISCONTINUOUS GALERKIN METHODS

Muhammed Toprak[*1]*

[1]*Technical University of Darmstadt*

ABSTRACT

Extended Discontinuous Galerkin (XDG) methods are advanced high-order techniques designed to solve multiphase problems characterized by jumps and kinks at interfaces. In the treatment of these discontinuities, XDG methods embrace a sharp interface approach and implement a cut-cell structure, in which complex geometries are immersed in a Cartesian grid to simplify mesh generation.

However, this approach can result in arbitrarily small cells due to the intersection of background cells with the interface, which cause discretization difficulties because of their diminutive size. In addition, if the size of the immersed geometries changes over time, topological inconsistencies in the mesh structure can occur at different time steps.

To account the issues associated with small-cut cells and topological changes, we present a cell agglomeration approach for XDG methods and tailor it for large-scale simulations. This approach merges problematic cells with suitable neighbors and has been acknowledged as a simple and convenient method [1]. However, it is important to note that cell agglomeration becomes challenging in three-dimensional space due to the high degree of neighborship between cells [2]. In addition, it can create cumbersome problems in large computational simulations, such as the formation of agglomeration chains and ineffective exchange of information in parallel, which are often considered drawbacks in implementations.

In our work, we provide a comprehensive strategy for the typical issues associated with cell agglomeration in three-dimensional and multiprocessor simulations. The proposed strategy is implemented into the open-source software package BoSSS [3] and tested with large-scale simulations of immersed boundary flows.

CONSTRAINED INTERPOLATION FROM SCATTERED DATA WITH RADIAL BASIS FUNCTIONS

Jason Torchinsky[*1], Arjun Sharma[1] and Peter Bosler[1]*

[1]Sandia National Laboratories

ABSTRACT

Radial basis functions (RBFs) are a powerful tool for constructing high-order accurate interpolants of scattered data in arbitrary dimension and on manifolds. We present a method of constructing RBF interpolants using constraints to ensure that properties such as, e.g., integral conservation or local bounds, are preserved. We defined a constrained quadratic minimization problem that combines possibly non-linear constraints with RBF interpolation. We demonstrate the method for applications of scattered data interpolation on the sphere.

MODELING DYNAMIC DUCTILE FRACTURE AND THERMAL SOFTENING WITH A VARIATIONAL PHASE-FIELD FRAMEWORK

David Torres[*1], John Dolbow[1], Andrew Stershic[2], Tianchen Hu[3] and Tim Shelton[2]*

[1]*Duke University*
[2]*Sandia National Laboratories*
[3]*Argonne National Laboratory*

ABSTRACT

A variational phase field model for ductile dynamic fracture is presented. The model is designed for elasto-viscoplastic materials subjected to rapid deformations in which the effects of heat generation and material softening are dominant. The variational framework allows for the consistent inclusion of plastic dissipation in the heat equation, coupled with mechanisms for thermal softening. The model employs a coalescence function that actively degrades fracture energy in conditions characterized by high plastic flow. The plastic yield surface is characterized by a variationally consistent form of the Johnson-Cook model developed for use with the model. A remeshing algorithm is applied to address mesh distortions from the combination of high plastic flow and damage, particularly evident in shear band formation. A distinctive feature of this model is its treatment of damage failure and shear band failure as two separate failure modes, each with distinct indicators for their initiation. The model's efficacy is demonstrated through a series of benchmark problems in dynamic ductile fracture. In particular, the ability of the model to regularize shear band formation and subsequent damage evolution in two and three-dimensional problems is demonstrated. Notably, these phenomena are captured intrinsically through the model's physics, eliminating the need for externally imposed criteria, such as stability thresholds, for the onset of shear band formation.

GRAPHS AND MIXED ADJOINT/DIRECT APPROACHES FOR DESIGN SENSITIVITY ANALYSIS WITH TRANSIENTS AND HISTORY DEPENDENT MATERIAL RESPONSE

Daniel Tortorelli[*12] and Brandon Talamini*[1]

[1]*Lawrence Livermore National Laboratory*
[2]*University of Illinois Urbana-Champaign*

ABSTRACT

The direct (forward) and adjoint (reverse) approaches are popular analytical sensitivity analysis methods which play prominent roles in design optimization and inverse/identification analyses. We present a graph-based mixed adjoint/direct method that enjoys some of the simplicities of the direct method and efficiencies of the adjoint method. It is particularly well suited for systems with transients and history dependent material response due to its straightforward implementation. Indeed, adaptive time-stepping algorithms and various constitutive models are readily accommodated. The computed sensitivities are consistent with the discretize and differentiate approach and as such pass the Taylor verification test. We demonstrate its effectiveness by computing shape and material parameter sensitivities for structures modeled with J_2 plasticity.

ABSTRACT

This work presents a multifaceted contribution to computational elastodynamics in three dimensions. Firstly, it relies on a robust variational formulation of the boundary integral equation tailored specifically for multi-domain scenarios. This formulation marks a significant contribution, enhancing the applicability of elastodynamic simulations using the boundary element method. Secondly, it employs extensive use of surface integration by parts techniques, effectively transforming the computational framework from one reliant on strong and highly singular quadrature to one that adeptly handles weakly singular quadrature. Finally, the study explores the computation of dynamic stress intensity factors, examining their intricate relationship with frequency and stiffness ratio between inclusions and the surrounding matrix.

A PREDICTOR-CORRECTOR SECOND-ORDER TIME-STEPPING SCHEME FOR MODELING WATER FLOW AND SOLUTE TRANSPORT IN UNSATURATED POROUS MEDIA

[1]*École de technologie supérieure*
[2]*Mohammed VI Polytechnic University*
[3]*University of Ottawa*

ABSTRACT

It is vital to model water flow and solute transport in unsaturated soils to comprehend and manage different environmental phenomena. The Richards equation is used to model water flow and is combined with the equilibrium advection-dispersion equation for solute transport. Several second-order time-stepping schemes have been developed for solving the coupled system (Kamil et al., 2024; Toutlini et al., 2024). The objective of this study is to numerically solve the coupled model by utilizing special temporal schemes in conjunction with standard and non-standard Galerkin finite element methods for spatial discretization. At each time level, we address the Leverett equation to derive the initial estimate of the pressure head. Subsequently, employing this initial estimate, we solve the Richards equation to obtain a more refined second approximation of the pressure head. The final prediction of the pressure head is corrected using these two approximations. The solute transport equation is then solved with the water content and flux that are derived from the Richards equation solution. The proposed schemes differ in their treatment of the Leverett equation. In a first approach, a constant pressure head is assumed within each element. However, to overcome discontinuities associated with this method, a smoothness technique has been adopted. This involves projecting the discontinuous pressure head onto the space of linear piecewise polynomials, resulting in a continuous profile. In contrast, a second approach considers a linear pressure head within each element, offering an alternative method to handle the Leverett equation. The proposed schemes offer distinct advantages due to the linear nature of the resulting system, facilitating easy implementation, parallelization, and avoiding the issues associated with the divergence of iterative schemes. We assessed the effectiveness and robustness of our approach through a series of numerical experiments. The results provide compelling evidence that confirms the efficiency of the proposed methods. In general, the second method shows better stability and accuracy for both homogeneous and heterogeneous soils. This implies that, in comparison to the first method, taking into account a linear pressure head within each element produces more consistent results, particularly when handling different soil properties.

THIN WAVEGUIDES WITH ROBIN BOUNDARY CONDITIONS

Guy Bouchitte[1], *Luisa Mascarenhas*[2] *and Luis Trabucho**[2]

[1]*Universite de Toulon*
[2]*Universidade NOVA de Lisboa*

ABSTRACT

We consider the Laplace operator in a thin three dimensional tube with a Robin type condition on its boundary and study, asymptotically, the spectrum of such operator as the diameter of the tube's cross section becomes infinitesimal. In contrast with the Dirichlet condition case, we evidence different behaviors depending on a symmetry criterium for the fundamental mode in the cross section. If that symmetry condition fails, then we prove the localization of lower energy levels in the vicinity of the minimum point of a suitable function on the tube's axis depending on the curvature and the rotation angle. In the symmetric case, the behavior of lower energy modes is shown to be ruled by a one dimensional Sturm-Liouville problem involving an effective potential given in explicit form.

[1]*University of Colorado Boulder*
[2]*ANSYS*
[3]*Lawrence Livermore National Laboratory*

ABSTRACT

Reduced order modeling is inspired by the need to address the computational and mathematical challenges posed by simulating complex, high-dimensional systems in various scientific and engineering domains. To address this, we introduce WLaSDI: Weak-form Latent Space Dynamics Identification, a data-driven projection-based reduced order model (pROM) simulation method that incorporates weak-form equation learning algorithms. Extended from LaSDI: Latent Space Dynamics Identification, WLaSDI first compresses data, then projects onto the test functions and learns the local latent space models. With WLaSDI, the local latent space is obtained using weak-form equation learning techniques. Notably, WLaSDI demonstrates significantly enhanced robustness to noise. Compared to the standard sparse identification of nonlinear dynamics (SINDy) used in LaSDI, the variance reduction of the weak form guarantees a robust and precise latent space recovery, hence allowing for a fast, robust, and accurate simulation. We demonstrate the efficacy of WLaSDI vs. LaSDI on several common benchmark examples including viscid and inviscid Burgers', radial advection, and heat conduction.

GEOMETRIC FORMULATION OF THREE-TEMPERATURE RADIATION HYDRODYNAMICS

Brian Tran[1], Benjamin Southworth*[1], Joshua Burby[1] and Melvin Leok[2]*

[1]Los Alamos National Laboratory
[2]University of California, San Diego

ABSTRACT

Radiation hydrodynamics is the study of the hydrodynamics of a fluid interacting with a radiation field, finding application in fields such as astrophysical hydrodynamics and inertial confinement fusion. The governing equations for three-temperature (3T) radiation hydrodynamics consist of fluid equations for an electron-ion fluid coupled to a radiation field, forming a complicated set of PDEs containing advection, diffusion, and strong nonlinear interaction terms. As such, the discretization of this system is a challenging problem and an active area of research. With the aim of developing geometric structure-preserving integrators for the simulation and optimal control of the 3T system, we develop a geometric formulation of 3T radiation hydrodynamics using a port-Hamiltonian framework. This gives a geometric framework for understanding the conservative properties of the 3T system. We further show that the 3T system is an irreversible port-Hamiltonian system, where irreversible internal entropy production arises from fluid-radiation interaction and diffusion. Finally, we develop a metriplectic formulation of the flux and the interaction terms.

FOUR-DIMENSIONAL PARALLELIZATION ENHANCED WITH ADAPTIVITY AND BATCHING FOR THE SOLUTION OF PHONON BOLTZMANN TRANSPORT EQUATION

Han Tran[*1], Siddharth Saurav[2], Sandip Mazumder[2], P. Sadayappan[1] and Hari Sundar[1]*

[1]*The University of Utah*
[2]*The Ohio State University*

ABSTRACT

The phonon Boltzmann transport equation (BTE) is suitable for modeling heat transport at submicron scales in semiconductor materials. However, the BTE is a seven-dimensional equation, bringing in challenges in parallelization regarding load imbalance due to the linear systems' conditioning variation. Furthermore, applications of the BTE solution, e.g., simulation of frequency-domain thermo-reflectance (FDTR) experiments, often require thousands of time-steps to obtain meaningful physical quantities, resulting in long time-to-solution. Here, we first present the combined band+cell-based method, which combines parallelization in frequency and spatial dimensions for the BTE solution [1]. The advantages of this approach are the inconsiderable communication costs (only reduction is required) in the frequency parallelization and the high level of parallelism in the spatial domain. Next, we present the batching technique that groups multiple linear systems into a batched system solved simultaneously. This technique merges many small MPI messages into a larger one, reducing communication overhead when the grain size of spatial parallelization becomes small. We also discuss our recently developed adaptive algorithms to minimize the load imbalance in frequency parallelization and the unnecessary computations in the batching technique of spatial parallelization. Finally, we present the numerical experiments simulating heat transports in semiconductor devices via the BTE solution, demonstrating that our developed methods achieved excellent speedups and maintained scalability up to 25k cores.

A MACHINE LEARNING FRAMEWORK FOR MODEL CALIBRATION OF MERCURY TARGET SIMULATION

*Hoang Tran**[1]

[1]*Oak Ridge National Laboratory*

ABSTRACT

As the most powerful pulsed spallation source in the world, the Spallation Neutron Source (SNS) at the Oak Ridge National Laboratory (ORNL) uses liquid elemental mercury as the target material to generate neutron beam lines for scientific and engineering discoveries. Due to the severe working condition, the mercury targets were prone to leak prematurely causing several interruptions to the SNS user program. The mercury constitutive model predicting the strain and stress in the target vessel plays a central role in improving the lifetime prediction and future designs of the targets at the SNS. In this effort, we leverage the experiment strain data collected over multiple years to improve the mercury constitutive model through a combination of large-scale simulations of the target behavior and the use of machine learning tools for surrogate modeling. We present two interdisciplinary approaches for surrogate-based calibration of expensive simulations using evolutionary neural networks and sparse polynomial expansions. The newly calibrated simulations achieve remarkable improvement on the prediction accuracy compared to previously reported reference parameters and can aid in fatigue analysis for more accurate estimation of the mercury target lifetime.

NUMERICAL STUDIES OF COMPRESSION FAILURE IN TRIPLY PERIODIC MINIMAL SURFACE-BASED CERAMIC FOAMS

Thi Ngoc Diep Tran[*1] and Romana Piat*[1]

[1]*Darmstadt University of Applied Sciences*

ABSTRACT

Microstructures with minimal surfaces can be often found in natural porous architectures, where the surface tension minimizes the area. The triply periodic minimal surfaces (TPMS) [1] are an example of such microstructures with minimal surfaces. Compared with other porous structures, TPMS have three significant features: firstly, their geometries can be completely expressed via analytical functions; secondly, TPMS are periodic in three independent directions and thirdly, the mean curvature of TPMS is zero [2]. Transforming the TPMS-based unit cell into a lattice structure has particular usage in aerospace, nuclear energy, and biomedical applications where light weight, high stiffness, and temperature resistance are of critical importance. In the presented studies, the linear elastic and failure behavior of four typical TPMS structures (Primitive, Gyroid, Neovius, and IWP) under compression were studied using finite element analysis. Numerical modeling of the damage propagation and strength prediction was provided by removing the finite elements in which the appropriate damage criterion is reached. Utilizing the equations of the generated TPMS structures, the wall thickness of unit cell was considered the main parameter that defined the ceramics volume fraction and should be taken into consideration. Therefore, various unit cell models for different wall thicknesses were generated and used to investigate the impact of the cell geometry on the damage initiation, propagation, and the overall compression strength. The results of compression strength and damage development were compared with those of other TPMS structures for the same wall thickness and volume fraction. Finally, the periodic repetition of TPMS unit cells was used to evaluate and understand the effect of boundary conditions on damage evolution on the macroscale.

DETERMINISTIC VERIFICATION OF ELECTROSTATIC, GYROKINETIC PARTICLE-IN-CELL CODES USING THE METHOD OF MANUFACTURED SOLUTIONS

Paul Tranquilli[*1], Lee Ricketson[1], Ben Sturdevant[2] and Luis Chacón[3]*

[1]*Lawrence Livermore National Laboratory*
[2]*Princeton Plasma Physics Laboratory*
[3]*Los Alamos National Laboratory*

ABSTRACT

As the scope and complexity of particle-in-cell (PIC) algorithms in plasma simulation continue to grow, the need for a robust and straightforward method to verify the correctness of PIC implementations becomes crucial. This presentation introduces a deterministic approach for rigorously verifying multidimensional, electrostatic, gyrokinetic particle-in-cell codes, utilizing the method of manufactured solutions. Our method demonstrates that thorough verification can be achieved by exclusively scrutinizing errors in grid quantities, enabling a lightweight and non-intrusive integration into existing particle-in-cell codes. The validity of our theoretical assertions is confirmed through numerical results obtained in XGC.

A FEASIBLE NUMERICAL MODEL FOR AN ANALYSIS OF A PIPE-LAY ON A ROUGH SEAFLOOR

Pavel Trapper[1]*

[1]*Ben-Gurion University of the Negev*

ABSTRACT

Submarine pipelines for the transportation of hydrocarbon fluids may spread hundreds to thousands of kilometers and are usually installed by lowering them down from the laying vessel. During this process, the pipelines are subjected to different types of loading, which should be given proper consideration in the pipeline design.
By default, a common practice to analyze pipelines in their installation is by considering a horizontal flat seafloor. In reality, however, the bathymetric maps of the sea bottom reveal faults, folds, and on-bottom channel systems. Those seafloor irregularities and potential pipeline crossings may result in severe stress concentrations within the pipelines, eventually leading to pipeline failure.
Analyzing a pipe-lay on a rough seafloor, however, is much more computationally involved since the pipe-lay front configuration, as well as its internal forces, are continuously changing throughout the pipe-lay process, such that considering solely a typical steady-state configuration at the pipe-lay front is no longer sufficient. To ensure pipeline integrity during the installation, it is essential to obtain internal force envelope diagrams, which provide the historical maximum and minimum force bounds at every location along the pipeline throughout the entire pipe-lay proceeding.
This work presents a feasible, simple numerical technique compliant with the adaptation of any possible load induced by the environment for calculating the internal force envelope diagrams. The entire pipeline is modeled as a single continuous segment considering geometrical nonlinearity induced by large deformations. Following the actual pipe-lay process, the numerical solution is proceeded sequentially by an incremental increase of the pipeline length and consistent minimization of the total potential energy of the system discretized as a Riemann sum, solving the subsequent algebraic system of nonlinear finite difference equations by a Newton-Raphson technique [1-2]. The feasibility of the proposed technique is demonstrated through several scenarios of a pipe-lay across the basic types of seafloor irregularity [3].
The proposed technique presents an efficient, time-saving alternative to the available general- and special-purpose commercial software, allowing the user, by developing his own in-house code, to take full control over the calculations.

ABSTRACT

Recent work in model order reduction has introduced an algorithm called LaSDI (Latent Space Dynamics Identification) as a tool to accelerate physical simulation by learning latent space dynamics. In many problems, high dimensional time series data may be driven largely by the dynamics of a latent space with lower dimension, and the LaSDI algorithm takes advantage of this dimension reduction. The original LaSDI algorithm uses SINDy (Sparse Identification of Nonlinear Dynamics) as a subroutine for symbolic latent space dynamics identification. However, symbolic learning is not robust to the presence of noise in the data; in response, additional work proposed WLaSDI, (Weak-Form LaSDI) which poses the latent space dynamics in weak form, which is shown to be more robust to noise. An additional challenge in dynamics modeling is incorporating parameter dependence. In LaSDI, a solution is linearly interpolated for new parameters between separately learning dynamics for multiple parameterizations. However, separate learning can be expensive, and it is desirable to have uncertainty quantification to inform future sampling. Along these lines, GPLaSDI (Gaussian Process-based LaSDI) uses Gaussian processes to interpolate between various parameters and obtain uncertainty quantification as well. In our work, we combine these two improvements to the LaSDI framework: the weak formulation of the latent space and interpolation with Gaussian processes. Theory is presented and experiments on benchmark problems such as the Vlasov equation for plasma physics are discussed.

TOPOLOGY OPTIMIZATION OF VISCOELASTIC LOCAL RESONATORS FOR SANDWICH METASTRUCTURES

Carlos Andrés Rincón Velásquez[1] *and Marcelo A. Trindade**[1]

[1]*University of São Paulo, São Carlos School of Engineering*

ABSTRACT

Metastructures have gained attention in recent years due to their noise and vibration control properties in tunable frequency ranges, basing their behaviour on the principle of phononic crystals, which exhibit frequency ranges known as bandgaps, in which elastic and acoustic waves do not propagate. Metastructures may be achieved through the inclusion of local resonator elements, which act as vibration absorbers and may be periodically distributed in host structures. The advantage of metastructures using local resonators is that, unlike phononic crystals, the bandgaps are generated based on the properties of the resonator elements. This paves the way towards compact and lightweight vibroacoustic solutions for the lower frequency ranges, since wave propagation and vibratory response can be affected by local resonators of sizes smaller than the host structure's wavelengths. An interesting approach in the investigation of metastructures design is the search for optimal geometries and damping properties for the local resonators, so that they can provide vibration attenuation in wider frequency ranges and/or for relatively distant resonance peaks. That is why this research work proposes a topology optimization strategy to find optimal geometry and damping properties for viscoelastic local resonators, as a building block for application in vibration control of sandwich metastructures. For that, standard topology optimization techniques, such as the Bi-directional Evolutionary Structural Optimization method, need to be adapted in order to simultaneously account for several design criteria, such as static and dynamic structural integrity, resonance frequency tuning and added structural damping. In this work, first, an assessment on different strategies to define a proper objective function for the topology optimization problem is presented. Based on preliminary results obtained so far, non-standard strategies must be considered to obtain well-performing solutions. Then, a discussion on the challenges posed to the methodologies by the viscoelastic behavior of the resonators is put forward. Indeed, the frequency and temperature dependence of viscoelastic resonators properties requires customized optimization techniques for resonance frequency tuning and added structural damping evaluation. Finally, an analysis of the applicability and expected performance of the solutions found for the local resonators when inserted into sandwich metastructures is performed. Given the current interest in the development of metastructures with local resonators making use of additive manufacturing with polymeric materials, which present viscoelastic behavior, it is expected that this work could bring some important contributions to this research area.

PHYSICS INFORMED NEURAL NETWORKS FOR PREDICTING SOFT SOLID DEFORMATION

Vikrant Pratap[1] and Bharat Tripathi[1]*

[1]University of Galway

ABSTRACT

Mild traumatic brain injury (mTBI) is a silent epidemic and is a major cause of disability and morbidity. Event like mechanical falls, military deployment, contact sports like American football, Rugby, etc., could lead to mTBI. However, still the primary injury-biomechanics remains unclear, novel mechanisms like shear shock formation in brain could provide some clarity [1]. Moreover, the existing finite element based computational solvers are mostly confined to research studies and are not deployable to predict the brain deformation given their computational cost. A real-time estimate of brain deformation in the event of an head impact can provide a quantitative insight towards development of mTBI injury metrics.

With this motivation, the current study aims to develop physics informed fully connected dense neural networks (PINNs) to predict the deformation of an hyperelastic soft solid without using any labelled data. The proposed data-free PINNs model employs an innovative incremental-training algorithm that captures the causality of the physical phenomenon, homogeneous deformation and incompressibility. Utilising non-dimensionalised governing equations to minimise residuals and enforcing the boundary conditions, our approach ensures efficient training of the model. We employ an adaptive training algorithm to incrementally train the model, ensuring satisfaction of governing equations and boundary conditions. The developed PINNs model accurately captures three-dimensional hyperelasticity, focusing on high order hyperelastic models for different homogeneous deformations. Once trained, the model swiftly responds to any spatial coordinate within the physical domain for the specified homogeneous deformation. Three different strain energy density functions were considered: 1) Neo-Hookean, 2) Moony-Rivlin, and 3) Landau (a fourth order elastic model [1]). The data-free PINNs solution for Landau hyperelastic model was compared to the analytical solution, revealing RMSE of 0.04%, 0.08%, 0.16%, 0.18%, 0.07%, and 0.10% for uniaxial tension, uniaxial compression, biaxial tension, biaixal compression, pure shear, and simple shear, respectively. These results affirm the effectiveness of the proposed approach across different deformation cases for Landau hyperelastic model. The success encourages the natural extension of PINNs to capture viscoelasticity in soft solids.

COMPUTATION INFRASTRUCTURE FOR MODELING DISCONTINUITIES WITHIN MATERIALS: DEIP, BEAVER AND MOOSE

Timothy Truster[*1] and Amirfarzad Behnam*[1]

[1]*University of Tennessee*

ABSTRACT

This presentation provides an overview of several open-source codes developed within our group for modeling interfaces (such as cohesive zone and Discontinuous Galerkin) within materials. The popularity of discontinuous formulations for computational solid mechanics has steadily increased for physical applications such as fracture mechanics. A common approach for numerically realizing these methods is using the so-called zero-thickness interface finite elements. Unfortunately, standard commercial finite element codes do not contain mesh generation features for zero-thickness elements. Also, the modeling and simulation of complex engineering materials using the representative volume elements (RVE) has become quite extensive, for which periodic finite element meshes are important. However, few mesh generators today will produce such interface elements along the boundary of the periodic RVE, which are needed for modeling behavior such as sliding along grain boundaries in polycrystalline metals. To tackle these challenges, our group has been continually enhancing the Discontinuous Element Insertion Program (DEIP), a MATLAB code for inserting interface elements into two and three-dimensional meshes of all standard element types. Its algorithm is topologically based and requires only nodal coordinates and element connectivity as input. API are provided for meshes from Abaqus, Gmsh, and Cubit formats. Additionally, for modeling the physics of these interfaces, our group has recently developed an application for the MOOSE object-oriented finite element framework, called BEAVER. This application includes realizations of the Variational Multiscale Discontinuous Galerkin (VMDG) method, which provides closed-form expressions of the stability parameters needed for methods such as the interior penalty DG and Nitsche methods. Representative simulations from these codes are provided to highlight various applications.

A TIME-RELAXATION REDUCED ORDER MODEL FOR THE TURBULENT CHANNEL FLOW

Ping-Hsuan Tsai[1], Paul Fischer[2] and Traian Iliescu[1]*

[1]*Virginia Tech*
[2]*University of Illinois Urbana Champaign*

ABSTRACT

Regularized reduced order models (Reg-ROMs) are stabilization strategies that leverage spatial filtering to alleviate the spurious numerical oscillations generally displayed by the classical Galerkin ROM (G-ROM) in under-resolved numerical simulations of turbulent flows. In this paper, we propose a new Reg-ROM, the time-relaxation ROM (TR-ROM), which filters the marginally resolved scales. We compare the new TR-ROM with the two other Reg-ROMs in current use, i.e., the Leray ROM (L-ROM) and the evolve-filter-relax ROM (EFR-ROM), in the numerical simulation of the turbulent channel flow at $Re_{\tau} = 180$ and $Re_{\tau} = 395$ in both the reproduction and the predictive regimes. For each Reg-ROM, we investigate two different filters:

(i) the differential filter (DF), and

(ii) a new higher-order algebraic filter (HOAF).

In our numerical investigation, we monitor the Reg-ROM performance with respect to the ROM dimension, N, and the filter order. We also perform sensitivity studies of the three Reg-ROMs with respect to the time interval, relaxation parameter, and filter radius. The numerical results yield the following conclusions:

(i) In terms of the Reynolds normal and shear stresses, all three Reg-ROMs are significantly more accurate than the G-ROM.

(ii) In addition, all three Reg-ROMs are more accurate than the ROM projection, which represents the best theoretical approximation of the training data in the given ROM space.

(iii) With the optimal parameter values, the new TR-ROM yields more accurate results than the L-ROM and the EFR-ROM in all tests.

(iv) For most N values, DF yields the most accurate results for all three Reg-ROMs.

(v) The optimal parameters trained in the reproduction regime are also optimal for the predictive regime for most N values, demonstrating the Reg-ROM predictive capabilities.

(vi) All three Reg-ROMs are sensitive to the filter radius and the filter order, and the EFR-ROM and the TR-ROM are sensitive to the relaxation parameter.

(vii) The optimal range for the filter radius and the effect of relaxation parameter are similar for the two $\rm Re_\tau$ values.

HYBRID ANALYSIS AND MODELING FOR TURBULENT FLOW PROBLEMS

Vasileios Tsiolakis[1], Adil Rasheed*[21] and Trond Kvamsdal[21]*

[1]*SINTEF Digital*
[2]*Norwegian University of Science and Technology*

ABSTRACT

The prospect of predictive Digital Twins opens up a lot of application possibilities, but it also brings forth the requirement for efficient and reliable simulators. While reduced order models (ROMs) have been shown to offer excellent speed-up for the approximation of complex physical problems, issues that characterize conventional methods remain true. Constructing ROMs for large problems and/or problems with significant parameterization is often infeasible. Moreover, the power of the reduced model is measured, often inadequately, in terms of how close it can get to the underlying high-fidelity model. In an effort to address such issues, this work will use the hybrid analysis and modeling [1] (HAM) strategy combining multiple reduced order modeling (ROM) techniques and data-driven corrections.

This work will initially consider the construction of a typical hybrid ROM scheme [2], combining the proper orthogonal decomposition (POD) with Galerkin projection and interpolation schemes. Aiming towards as sparse a training set and reduced bases as possible, we use HAM, and more specifically the corrective source term approach (CoSTA). We introduce an extra correction step in the typical ROM online problem that uses a meta-model to evaluate the residual error of the ROM approximation, modify the algebraic problem and improve the final solution.

Finally, the ability of the proposed strategy is measured in terms of computational acceleration and increase in accuracy when approximating turbulent flow around known wing geometries.

SELF-SUPERVISED LEARNING FOR HEALTH ASSESSMENT OF LITHIUM-ION BATTERIES IN ELECTRIC VEHICLES

Jie-Chung Chen[1] and Nien-Ti Tsou[1]*

[1]National Yang Ming Chiao Tung University

ABSTRACT

Health evaluation for lithium-ion batteries (LIBs) typically relies on constant charging/discharging protocols, often neglecting scenarios involving dynamic current profiles prevalent in electric vehicles. Conventional health indicators for LIBs also depend on the uniformity of measured data, restricting their adaptability to non-uniform conditions. In this study, a novel training strategy for estimating LIB health based on the paradigm of self-supervised learning is proposed. A multiresolution analysis technique, empirical wavelet transform [1], is utilized to decompose non-stationary voltage signals in the frequency domain. This allows the removal of ineffective components for the health evaluation model. The transformer neural network serves as the model backbone, and a loss function is designed to describe the capacity degradation behavior with the assumption that the degradation in LIBs across most operating conditions is inevitable and irreversible.

The results show that the model can learn the aging characteristics by analyzing sequences of voltage and current profiles obtained at various time intervals from the same LIB cell. The proposed method is successfully applied to the Stanford University LIB aging dataset [2], derived from electric vehicle real-driving profiles. Notably, this approach achieves an average correlation coefficient of 0.9 between the evaluated health index and the degradation of actual capacity, demonstrating its efficacy in capturing LIB health degradation. This research highlights the feasibility of training deep neural networks using unlabeled LIB data, offering cost-efficient means and unleashing the potential of the measured information.

FINITE STRAIN ELASTIC-PLASTIC CRACK ANALYSIS BY USING S-VERSION ISOGEOMETRIC ANALYSIS

Yuhi Tsuchiyama[1], Yusuke Sunaoka[1], Takashi Kurosawa[1], Yuto Otoguro[1] and Hiroshi Okada[1]*

[1]*Tokyo University of Science*

ABSTRACT

In the presentation, the formulation and the numerical implementation of the s-IGA (S-version Isogeometric Analysis, see [1] for IGA) for finite strain elastic-plastic analysis including elastic-plastic fracture mechanics problem are presented. S-IGA follows the idea of s-FEM (s-version finite element method [2]). IGA patches for the structure/solid as whole and for local features such as cracks are generated separately. They are superposed each other. Such process of building analysis model makes adding local features, such as cracks, to the analysis model very tractable. In a similar way of the thoughts, X-IGA is found to be a popular methodology. S-IGA may be one of alternatives to the existing methodologies.

In the presentation, S-IGA for finite strain elastic-plastic problems is presented. In the present research, a finite strain elastic-plastic constitutive law assuming the multiplicative decomposition of plastic and elastic deformations (see de Souza Neto et al. [3]) is adopted. The hyperelasticity is assumed for the elastic deformation part. In the presentation, the basic equation formulation of S-IGA for finite strain elastic-plastic analysis, its numerical implementation including ways to store the strain history parameters, ways to effectively model the crack, etc., are described. Then, a few example problems and some concluding remarks at present moment will be presented.

THE HYBRID RESOLVED-UNRESOLVED SPH(2)-DEM COUPLING SIMULATION FOR THE INTERNAL SOIL-EROSION IN SOIL-STRUCTURES

ABSTRACT

Internal erosion induced by seepage flow inside the soil accelerates soil failure during a flood disaster. Numerical simulation, which enables microscopic observation through hypothetical numerical experiments, can be an effective tool to quantitatively evaluate the relationship between internal erosion and the instability of the soil-structure.
Fluid-Soil multiphase flow simulation requires coupling technologies that can represent the interaction between soil-particles and fluid and the movement of particles. There are two main concepts for coupling models: "Resolved coupling model," which can calculate detailed flow and fluid forces, and "Unresolved coupling model," which is based on empirical drag and seepage flow models. However, previous studies have indicated that both models should be judged appropriately based on the ratio of solid particle to fluid spatial resolution [1]. However, applying a resolved coupling model to the vast number of soil particles composed of ground is impractical from a computational cost perspective, and empirical unresolved coupling model has difficulty in representing localized failures such as internal erosion [2]. Moreover, to solve the seepage flow accurately using particle methods, it is essential to employ high-order schemes that distribute the particles in an ideal configuration consistent with the space-time varying porosity distribution. Novel coupling models that satisfy both computational accuracy and efficiency are desirable. In this study, we developed a fluid-soil particle coupled model that directly represents the transport of soil particles during the erosion process. That is, it couples a DEM-based soil-particle model with a seepage flow simulation, enhanced by SPH(2) [3]. The proposed method is a hybrid coupled model that suitably employs both resolved and unresolved models depending on the resolution of the soil particles. This paper reports on the verification of the accuracy of the seepage flow simulation with SPH(2) and numerical experiments on internal erosion using the proposed hybrid coupled model.

DETERMINATION OF ORTHOTROPIC ELASTIC MODULUS OF WOOD BY INDENTATION WITH NONE-AXISYMMETRIC INDENTER AND FEM SIMULATION

Tomoaki Tsuji[*1] and Kouhei Saito*[1]

[1]*Chuo University*

ABSTRACT

Woods are biomaterial and have complex structures. The annual rings are made by seasons. Then, the rigidity of wood is difference along direction. Thus, the elastic modulus of the wood can be considered as the orthotropic material in the macro scale. It is necessary to clarify these mechanical properties in order to expand the range of applications of woods [1]. On the other hand, the indentation method is a quasi-nondestructive testing method and there are many applications to measure the rigidity of materials. In order to give the orthotropic mechanical properties by using an axisymmetric indenter, the indentation test should be made from the different directions. On the other hand, different load-depth data can be obtained by rotating a none-axisymmetric indenter along to an axis normal to a wood surface.

Therefore, in this study indentation tests are performed to woods by using cylindrical indenter with both sides are sphere, that is none-axisymmetric indenter. This indenter is made from aluminum with about 20 mm length and 5 mm radius by using 3D processing machine. Many load-depth curves can be given by rotating the indenter along the normal axis to the wood surface. In order to determine orthotropic mechanical properties, FEM simulations are performed with the parameters as orthotropic elastic modulus along tangential, radial and longitudinal direction of the wood. By minimizing the error between measured and simulated load-depth curves, the orthotropic elastic modululi can be given. The determined orthotropic elastic moduli are compared to the measured ones by using compress tests.

NUMERICAL ANALYSIS OF DROPLET FREEZING ON COLD SURFACES USING THE MOVING PARTICLE SIMULATION METHOD

Hiroki Tsujimura[*1] and Kenichi Kubota*[1]

[1]*Japan Aerospace Exploration Agency*

ABSTRACT

Icing is hazardous to in-flight aircrafts because the ice disturbs airflow around the airfoil, decreases the aerodynamic performance, and in some cases, forces the aircraft to be uncontrollable. Established numerical tools for icing prediction are based on Euler grid methods. They can predict rough estimates of ice thickness over a large surface, for example a whole wing, at low cost. However, icing in some conditions, for example, when supercooled large droplets (SLD) splash on the aircraft surface, or when complex shaped ice is formed, are difficult to predict. The reason is because some key mechanisms of ice formation, namely droplet merging, accumulation, and freezing, are not fully described. The moving particle simulation (MPS) method is effective in solving free surface flow. Droplet dynamics involving splitting and merging can be simulated with no special treatment. We therefore expect that the MPS method is a potential means to improve the physical fidelity of icing prediction.

In this presentation, extensions to the explicit-MPS method for solving freezing problems, and validations through analyses of droplet freezing, will be described. To solve the thermodynamics of a freezing liquid, we adopted a common approach that is used in the nuclear engineering field (e.g. Koshizuka et al, Int Conf Nucl Eng, 2001). Surface tension and wettability was introduced by our original surface-tension-as-pressure model (Tsujimura et al., Comput Particle Mech, 2023). As the first validation of our MPS code, a one-dimensional heat conduction problem and a freezing front propagation problem was solved, and the time-dependent results agreed well with theoretical solutions. Second, a sessile droplet freezing on a cold plate was solved. Theoretically, the frozen droplet’s shape becomes either concave up or concave down depending on the surface wettability and the liquid-solid density ratio. The ices’ shapes were successfully predicted. As the third validation, a droplet impinging on a flat surface was simulated. The droplet bounded in a room temperature condition while it adhered to the plate in a supercooled condition, which are behaviors that agree with an experiment (Zhang et al., Int J Heat Mass Transfer, 2020). The droplet’s overall shape during impact was qualitatively similar to the experiment. The presentation will demonstrate our initial attempt of applying the MPS method to icing problems.

[2]*Panasonic Connect Co., Ltd.*

ABSTRACT

In recent years, CAE analysis has reduced the number of experiments and costs in the design process of manufacturing. However, CAE analysis for high accuracy is computationally expensive. The prediction by machine learning would be expected to be accurate as same as CAE and shorter time than CAE. In general, it is difficult to predict extrapolation in regression problems. Rules-based on physical phenomena should be well-trained in the predictor for extrapolation. Therefore the predictor is required to improve generalization performance and adapt to engineering problems.

In our previous study, we proposed a method for constructing a surrogate model to analyze the temperature distribution on a circuit board with ICs. The input data consists of the positional relationship between different ICs placed on the board and the coordinate values of the evaluation points and ICs. In this study, the predictor computes a temperature at a point using local differential physical quantities and local material properties. We'd like to propose a new training technique using the sub-voxels which is a container of local physical quantities and material properties as input parameters in the analysis field. The predictor can extrapolate the physical temperature field because physical rules are trained in the predictor. The objective of this study is the construction of a surrogate model that continuously predicts an unsteady temperature field on a circuit board using sub-voxels input data structure.

The input matrix which is configured using sub-voxels is suitable for convolutional neural networks. The predictor was composed of a CNN. The advantage of the sub-voxels is that a large amount of training data can be obtained from a single analysis result. Dummy temperatures for ICs were created to extract initial temperature features. The low-temperature data was down-sampled to eliminate bias in the data distribution. Thus, the accuracy of the predictor was improved and the training cost was reduced. We will discuss effective input data design to improve prediction accuracy and reduction of training computation.

PREDICTION OF THE EFFECTIVE RESPONSE OF CARBON-BLACK/ULTRA-HIGH-MOLECULAR-WEIGHT-POLYETHYLENE NANOCOMPOSITES BY MULTISCALE NUMERICAL MODELS

Igor Tsukrov[*1]

[1]*University of New Hampshire*

ABSTRACT

Stanislav Buklovskyi, Kateryna Miroshnichenko, Igor Tsukrov (University of New Hampshire, USA)
Rebecca Thomson, Peder Solberg, Douglas Van Citters (Dartmouth College, USA)

The incorporation of carbon nanoparticles into ultra-high-molecular-weight-polyethylene (UHMWPE) provides opportunities for multifunctionality, such as increased electrical and thermal conductivity, as well as potential improvements in mechanical properties, including stiffness and wear resistance. In this study, we developed mesoscale numerical models of carbon-black (CB) reinforced UHMWPE based on micro-computed tomography (μCT) images of the material. The models incorporate the CB-containing layers around UHMWPE granules observed in the μCT images. These layers are treated as two-phase composites, and their properties are evaluated using analytical micromechanical schemes.

Mesoscale models of representative volume elements are analyzed by the finite element method. Numerical predictions of the overall elastic and thermal properties of the composites are compared with experimental measurements conducted on the same material systems, consisting of UHMWPE with various weight fractions of CB, ranging from 0.5% to 10%. The results emphasize the importance of incorporating accurate information on the distribution of carbon particles in the composite for the precision of the numerical models.

MODELING OF CELL CORTICAL TENSION BY A CO-DYNAMICS MODEL OF ACTIN, MYOSIN AND CROSSLINKER IN ACTOMYOSIN CORTEX

Kohsuke Tsukui[*1], Hiromi Miyoshi[1], Naoya Sakamoto[1] and Satoshi Ii[1]*

[1]Tokyo Metropolitan University

ABSTRACT

The cell membrane comprises plasma membrane and actomyosin cortex with their linker proteins. The actomyosin cortex, a composite material of actin filaments, myosin mini-filaments and crosslinkers, plays an important role in regulating a membrane stiffness. The myosin moves over actin filament through molecular interactions between the myosin head and actin, and this local event generates local contraction of cortex that results in cortical tension. A regulation of cortical tension is a crucial issue for various cell motions, and a recent study has shown its spatial difference also contributes the regulation [1]. However, how each of filaments mechanically works during generation of cortical tension remains unclear. Some mathematical models have been proposed to tackle this question (e.g., [2]); however, a comprehensive model being across different scales from filament to cell level has not been developed. In this study, we propose a mechanical model of a cellular-scale actomyosin cortex composed of multiple filaments. Line elements including resistances in stretching and bending are applied for dynamics of actin filaments, where their interconnection via crosslinkers is modeled by a spring element. The myosin mini-filament is modeled by a spring element that interconnects with actin filaments, and its sliding motion over the actin filament is described as a relative motion of myosin head to the actin filament. To reproduce a realistic structure and tension in cell cortex, the filaments are initially distributed within a domain of thin spherical shell, and a simulation is carried out until quasi equilibrium is reached. Present results showed overall cortical tensions increase as the number of myosin filaments and crosslinkers increase that is consistent with an experimental trend [3], and deformation of actin filaments has relatively little effect on generation of the cortical tension than those of myosin and crosslinkers. Our results also suggest that not a few compressed actin filaments appear that causes local negative cortical tension even though the overall cortical tension is positive, and temporal variation in cortical tension is happened by co-dynamics of actin, myosin and crosslinker.

ABSTRACT

We propose an algorithm for computing the time-harmonic scattering of a scalar field about an obstacle of an arbitrary shape immersed into a homogeneous environment. The algorithm is completely free of any spurious reflections from the artificial outer boundaries. It handles complex shapes not conforming to the discretization grid with no loss of accuracy, contains a reusable core that allows one to change the boundary conditions conveniently and at a low cost, and is easily parallelizable. It is a finite difference algorithm and can employ any standard or high-order accurate scheme. The implementation and error control are straightforward.

The algorithm relies on the method of difference potentials and interpretation of the time-harmonic wave field (solution to the Helmholtz equation) as a solution to the corresponding unsteady wave equation left behind the aft front of the outgoing wave (i.e., solution inside the lacuna of the wave equation).

We demonstrate the performance of the proposed methodology by computing the scattering about a sphere on a Cartesian grid, as well as scattering about a more realistic patch-based configuration built with the help of the CAD software. Extension to the case of a vector Helmholtz equation can also be considered.

ELECTRO-CHEMO-MECHANICS IN THE APPLICATION OF SOLID STATE BATTERIES

Howard Tu[*1]*

[1]*Rochester Institute of Technology*

ABSTRACT

Electro-chemo-mechanics is the relationship between electrical, chemical, and mechanical properties and the study of adjusting one property through the control of another. This relationship can result in special properties for solid-state materials, for instance, the mixed ionic and electronic conductivity (MIEC) of solid electrolytes (SE) in solid-state batteries (SSB). [1] In addition, the ionic and electronic mobility of solid electrolytes can be modified in strained systems (electro-mechanic) [2], and large stresses may be developed in the crystal structure due to non-stoichiometry-induced lattice dilation (chemo-mechanic) [3]. While the origins and characteristics of the electro-chemical relationships have been the focus of many studies, much less is known about the electro-mechanical, chemo-mechanical, and electro-chemo-mechanical relationships.

In this work, we are presenting an electro-chemo-mechanical model which incorporates mixed ionic-electronic conduction for SSBs to describe dendrite propagation in an SE with microstructural defects. A new framework for the metal deposition inside isolated pores of the SE and its coupling with SE fracture is established. The metal deposition in the voids is divided into three stages (metal initiation, metal growth, and metal compression), and the time needed to complete each stage is derived and related to the void size, applied current density, and SE material properties (such as ionic/electronic conductivity and fracture toughness). The electrochemical potentials, deposition overpotential, and current densities of the metal deposition in the void are presented. The deposition-induced pressure and the total time needed for the different stages are quantified. We find that anode voltage, current density, and overall cell potential play a very significant role in determining the vulnerability for metal plating in the SE. Two efficient strategies to reduce/prevent electronic conductivity-driven metal propagation are proposed based on our analysis, including surface coating (or densification) and anode alloying.

MULTI-LEVEL OPTIMIZATION-BASED SOLVERS FOR QUASI-STATIC PROBLEMS WITH INSTABILITIES

Michael Tupek[*1] and Brandon Talamini*[1]

[1]*Lawrence Livermore National Laboratory*

ABSTRACT

Many interesting nonlinear mechanics problems can be formulated as constrained optimization problems with non-convex objective functions in the quasi-static limit. Important examples include buckling, fracture and phase transition. Mathematically, these scenarios are characterized by the possible presence of negative eigenvalues in their linearized stiffness matrix. We explore trust-region algorithms which attempt to efficiently identify negative eigenvalue directions using multi-scale information, and which can also utilize a running approximation to the ‘left-most’ eigenvector to further accelerate progress when far away from local minima. When approaching a local minimum, effective preconditioning become essential. Here we use multi-level algorithms which leverage ideas from domain-decomposition and multi-grid preconditioners. We discuss trade-offs between various linear and nonlinear multi-level algorithms for solving these nonlinear equations at scale and give examples involving complex buckling structures.

SECOND-ORDER SOLVERS FOR TRAINING REGRESSION PROBLEMS IN SCIENTIFIC MACHINE LEARNING

George Turkiyyah[*1], David Keyes[1] and Stefano Zampini[1]*

[1]KAUST

ABSTRACT

In recent years, we have witnessed the emergence of scientific machine learning as a data-driven tool for the analysis, by means of deep-learning techniques, of data produced by computational science and engineering applications. At the core of these methods is the supervised training algorithm to learn the neural network realization, a highly non-convex optimization problem that is usually solved using stochastic gradient methods. However, distinct from deep-learning practice, scientific machine-learning training problems feature a much larger volume of smooth data and better characterizations of the empirical risk functions, which make them suited for conventional solvers for unconstrained optimization. We introduce a lightweight software framework built on top of the Portable and Extensible Toolkit for Scientific computation to bridge the gap between deep-learning software and conventional solvers for unconstrained minimization. We empirically demonstrate the superior efficacy of a trust region method based on the Gauss-Newton approximation of the Hessian in improving the generalization errors arising from regression tasks when learning surrogate models for a wide range of scientific machine-learning techniques and test cases. We show that the conventional second-order solvers tested, including L-BFGS and inexact Newton with line-search, compare favorably, either in terms of cost or accuracy, with the adaptive first-order methods used to validate the surrogate models.

UNCERTAINTY QUANTIFICATION OF THE LIFETIME OF SELF-HEALING THERMAL BARRIER COATINGS

Sergio Turteltaub[*1], Anuj Kumthekar[1], Sathiskumar Ponnusami[2] and Sybrand van der Zwaag[1]*

[1]Delft University of Technology
[2]University of London

ABSTRACT

Thermal barrier coatings (TBCs) are widely used in jet engines operating at high temperatures to protect the underlying structural components from oxidation and degradation. They consist of a ceramic top coat (TC) layer that is adhered to the substrate with the help of a metallic bond coat (BC) layer. Upon prolonged exposure to thermal cycling, microcracks form and grow slowly parallel to the TC/BC interface, eventually leading to separation and final failure of the TBC. In order to increase its lifetime, a self-healing (SH) TBC composite system has been designed based on including encapsulated healing particles in the top coat near the TC/BC interface. Upon being opened by the passing microcrack, the particles supply a ceramic adhesive that heals the microcracks, thus delaying final failure. To simulate this system, a micromechanical model that incorporates a cohesive-zone based crack healing model was developed, which allows to estimate the lifetime of the TBC upon thermal cycling [1]. Nonetheless, this deterministic model cannot on its own cope with the uncertainties associated to the variability in the micro-structural design variables. In order to consider the uncertainties in input variables, a surrogate model based on a Polynomial Chaos Expansion was developed to emulate the original model in a computationally efficient manner [2]. Variables such as the TC/BC interface amplitude, growth rate of thermally grown oxide layer at the TC/BC interface, diameter and volume fraction of healing particles, and the mean distance of particles from the TC/BC interface were used in the TBC FE model. The trained surrogate model allows to establish the statistical characteristics of the TBC lifetime as well as the sensitivity indices of the input variables. This insight is critical for the design of a robust SH-TBC system in which the role of each parameter is clarified and the variability in the lifetime can be quantified.

NONLOCAL MODELING OF MACROSCOPIC NON-UNIFORM DEFORMATION INDUCED BY MICROSCOPIC HETEROGENEITY

Makoto Uchida[*1] and Yoshihisa Kaneko*[1]

[1]*Osaka Metropolitan University*

ABSTRACT

Engineering materials have microscopic heterogeneity such as a polycrystalline structure in the metallic material, which induces non-uniform deformation in the macroscopic scales when the size differences between macro- and microstructures are small even under macroscopic uniform stress state. In this study, we attempt to directly describe the non-uniform deformation induced by the microscopic heterogeneity and evaluate the development of non-uniform deformation characterized by the interaction between those caused by external factors such as boundary condition and specimen shape and internal factors such as the heterogeneous microstructure.

In the modeling process, the strain distribution obtained from the digital image correlation was used to quantify the non-uniform deformation induced by the microscopic heterogeneity. The average stress-strain relationship is first evaluated based on the distribution of the local equivalent stress and strain. Using the strain calculated using the averaged relationship, we evaluated the strain deviating from the averaged relationship, and they were assumed to be induced by the microscopic heterogeneity of the material. This strain was represented using a constitutive model including the gradient of the plastic compliance, and the parameters employed in the models were fitted using the experimentally measured strain field.

Subsequently, a multiaxial elastoplastic nonlocal constitutive equation was formulated. As the plastic strain field is directly related to the stress field in the proposed method, the nonlocal constitutive equation without an unknown plastic field can be formulated. Finite element (FE) simulations introducing the proposed nonlocal effect indicated that a scale-dependent non-uniform deformation characterized by the interaction between those induced by external and internal factors was predicted.

PHASE-FIELD SIMULATION OF MORPHOLOGICAL CHANGE AND STABILIZATION OF FOAM STRUCTURE

*Takuya Uehara**[1]

[1]*Yamagata University*

ABSTRACT

In this study, foam structure consisting of many separate cells was focused, and its formation and stabilizing process was simulated using phase field model. In a liquid foam formation process, each cell grows spherically before the neighboring cells collide, and then polyhedral shapes are formed. The initial shapes are determined depending on the nuclei distribution, while the cell-shape changes as time passed. The morphological change and the stabilization process were simulated. Multi-phase-field model was used by applying an individual index to each cell, and time evolution was simulated by the finite difference method. As a result, we successfully obtained the expected variation of the foam structure.

OPTIMIZATION OF ULTRASONIC CEREBROVASCULAR STIMULATION THERAPY FOR ALZHEIMER'S DISEASE

Tsuyoshi Ueta[*1]*

[1]*The Jikei University School of Medicine*

ABSTRACT

In Japan, as the population ages, the number of cases of Alzheimer's disease is increasing. Alzheimer's disease has traditionally been regarded as a disease of the nervous system, but it has been revealed that it is caused by arteriosclerosis due to the deposition of amyloid β in the capillaries of the brain. It has been found that amyloid β is discharged by stimulating cerebral blood vessels with weak ultrasonic waves. Treatment with that method is about to enter Phase 3 clinical trials. Existing devices for other applications are, however, used for brain stimulation, and the sound field used for stimulation has never been optimized. In this study, we propose to uniformly stimulate the brain with a single irradiating plane wave using a transcranial lens. We have already proposed transcranial lenses with appropriately placed point-like scatterers.

Modifying the already developed Monte Carlo method, we attempted to optimize the arrangement of point scatterers so that the incident plane wave ultrasound has a uniform intensity within the brain.
When a plane wave is incident from the front of the skull, however, a remarkable reflection occurs at the back of the head, which cannot be canceled out. In this study, therefore, we propose incidence from the temporal region.

In order to optimize the arrangement of the point scatterer array lens, we minimized the weighted sum of the objective function that makes the ultrasound intensity at each point within the skull a specified value and the objective function that smoothes the sound field intensity. We systematically investigated the smoothing effect by varying the weight of the weight sum. This problem turned out to be much more difficult than optimizing a lens that focuses transcranially into the brain.

This work was supported by JSPS Grant-in-Aid for Scientific Research, Grant Nos. 19H00740 and 22K03987.

DIGITALIZATION OF MANUFACTURING SYSTEMS BY USING DIGITAL TRIPLET

Yasushi Umeda[1]*

[1]*The University of Tokyo*

ABSTRACT

Digitalization is eagerly required in all domains for increasing added value and decreasing costs including labor costs. In this research, digitalization includes the introduction of IoT (Internet of Things), digital tools, software, and the automatization that reduces manpower. This paper discusses digitalization in the domain of manufacturing systems.
Features of Japanese manufacturing style include high quality of products and continuous improvement of manufacturing systems. Both of them are driven by skilled workers and engineers, who are working together. Inappropriate digitalization may bring about negative side-effects on the features of the Japanese manufacturing style. Namely, inappropriate digitalization may eliminate skilled workers and engineers and, as a result, the company cannot maintain the quality and cost-effectiveness of the product and high productivity of the manufacturing system. Moreover, the digitalization may bring about the stagnation of technological progress of the manufacturing system if the digitalization impedes the continuous improvement.
In order to avoid these problems, this paper proposes a method for digitalizing manufacturing systems based on knowledge and skills of engineers. We have proposed the concept of Digital Triplet [1], which records the process of problem-solving of skilled engineers, models the process, and reuses it. In addition to physical world and cyber world, which constitute the traditional digital twin, Digital Triple consists of intelligent activity world, where engineers solve problems using digital twin. In the framework of D3, a problem-solving process driven by an engineer is modeled as “Generalized Process Model (GPM)” by using the process description language for D3 (PD3). Examples of GPM include design, continuous improvement, and fault diagnosis of a manufacturing system. The main idea of the proposed method is to digitalize a manufacturing system based on GPM. This type of digitalization preserves knowledge and skills of engineers described in GPM. And, since D3 is inherently embedded with the mechanism of continuous improvement, the digitalized manufacturing system based on the proposed method inherits the mechanism of continuous improvement. In this manner, the proposed method solves the above-mentioned two problems.
This paper describes the procedure of the proposed method, which supports a team of field engineers and system engineers to accomplish the digitalization and illustrates an example of practical application of the proposed method.

DEDUCTION-INDUCTION INTEGRATED MULTISCALE SIMULATION: DISLOCATION PATTERN FORMATION IN FATIGUE

Yoshitaka Umeno[1] and Emi Kawai*[1]

[1]*The University of Tokyo*

ABSTRACT

Fatigue fracture in metal is a major failure mode in industrial mechanical components. While the mechanism of fatigue crack propagation can be understood in the mechanical point of view considering the effect of microstructures and crystal orientations on crack growth, there is still much room for investigations of the mechanism of fatigue crack formation under cyclic loading. As the fatigue crack formation is closely related to dislocation network patterns that emerge as a result of mutual interaction between a number of dislocations [1], it is important to clarify the mechanism of dislocation structure formation under cyclic loading.

The reaction-diffusion equation approach is a method widely used to model the dislocation structure formation. A challenge in the approach is, however, the difficulty in the determination of appropriate parameters in the governing equations because deductive (bottom-up) determination for such a phenomenological model is problematic.

To address this problem, we propose an inductive approach with the machine-learning method to search a parameter set that produces simulation results consistent with experiments [2]. Using a thin film model, we performed numerical simulations for various sets of input parameters to obtain dislocation patterns. The resulting patterns were represented by the following two parameters; the number of dislocation walls, and the average width of the walls. Then, we constructed an artificial neural network (ANN) model to successfully map between the input parameters and the output dislocation patterns. This scheme of inductive approach to scale-bridging enables top-down determination of appropriate constitutive laws of materials.

In addition, we propose statistical atomistic models to estimate coefficients of dislocation diffusion and interaction that appear in the reaction-diffusion equation. This way one can determine the phenomenological model parameters in the bottom-up (deductive) fashion. Combined with the aforementioned top-down approach, a new scheme to bridge models for different length scales, which we call DIMS (deduction-induction integrated multiscale simulation), can be established. This framework employing the two-way determination of model parameters is expected to enhance the reliability of hierarchical multiscale simulation models.

ELASTO-MECHANICAL CHARACTERIZATION OF BIOFIDELIC SOLID-LIQUID COMPOSITES

Karthik Kundapur[1] and Vinu Unnikrishnan[1]*

[1]West Texas A&M University

ABSTRACT

Biofidelic soft composite materials that mimics the mechanical properties of human tissues have numerous applications ranging from prosthesis development to wearable devices. These composite materials typically comprises of a soft inclusion phase embedded in a soft matrix. In this work, a category of soft composite materials exhibiting biofidelic characteristics with liquid inclusions embedded in a soft matrix called Solid-Liquid Composites (SLCs) are developed [1]. The introduction of a liquid phase, such as water, liquid metals, or complex fluids, into the soft matrix imparts distinct properties and characteristics that may differ from those of pure solids or liquids. The soft and functional nature of SLCs makes them well-suited for use in soft robotics, biomedical applications, sensing devices, flexible electronics, targeted drug delivery systems, impact resistance, and energy dissipation applications. Tailoring the properties of SLCs to specific needs is achievable by controlling the type and volume fraction of the liquid inclusions.

A unique approach to fabricating Solid-Liquid Composites (SLCs) using commercially available soft silicone matrix (Smoothon Ecoflex 00-30) and laboratory-grade liquid glycerin will be discussed [2]. While Eco-flex 00-30 replicates the behavior of a specific class of human tissues, glycerin is selected due to its non-toxic and immiscible properties with silicone. An experimental approach to characterize the elastic properties of the SLCs, followed by the development of linear-elastic based study to understand size-effect of the inclusion phase, and hyperelastic based material models will be discussed.

SINGLE- AND DOUBLE-GENERATOR BRACKETS FOR THERMODYNAMICS-INFORMED NEURAL NETWORKS

ABSTRACT

The development of neural networks consistent with the laws of thermodynamics can be achieved by imposing inductive biases on the network by defining the problem structure with thermodynamically coherent formalisms such as Poisson brackets. This formalism can be extended to take into consideration dissipative effects in dynamic processes by introducing dissipative brackets and changing the energy generator for a combination of the conservative energy and the entropy. Different approaches can be used as different generators (energy descriptors of the problem) can be defined [1]. By considering a single energy generator, the generalized free energy of the system (a combination of the internal energy and the entropy, i.e., F=E+S), the Single Bracket can be defined. Another option, as in the case of the GENERIC formalism, is to define two separated energy generators corresponding to the conservative energy (E), and the dissipative energy (S) [2].
The differences in the reconstruction of different non-conservative dynamics through the described formalism, Single Bracket (SB) and double bracket or GENERIC (G), have been analyzed in the development of thermodynamics-informed neural networks [3]. Different advantages and limitations have been found in each formulation in data reconstruction.
Even when both formulations are thermodynamically consistent, GENERIC can impose easily thermodynamic restrictions on the system through consideration of the degeneracy conditions in the system. Even though the energy conservation is not explicitly imposed in SB, this is fulfilled to the extent that the network learns the state variables in latent space.
Despite the similarity in the formalisms, the net hyperparameters play different roles in both formulations. As SB formalism depends only on the data training, it increases precision as the available data increases, but it is highly dependent on network capacity. For its part, the degeneracy conditions on G formalism improve the generalization of the problem, providing robustness to the system, limiting the overfitting of the network, and being able to reconstruct the system with less data.

GOAL-ORIENTED ADAPTIVITY FOR SOLVING PARTIAL DIFFERENTIAL EQUATIONS USING ARTIFICIAL NEURAL NETWORKS

ABSTRACT

Over the last two decades, Goal-Oriented Adaptivity (GOA) has been extensively studied and developed for the Finite Element Method (FEM). It is a technique that consists of enhancing the discretization of the underlying mesh with the aim of approximating a specific Quantity of Interest (QoI) rather than the error in the energy norm [1].

In this work, instead of considering a FEM discretization, we use neural networks. By adopting an Extreme Learning Machine interpretation for feed-forward neural networks [2], we are able to establish a Petrov-Galerkin-type approach such that: (i) the basis functions are no longer locally supported, and thus possess the potential to overcome the curse of dimensionality; (ii) the basis functions are governed by trainable parameters, yielding a highly non-linear scheme; and (iii) for each choice of trainable parameters, the optimal coefficients of the corresponding linear combination are efficiently computable following a minimum residual methodology. In this way, each GOA iteration is identified in our proposal as a training step of neural networks where the loss function represents an appropriate upper bound of the QoI.

We restrict ourselves to symmetric and positive-definite problems to ensure that we can incorporate robust error estimators for the primal and dual problems within the loss function. Extending it to non-symmetric or indefinite problems requires special care, which we plan to address in future work. The numerical experiments conducted in different spatial dimensions demonstrate the effectiveness of our strategy, up to the optimizer performance capacity and the usual numerical integration challenges.

NUMERICAL MODELING OF ANISOTROPIC DAMAGE BEHAVIOR IN CONCRETE USING GRADIENT ENHANCEMENT OF TENSILE AND COMPRESSIVE INTERNAL VARIABLES

Athira Vadakkekkara[*1] and Ursula Kowalsky*[1]

[1]*Technische Universität Braunschweig, Germany*

ABSTRACT

The most basic damage model treats damage as isotropic using a scalar variable to represent the progressive damage evolution. However, in the case of brittle materials like concrete, failure mechanisms are more complex and dependent on the direction of loading and the mutual interactions of microcracks in the structure. An anisotropic damage law using a second-order damage variable is used in the proposed model to get a better prediction of stress response of concrete under multiaxial loading conditions. The finite element implementation of such a damage model results in spurious mesh sensitivities due to softening-induced localization phenomena of the material. To overcome this, a gradient enhancement technique that introduces an internal length scale is utilized in the model. In this method, higher gradients of certain damage-dependent variables are introduced in order to enrich the standard continuum. To account for the asymmetry in the tensile and compressive behavior of concrete, two separate equivalent strains are incorporated as the regularizing or nonlocal variables in the proposed model. These variables are introduced as the nodal degrees of freedom in the finite element system. The model is validated for different experimental results under various load conditions. A few examples are also provided to show the adequacy of the model in the prediction of cracking patterns in concrete structures.

ENERGY CONSERVATIVE QUADRATURE BASED HYPERREDUCTION OF LAGRANGIAN HYDRODYNAMICS PROBLEMS

Chris Vales[1], Siu Wun Cheung[2], Dylan M. Copeland[2] and Youngsoo Choi[2]*

[1]*University of New Hampshire*
[2]*Lawrence Livermore National Laboratory*

ABSTRACT

Dimension reduction methods are used to approximate the numerical discretization of a model in order to reduce the computational cost of its simulation while staying faithful to the full dynamics. To achieve this, projection-based methods construct a reduced basis from full simulation data and project the dynamics onto the spanned linear subspace. For nonlinear problems, hyperreduction methods are additionally needed to remove the dependence of the nonlinear terms on the full problem's size, completing the reduction process. In this work, we develop an energy conservative hyperreduction method for hydrodynamics PDE problems discretized on a Lagrangian moving grid by high order finite element methods [2]. Based on an existing empirical quadrature procedure [3], our method employs sparse numerical quadrature rules to estimate the model's nonlinear integral terms with a chosen degree of accuracy while ensuring that energy is conserved. We apply our method to well established benchmark problems, such as the Sedov blast and Gresho vortex problems [1], demonstrating that it achieves superior energy conservation and similar accuracy and computational speedup compared to the preexisting, non-conservative method.

A MONOLITHIC FINITE ELEMENT METHOD FOR AN ENERGY-MINIMIZING PHASE-FIELD MODEL OF FULLY EULERIAN FLUID-STRUCTURE INTERACTIONS

Navid Valizadeh[*1], Xiaoying Zhuang[1] and Timon Rabczuk[2]*

[1]*Leibniz University Hannover*
[2]*Bauhaus University Weimar*

ABSTRACT

In this study, we present a fully monolithic finite element method designed for the simulation of incompressible fluid-structure interaction problems within an Eulerian framework. The fluid dynamics is characterized by the Navier-Stokes equations, while the structural behavior is represented using a hyperelastic neo-Hookean material. The continuum model [1] comprises a system of Navier-Stokes equations coupled with a Cahn-Hilliard phase-field model and an Oldroyd-B type equation. To ensure thermodynamic consistency, forces and fluxes closing the system of equations are derived through energy variation principles. Within this framework, the Cahn-Hilliard model governs the interface position, and the Oldroyd-B equation is utilized to determine the left Cauchy-Green stress tensor, essential for computing elastic stresses within the solid. The solution methodology involves employing a residual-based variational multiscale method for the Navier-Stokes equations, while the Cahn-Hilliard and Oldroyd-B equations are addressed through a mixed finite element method and a standard Galerkin finite element method, respectively. To verify the model formulation and implementation, we conducted simulations for various two-dimensional examples. Furthermore, we expanded the applicability of the method to address frictionless contact problems and three-dimensional scenarios.

A CONTINUOUS-DISCONTINUOUS SHALLOW WATER SOLVER FOR COMPOUND FLOOD MODELING

Eirik Valseth[*1], Chayanon Wichitrnithed[1] and Clint Dawson[1]*

[1]*Oden Institute for Computational Engineering and Sciences*

ABSTRACT

Recent tropical cyclones, e.g., Hurricane Harvey (2017) and Hurricane Matthew (2016), have lead to significant rainfall and resulting riverine runoff with accompanying flooding in addition to catastrophic storm surge from the sea. As the interaction between river runoff and storm surge is nonlinear, thus superposition of the two phenomena from separate models is not applicable. Current existing numerical models based on surrogates to the shallow water equation (SWE) incorporate both rain and riverine processes. However, the simplifications make their use limited to inland regions and unsuitable for flow in coastal regions with storm surge. Coastal and storm surge models such as ADCIRC [2], based on continuous Galekrin methods may have issues with mass balance due to their conservation properties. On the other hand, SWE solvers based on discontinuous Galerkin (DG) methods, such as those introduced in [1] avoid these issues due to their local mass conservation property. Recently, we introduced DG solver for a modified SWE for compound flood simulations [3] which incorporated rainfall onto the finite element mesh. In this presentation we explore the use of mixed continuous and discontinuous approximation spaces for the modified SWE to optimize the computational cost. Numerical experiments for past hurricane events will be presented to highlight the capabilities of the proposed scheme and comparison to existing numerical models.

MULTI-DIMENSIONAL FLOOD MODELING OF AN EXTREME RAINFALL EVENT IN NORWAY

Kristen Valseth[*1], Lars Valnes[1], Eirik Valseth[2] and Kent-Andre Mardal[1]*

[1]*University of Oslo*
[2]*Norwegian University of Life Sciences*

ABSTRACT

Public availability of large high-resolution datasets and advancements in computational capabilities have made the use of partial differential equation based numerical models in hydrology an effective tool for predictions of extreme events and management of water supplies. These developments combined with climate change driven increases in extreme hydrologic events, such as flooding, has generated a need for more accurate and informed water management and prediction tools. As a test case Hans, an extreme storm event in 2023, that saw 100-139 mm of precipitation over a large interior area of Norway in a short time frame was modeled. The event caused widespread damage of infrastructure and property from flooding and landslides, particularly in the area of Nesbyen where the model is focused. To improve future responses and preparation to these types of events this study aims to create more accurate and informed runoff model based on finite element discretizations of surrogates to the shallow water equations. These surrogates include the Diffusive Wave Approximation [1] and the multi-dimensional Kinematic Wave Approximation [2].

In the present work, we develop finite element approximations of these shallow water surrogates. Our focus in the development of a model that utilizes the elevation and landcover data for the Nesbyen catchment and precipitation data from the Hans event as input and model data. Focus is given to the validation of the developed approximations utilizing the diffusive wave model, whereas a novel 1D-2D coupled model utilizing the kinematic wave equation is also presented.

THEORY OF DESIGN SPACE FILTERING VIA INTEGRAL TRANSFORMS

Hazhir Aliahmadi[1], *Ruben Perez*[2] *and Greg van Anders**[1]

[1]*Queen's University*
[2]*Royal Military College*

ABSTRACT

Optimization problems provide some of the earliest, most well-developed, and powerful applications of computation. However, all optimization problems that require significant computation do so because the ultimate, optimal solution cannot be easily deduced from the structure of the problem. Because problem structure—solution structure connections are obscure, it is difficult to understand the relationship between problem and solution features to answer questions about sensitivity, robustness, etc. Here, we describe an integral transformation approach to elucidating the structure of optimization problems. Analogously to the way that integral transforms provide critical insight into problems in signal processing and in control, the integral transform framework we describe here provides new perspectives on the underlying solution space of optimization problems. We show that this framework gives geometric, statistical, and physical perspectives on the form of the solution space of a design problem as a function of the design objectives. We relate the present framework to other known approaches to optimization, some of which emerge as special or limiting cases of the present framework. The framework we present can be applied to a broad range of problems, and we briefly discuss example applications.

ANALYSIS OF DIVERGENCE-PRESERVING UNFITTED FINITE ELEMENT METHODS FOR THE MIXED POISSON PROBLEM

Christoph Lehrenfeld[1], *Tim van Beeck**[1] *and Igor Voulis*[1]

[1]*University of Göttingen*

ABSTRACT

Geometrically unfitted finite element methods, such as CutFEM, XFEM, or unfitted DG methods, have been developed and applied successfully in the last decades to a wide range of problems ranging from scalar PDEs on stationary domains to systems of PDEs on moving domains and PDEs on level set surfaces. These methods commonly rely on stabilization techniques, for instance, ghost penalty (GP) stabilization to ensure stability independent of the local cut configuration. Mixed finite element methods based on special vectorial finite element spaces, e.g. H(div)-conforming finite element spaces, however, are tailored to preserve conservation properties like mass conversation exactly on the discrete level. By introducing stabilization terms such as GP stabilization, these conservation properties are perturbed. In this work, we introduce and analyse a stable discretization of the unfitted mixed Poisson problem with Dirichlet boundary conditions. Notably, our approach does not require stabilization terms that pollute the mass balance. The key idea is to formulate the divergence constraint on the active mesh instead of the physical domain, which yields a robust discretization independent of the cut configuration without the need for stabilization. This modification does not affect the accuracy of the flux variable and by applying postprocessing strategies to the scalar variable, we achieve optimal convergence rates for both variables and even superconvergence for the scalar variable.

COUPLED CALIBRATION FOR COHESIVE AND FREE-FLOWING GRANULAR MATERIALS USING DEM

Marcel van Benten[*1], Dingena Schott[1] and Johan Padding[1]*

[1]TU Delft

ABSTRACT

Sodium borohydride (NaBH4) is considered as an alternative fuel for the maritime industry [1]. In contrast to conventional fuels, NaBH4 is a granular material. To use a simulation-supported design for assessing the feasibility of equipment designs for storing and handling this material, its mechanical characteristics are required. These are then used to calibrate and verify simulations using the Discrete Element Method (DEM). However, as this is a novel application for this material, virtually no bulk characteristics are known yet. Therefore extensive testing has been done to extract required mechanical characteristics, such as cohesion, adhesion, internal friction, wall friction, and the Angle of Repose (AoR). These experiments showed that NaBH4 is initially free-flowing, but an increase in the moisture content because of an increase in relative humidity leads to an increase in cohesion, effectively reducing the flowability of the bulk material. Furthermore, our experimental results showed plastic deformation of individual NaBH4 particles.

This work focuses on capturing both the free-flowing and cohesive behaviour of NaBH4 in DEM. To this end, the two-step calibration approach introduced by Grima [2] is adopted and adjusted. First, the free-flowing behaviour is calibrated using a non-cohesive contact model, Hertz-Mindlin (HM). Second, the cohesive material is calibrated using the appropriate cohesive parameters of the Edinburgh Elasto-Plastic Adhesion contact model (EEPA), while the (calibrated) non-cohesive parameters are kept constant. The novelty of this work is the use of EEPA for the second calibration step, which allows the modelling of both the cohesive behaviour and the plastic deformation of the individual particles in the bulk material.

SIMULATING DYNAMIC MATERIAL EXPERIMENTS USING A LAGRANGIAN CODE IN TWO- AND THREE- DIMENSIONS

Kendra Van Buren[1], Saryu Fensin[1] and Anna Llobet[1]*

[1]*Los Alamos National Laboratory*

ABSTRACT

Experiments simulated with Lagrangian codes will often try to take advantage of axi-symmetry to model experiments in two-dimensions, thus requiring less computational expense. However, the necessary assumptions break down when simulating experiments with real-life defects or other three-dimensional features. In this talk, I will discuss some recent results for simulating explosively-driven shock experiments used to better understand material behavior undergoing plane-wave shocks. The plane wave shocks used in these experiments result in higher pressures than dynamic experiments such as flyer-plate experiments, which have been routinely used to study material strength. These experiments, known as the "Lens" experiments to describe how the plane-wave shock is generated, were performed at the Proton Radiography (pRad) facility at Los Alamos National Laboratory (LANL) [1]. The experimental data that are used to evaluate the models include experimental velocimetry data and radiographs. The velocimetry data measure how the face of the material sample is accelerated by the plane-wave shock, and the radiographs provide snapshots of the material areal density at discrete timesteps.

The Lens experiments are simulated using FLAG, a langrangian hydrodynamics code developed at Los Alamos National Laboratory, in both two- and three-dimensions. These simulations are performed using conformal meshing and Arbitrary Langrage Euler (ALE) to mitigate mesh tangling issues, and the material behavior is simulated with models for material strength and spall. Efforts have been made to compare both two- and three- dimensional simulation results to experimental data, and results will be presented that compare how the simulation performs in both dimensions. Progress toward simulating defects in the material sample will also be presented, and the presentation will include discussion about how we intend to develop our simulations and future Lens experiments to continue studying material strength and damage behavior.

ABSTRACT

We present a new approach for tracking high-order shocks, drawing on ideas from implicit shock tracking (developed by Matthew Zahr et al.) and extended discontinuous Galerkin (XDG) methods tailored for solving partial differential equations (PDEs) characterized by abrupt changes.

Within XDG methods, interfaces like phases in multi-phase flow are sharply represented using level set functions. This locally enriches the approximation space, accommodating additional jumps in the solution. We focus on devising an XDG method specifically for accurately portraying shock fronts in supersonic flows.

At the heart of our method lies a PDE-constrained optimization problem. Here, both the XDG coefficients of the solution and the level set serve as variables. We tackle the iterative computation of shock-aligned solutions using a Sequential Quadratic Programming (SQP) method, reinforced by various measures to ensure robustness.

To validate our XDG shock tracking method, we demonstrate a proof-of-concept through a range of two-dimensional problems. These include the 1D space-time advection equation, 1D space-time Burgers equation, 1D space-time Euler equations, and the steady 2D Euler equations.

LEARNING TO CHOOSE OPTIMIZERS

Martin van der Schelling[*1], Deepesh Toshniwal[1] and Miguel Bessa[2]*

[1]*Delft University of Technology*
[2]*Brown University*

ABSTRACT

Optimization plays a central role in Computational Mechanics. However, selecting the right optimization algorithm for a particular task is usually not trivial, as that results from the nature of the optimization problem to be solved and constraints such as available resource budget and training data. In order to address this, there has been a transition from creating hand-designed optimization algorithms to learning how to optimize (L2O), i.e. an approach attempting to learn the optimization conditions themselves. While many studies in the field of L2O have demonstrated good performance on a specific task distribution, they often suffer from poor generalization to other distributions. In addition, established L2O methods are often limited to a specific class of optimization algorithms.

We propose a new approach called "Learning to Choose Optimizers" (L2CO). Our method allows a meta-learner to select at test time from a range of static and well-established optimizers, also allowing to switch to a different optimizer during the optimization process itself. This enables the system to adapt to different task distributions and enhance generalization performance. The framework is set up to continuously incorporate new optimization algorithms and problems, inviting domain experts to contribute their insights and expertise for ongoing expansion.

In this study, we train our model offline on a diverse set of benchmark loss-functions and apply a range of gradient-based, population-based, and probabilistic model-based optimizers. The potential of this approach is demonstrated by comparing its performance to classical optimizers and established L2O-architectures on benchmark loss-functions and simple material design studies. The results suggest that L2CO can be a useful tool and exhibits better generalization. Our code and documentation is available as open-source using f3dasm (framework for data-driven design and analysis of structures and materials): https://github.com/bessagroup/f3dasm.

ADAPTIVE MESH REFINEMENT AND COARSENING PROCEDURES FOR THE VIRTUAL ELEMENT METHOD

Daniel van Huyssteen[*1], Felipe Lopez Rivarola[2], Guillermo Etse[2] and Paul Steinmann[1]*

[1]Friedrich-Alexander-University Erlangen-Nuremburg
[2]Universidad de Buenos Aires

ABSTRACT

The virtual element method (VEM) is a recent extension of the finite element method that permits arbitrary polygonal element geometry in two dimensions. This mesh flexibility means that the VEM is well-suited to problems involving adaptive mesh refinement. However, the VEM function spaces are defined such that quantities are only explicitly known on element edges. Thus, the well-known approaches to mesh adaptivity developed for finite elements cannot be directly applied to problems involving the VEM.

A simple energy error estimator has been implemented using a super-convergent patch recovery procedure. Using this error estimator elements are flagged for refinement or coarsening. The refinement [1] and coarsening [2] of the elements is performed using novel remeshing procedures that are suitable for the arbitrary polygonal element geometries permitted by the VEM. The remeshing procedures have been implemented for the VEM for the case of two-dimensional elastic problems. The procedures are motivated by seeking to reduce the global error approximation and to improve/smooth the error distribution over a problem domain to improve the efficiency of the VEM approximation. The performance of the remeshing procedures has been investigated in terms of accuracy in the H1 error norm with respect to computational cost and is compared to a traditional reference uniform mesh refinement procedure.

Numerical results over a wide range of benchmark problems demonstrate that the proposed remeshing procedures represent significant improvements in computational efficiency. Specifically, the adaptive refinement procedure generates solutions of equivalent accuracy to the reference procedure while using significantly fewer degrees of freedom, and significantly less run time. While the adaptive coarsening procedure can generate meshes comprising significantly fewer degrees of freedom compared to uniform meshes while introducing only a small amount of error into the approximation. Finally, preliminary results from concurrent refinement and coarsening schemes show great promise.

ABSTRACT

Mecha(tro)nic systems often incorporate complex nonlinear mechanical elements like bushings and shock dampers for which high-fidelity modeling approaches, such as nonlinear finite element analysis and computational fluid dynamics, offer precise analysis of these components. However, their computational cost often prohibits their inclusion in broader systems-level simulations, particularly for complex industrial systems featuring numerous such components. Conversely, the approximation of these complex components through idealized models and low-fidelity approaches proves challenging, as these models often lack the requisite accuracy, leading to suboptimal analyses of the system's dynamic behavior.

This contribution presents a Neural Network (NN) structure designed to emulate this first-principle modeling approach. The dynamics of physical systems are typically characterized by underlying states (h), often unknown for complex mechanical components, and describable by ordinary differential equations (ODEs). The system typically initiates in a specific state (h0) and can be excited by inputs (x). Engineers seek specific quantities (y), such as forces or accelerations, through a measurement equation (m) that relates these quantities to the system's states (h) and inputs (x).

In the present approach, gated recurrent units (GRUs) are employed to approximate the ODEs describing the system's states over time, followed by a deep feedforward neural network (FFN) mapping these states to a target variable. The networks are shown to predict a latent space capable of modeling the underlying dynamics, without the need for measuring the full state vector and only relying on the target values y and inputs x. Subsequently it is shown that a nonlinear coordinate transformation exists between the latent space of the network and the states obtained from the reference ODE integration (simulation).

To have a verification of the network’s performance, it is applied to simulation-based data of an academic example for which the states and equations are known beforehand. Furthermore, the methodology is also applied to real measurement data from an INSTRON testing system capturing shock damper and bushing dynamic behavior.

Lastly, it is demonstrated that the trained network can be symbolically approximated, resulting in an ODE expression of the dynamics of the latent states, and a measurement equation for mapping the states to the target variable. This feature allows seamless integration of these networks into variable time-step, system-level simulation software.

HYBRID PHYSICS-NN MODEL FOR DYNAMIC ANALYSIS OF MULTI-COMPONENT SYSTEMS

P Varsha[1] and Debraj Ghosh*[1]

[1]*Indian Institute of Science*

ABSTRACT

Dynamic analysis of multi-component systems is a challenging task, as in some systems, a few components can be predominantly inaccessible. It may be impossible to obtain sensor readings or measurement data from these components or subsystems. In more complicated scenarios, even a baseline mechanistic model may not be available for updating these subcomponents. Practical instances of such systems include the support of bridges and the enclosed core of nuclear reactors. This lack of mechanistic detail and relevant measurement data of a subsystem, along with measurement noise, poses a mathematical challenge for system identification. When dealing with such intricate multi-component dynamic systems, relying on physics-based models may yield inaccurate predictions due to model approximation errors and purely data-based models need large amount of training data and may result in predictions inconsistent with physics laws.

To address this challenge, we propose a hybrid approach that blends physics-based and neural network (NN) methodologies for modeling two subsystems. The primary challenges lie in (i) integration of these two approaches --- as there is an interaction between subsystems, and (ii) extraction of the system parameters of the unknown subsystem. Extensive research has been done on combining data driven and physics-based methods. For instance, discrepancy modeling, where the model form error is learned through machine learning techniques [1,2]. In [3], the authors have attempted to learn the interaction force through data-based models.

The novel aspect of this paper is to propose a numerical framework to couple a dynamical system and a neural network when only one subsystem is instrumented and known. It focuses on understanding the modes of interaction, effect of nonlinearities, and the demand on measurement data within this coupling framework. These aspects are studied using a two span beam model, with one span being inaccessible --- leading to uncertainty in the system parameters and boundary conditions. The response of the coupled system subjected to an untested external input, as well as the system parameters, are estimated.

APPLICATION OF THE FREE ENERGY PRINCIPLE IN MATERIALS SCIENCE (INTELIGENT MATERIALS AND STRUCTURES)

Ekaterina Vasileva[*1]*

[1]*St. Petersburg University*

ABSTRACT

This paper presents an approach to the design of intelligent materials [1] based on multilevel modeling, the free energy principle and the method of nonequilibrium statistical operator developed by Zubarev [2]. The method of multilevel modeling is based on the postulation of scale levels. For each scale level, a system of structural levels reflecting the real internal organization of a particular material is introduced. The method of nonequilibrium statistical operator is used to construct integral-differential equations at each of the micro- and meso-levels to describe the behavior of an intelligent material and allows us to take into account the dynamic correlations between the material, as an open system, and its environment. The free energy principle is used as a functional to optimize the performance of the material at each of these levels. At the macroscopic scale, the concept of effective material characteristics is used to describe the behavior of intelligent material structure, which are used as input data for finite element modeling in CAE systems. The transition from mesoscale to macroscale is carried out through obtaining effective material characteristics on the basis of periodicity cell investigation. Based on the developed approach, the characteristics of active material components (sensors and actuators) were calculated to control the shape and size stability of the thin-layer structure of the space antenna mirror.

MODELING OF WOVEN CERAMIC MATRIX COMPOSITES USING AN EMBEDDED FIBERS APPROACH

*Anthony Vassalié**[1], Guillaume Couégnat[1] and Sébastien Denneulin[2]*

[1]Laboratoire des Composites Thermo Structuraux
[2]Safran Ceramics

ABSTRACT

Ceramic matrix composites (CMCs) exhibit exceptional mechanical properties at elevated temperatures, making them promising candidates to replace metal alloys in high-temperature components of aircraft engines. However, CMCs also exhibit variability due to both their internal structure and the inherent properties of their constituent phases. To better understand and predict their mechanical behavior within the context of this variability, the development of numerical models that capture crucial phenomena at both micro- and meso-scale levels is of paramount importance.

The proposed ”embedded fibers” approach aims to overcome the challenge of scale separation by explicitly incorporating fibers and interfaces at the meso-scale, but without demanding excessive computational burden when compared to direct numerical simulations. Expanding upon previous studies [1, 2], our approach employs a discrete representation of fibers and their interaction with the matrix to faithfully capture the material’s structure and woven architecture. The proposed model is first validated against direct numerical simulations featuring explicitly meshed fibers and cohesive zone models. Virtual tensile tests are then compared with experimental observations to gain deeper insights into microscale mechanisms. Lastly, a parametric study is conducted to evaluate the impact of model parameters on the material’s mechanical behavior and failure characteristics.

The developed approach demonstrates the ability to capture both the micro-scale mechanisms and meso-scale behavior of CMCs, offering a valuable tool for understanding and predicting their mechanical performance in the context of their variability. This work paves the way for further developments towards the optimization of the design and performance of CMC components.

PREDICTION OF RESIDUAL STRESSES IN METAL LPBF PARTS THROUGH A HOLISTIC MULTISCALE SIMULATION APPROACH

ABSTRACT

Laser Powder Bed Fusion (LPBF) has emerged as a revolutionary additive manufacturing process for the manufacture of complex metallic components, but various challenges still curtail its widespread use by industries. Among these challenges, deformations caused by residual stresses accumulated during printing can lead to severe defects ranging from low geometric accuracy of the as-printed parts to build failure caused by cracking or warpage. Numerical simulation of the LPBF process can help understanding the thermomechanical behavior of a part during printing and predicting its warpage without actually running any costly printing job. In this context, we present a holistic multiscale finite element analysis (FEA) simulation methodology that is able to predict the residual stresses and their associated deformations in metal LPBF parts.

A common obstacle in the numerical simulation of the LPBF process is the number of different spatial and temporal scales involved. While part-scale builds usually have a size in the scale of centimeters and take hours to be built, the laser beam operates on a much smaller scale, typically in the scale of micrometers and the timescale of the order of microseconds. Simulating the entire process at the meso-scale level is not tractable in practice and a multiscale simulation methodology is thus warranted. The continuum approach we have developed involves solving two distinct numerical problems at the meso-scale and at the part-scale levels, respectively.

The meso-scale model is a high-fidelity coupled thermomechanical simulation of the LPBF process that takes into account the dynamics of powder melting and solidification caused by a moving heat source representing the laser beam and its resulting strains and stresses in the material. This problem is solved on a small domain representative of the laser hatch pattern over short time periods (millimeters / seconds) and yields so-called “inherent strains” that are extracted in accordance with the modified Inherent Strain method. The part-scale model uses a layer-by-layer approach, with possible layer lumping, to simulate the LPBF process on full-scale parts. Its simplified physical models give access to the evolution of temperature in the part over the duration of the build and leverages the inherent strains extracted from the meso-scale model to predict the deformations of as-built parts. Our approach will be demonstrated on cantilevers and results will be compared with experimental data.

[1]Sandia National Laboratories

ABSTRACT

Finite element modelers of fracture and failure are frequently constrained by the numerical limitations presented by a single discretization of the domain. A Lagrangian finite element mesh limits the ability to model both large deformations in ductile failure and fragmentation in higher rate brittle failure. Furthermore, the refined, well-structured mesh required for resolution of localization and near-crack fields can be numerically intractable to include in models of entire parts or systems. These limitations can be greatly reduced by the ability to model a problem with multiple meshes, but only with careful consideration of the transfer operation.

This presentation revisits recently implemented finite element technology focused on preserving solutions across transfers and shows multiple applications. These applications include: large-deformation, ductile failure with a sequence of mesh adaptions and transfers; brittle material fragmentation with transfers between Lagrangian meshes and particle meshes; and, computation of high resolution fracture energies along a small, stationary crack in a large body by transferring deformation and stress fields onto a well-structured, templated mesh of the crack.

ON AN EFFICIENT PARAMETRIC PGD SOLVER FOR DAMPED ELASTODYNAMICS OPTIMIZATION

Clément Vella[1], Pierre Gosselet[2] and Serge Prudhomme[3]*

[1]*LaMcube*
[2]*LaMcube, CNRS*
[3]*Polytechnique Montréal*

ABSTRACT

The talk will focus on a parametric Galerkin-based Proper Generalized Decomposition (PGD) solver for the simulation of damped mechanical structures. The solver builds on recent developments of a space-time PGD solver [1,2] which relies on the Hamiltonian formalism, for the construction of reduced-order models (ROM). Some key ingredients greatly improve the computational efficiency of the classical PGD approach when applied to structural dynamics. The novelty of our approach lies in the design of a solver that is halfway between the Modal Decomposition method and the conventional PGD framework and aims at accelerating the fixed-point iteration algorithm. It essentially consists in pre-processing the eigen-pair approximations of the operators, namely the Ritz pairs, that provide a subspace in which the PGD problem in space remains diagonal throughout the fixed-point iterations. All computations are then carried out in the subspace spanned by the Ritz vectors [3] hence drastically decreasing the computational burden while capturing most of the information from the full model using only a small number of modes. Additional procedures such that Aitken's delta-squared process and mode-orthogonalization are also employed to ensure convergence and stability of the algorithm while progressively computing the new modes.

The methodology has been straightforwardly extended to viscoelastic systems modeled with Rayleigh damping, writing the damping matrix as C=aM+bK, where M and K are respectively the mass and stiffness matrices. It allows for the construction of a parametric ROM with respect to the Rayleigh damping coefficients a and b. Subsequently, the ROM can be used to efficiently identify the damping parameters with respect to given snapshots. The goal is to find the optimal pair (a*,b*) that minimizes the error between the solution of the model and the snapshots. The optimization problem is solved using the Particle Swarm Optimization (PSO) approach in which the pair (a,b) for each particle in the search space is updated in parallel based on the surrogate ROM. The relevance and performance of the proposed approach, namely the ROM accuracy, time complexity, and scalability, will be demonstrated on several numerical examples dealing with three-dimensional structures.

IN HONOR OF PROFESSOR J. TINSLEY ODEN: A UNIFIED PHASE FIELD APPROACH TO ELASTIC-PLASTIC FRACTURE

Kumar Vemaganti[*1], Pietro Pascale[2] and Krishna Kenja[2]*

[1]*Sandia National Laboratories*
[2]*University of Cincinnati*

ABSTRACT

There are few, if any, disciplines within computational science and engineering left untouched by the pioneering contributions of Professor J. Tinsley Oden. Phase field modeling, the idea of capturing sharp changes in the material phase with a diffuse interface, is one such computational approach studied by Professor Oden more than a decade ago [1].

In this talk, we present a unified phase field approach to modeling elastic-plastic fracture. The proposed approach is an extension of the classical variational model of fracture, and can represent a wide range of behaviors, from brittle to ductile, without resorting to phenomenological assumptions. This is achieved by independently modeling the phenomena of plasticity and separation using two phase fields: a slip field to represent plasticity and a damage field to represent cracks.

The slip field seeks to capture plasticity at the meso-scale [2] and extends to the general load case the model of plastic slip presented by Ambrosio et al [3]. The damage field interacts with the slip field by the known phenomenon of pre-localization that is characteristic of some free-discontinuity formulations. Numerical results show that the proposed mesoscopic two phase field model is capable of reproducing a wide range of fracture behaviors, and can be easily correlated to ASTM standard testing results.

AN APPROACH TO THE BAYESIAN CALIBRATION OF PHASE FIELD MODELS USING DIMENSIONAL ANALYSIS: APPLICATION TO ELASTOPLASTICITY

Krishna Kenja[1], Pietro Pascale[1] and Kumar Vemaganti[2]*

[1]University of Cincinnati
[2]Sandia National Laboratories

ABSTRACT

Model calibration is a fundamental part of developing and deploying reliable and predictive computational models. A vast amount of literature exits on the topic, but a black-box approach may not always be feasible and considerations based on the nuances of the specific model under investigation are often necessary. This is especially true for phase field models where calibration is a challenging task because of the multiscale nature of problems, non-unique mappings of input parameters to output quantities, and the nature of the regularization length-scale parameter.

In this talk, we present an approach that brings together dimensional analysis, conditional latin hypercube sampling and Bayesian calibration to determine posterior distributions on the parameters for a phase field model. The phase field model under consideration [1,2] seeks to approximate plastic slip lines as degenerated gradients and its response is governed by three parameters: a length scale parameter to regularize the displacement discontinuity across the slip line, an unpinning energy parameter that characterizes the bulk energy density needed to initiate slip, and a gliding resistance parameter that represents the dissipation during sliding along the slip lines. It is known that the model's parameters cannot be calibrated from its macroscale response alone, a manifestation of the Hall-Petch effect.

The proposed approach relies on data from a combination of macro-scale tension tests and meso-scale indentation tests to calibrate the phase field model parameters. Using a series of simulations, we establish relationships between input and output pi groups of the model. These relationships then allow us to calibrate the phase field model. A Gaussian Process (GP) surrogate is used as part of a Bayesian approach to obtain posterior distributions on the phase field model parameters. Our results show that the proposed approach is robust. Equally importantly, we find that the length scale parameter acts both as a numerical parameter and a model parameter for the phase field model under consideration.

TOPOLOGY OPTIMIZATION OF MULTI-MATERIAL STRUCTURES VIA TRANSFER-MATRIX NORM MINIMIZATION

*Paolo Venini**[1]

[1]*University of Pavia*

ABSTRACT

The author's group has recently proposed a topology optimization method that is based on the minimization of a suitable norm of the transfer matrix that maps the input to the outputs [1]. The approach is general enough to allow the simultaneous minimization of quantities of engineering interest at the (global) structural level and at the (local) material level in a multi-material framework. For the sake of this paper, multi-material topology optimization shall be exploited with applications to static and dynamic problems. As for the specific applications under investigation, the so called exo-skeleton design problem shall be considered. The idea is to improve the response of existing buildings to horizontal actions, typically of seismic nature, by adding a few exoskeletal structures in strategic locations. Finding the optimal topologies of such kind of structures, as well determining whether a quasi-static idealization may suffice for the scopes, or a dynamic model is needed are among the goals of the paper.

REAL-TIME HIGH-FIDELITY ALGORITHMS FOR EXTREME-SCALE BAYESIAN INVERSE PROBLEMS INVOLVING SHIFT-INVARIANT SYSTEMS

Sreeram Venkat[*1], Stefan Henneking[1], Milinda Fernando[1] and Omar Ghattas[1]*

[1]*The University of Texas at Austin*

ABSTRACT

Tsunamis resulting from megathrust earthquakes have taken the lives of millions and caused hundreds of billions of dollars in damages. To prevent such destruction by future tsunamis, authorities plan to install acoustic pressure sensors on the seafloor to act as an early-warning system. At the core of designing such an early-warning system lies the ability to --- in real-time --- infer the spatiotemporal seafloor deformation from the pressure data and use the inferred deformation to predict the trajectory of a potential tsunami. To this end, we aim to create a digital twin for the Cascadia subduction zone, one of the targeted regions for installing seafloor pressure sensors. The digital twins we target have the following properties: (1) they employ discretizations of high-fidelity PDEs, leading to extreme scale forward problems; (2) they solve an inverse problem to assimilate observational data to infer uncertain model components followed by a forward prediction of the evolving dynamics; (3) the entire end-to-end data-to-inference-to-prediction computation is carried out in real-time through a Bayesian framework that rigorously accounts for uncertainties.

Creating digital twins with the above properties is challenging due to the enormous size and complexity of the high-fidelity models. For example, a reasonable discretization of the Cascadia subduction zone gives rise to a system with O(10^10) parameters and a formal flop count of O(10^30)! Developing accurate and predictive surrogates over a 10^10-dimensional parameter space for tsunami dynamics described by hyperbolic PDEs is seemingly intractable as the PDEs do not admit low-dimensional subspace representations. However, we can circumvent these challenges by exploiting the intrinsic structure of the problem. Namely, our methodology (1) exploits the time shift-invariance of autonomous dynamical systems to reduce the required number of adjoint wave propagations from 10^5 to 100; (2) uses the same property to extract the block Toeplitz structure of the parameter-to-observable (p2o) map; (3) employs FFTs to diagonalize the p2o map; (4) constructs the inverse operator, and thus the posterior precision operator, in the data space rather than the parameter space; (5) decomposes the computation into a more expensive offline phase (done once) and an online phase of inference and prediction that executes in a few seconds; and (6) designs all underlying algorithms to maximize locality, arithmetic intensity, and communication efficiency to run and scale well on large GPU clusters. The result is a framework for extreme-scale, high-fidelity Bayesian inference and posterior prediction in real-time, with application to tsunami early warning.

ABSTRACT

Tsunamis resulting from megathrust earthquakes have taken the lives of millions and caused hundreds of billions of dollars in damages. To prevent such destruction by future tsunamis, authorities plan to install acoustic pressure sensors on the seafloor to act as an early-warning system. At the core of designing such an early-warning system lies the ability to --- in real-time --- infer the spatiotemporal seafloor deformation from the pressure data and use the inferred deformation to predict the trajectory of a potential tsunami. To this end, we aim to create a digital twin for the Cascadia subduction zone, one of the targeted regions for installing seafloor pressure sensors. The digital twins we target have the following properties: (1) they employ discretizations of high-fidelity PDEs, leading to extreme scale forward problems; (2) they solve an inverse problem to assimilate observational data to infer uncertain model components followed by a forward prediction of the evolving dynamics; (3) the entire end-to-end data-to-inference-to-prediction computation is carried out in real-time through a Bayesian framework that rigorously accounts for uncertainties.

Creating digital twins with the above properties is challenging due to the enormous size and complexity of the high-fidelity models. For example, a reasonable discretization of the Cascadia subduction zone gives rise to a system with O(10^10) parameters and a formal flop count of O(10^30)! Developing accurate and predictive surrogates over a 10^10-dimensional parameter space for tsunami dynamics described by hyperbolic PDEs is seemingly intractable as the PDEs do not admit low-dimensional subspace representations. However, we can circumvent these challenges by exploiting the intrinsic structure of the problem. Namely, our methodology (1) exploits the time shift-invariance of autonomous dynamical systems to reduce the required number of adjoint wave propagations from 10^5 to 100; (2) uses the same property to extract the block Toeplitz structure of the parameter-to-observable (p2o) map; (3) employs FFTs to diagonalize the p2o map; (4) constructs the inverse operator, and thus the posterior precision operator, in the data space rather than the parameter space; (5) decomposes the computation into a more expensive offline phase (done once) and an online phase of inference and prediction that executes in a few seconds; and (6) designs all underlying algorithms to maximize locality, arithmetic intensity, and communication efficiency to run and scale well on large GPU clusters. The result is a framework for extreme-scale, high-fidelity Bayesian inference and posterior prediction in real-time, with application to tsunami early warning.

ABSTRACT

This study involves modeling of high-speed flows using a finite element based stabilized framework along with standard Spalart-Allmaras (SA) model [1]. The set of Navier-Sokes equations for compressible flow in thermal equilibrium is formulated in pressure-primitive variables and Streamline Upwind Petrov-Galerkin (SUPG) method with Discontinuity Capturing (DC) operator are used for stabilization. The formulations was originally proposed in [2]. For time integration the second-order accurate generalized-α method is used. Equations of SA model includes a non-viscous destruction term which relies on the distance to wall. Unlike to the old one equation models, in this model the solution depends on other points of the domain, enabling it to be flexible for all types of grid. Moreover, SA model has proved to be effective in capturing the smooth transition of flow from laminar to turbulent and boundary layers developed at the wall surface. This research focuses on modeling the effects of turbulence on benchmark 2D NASA flat plate case at Mach 2 and Mach 5. Moreover, this study is also extended to analyse a 3D ONERA M6 wing transonic case. The results obtained using present methodology are in strong correlation to the experimental results for both 2D and 3D case. The accuracy of results strongly reflects the stability of the present numerical formulation.

ABSTRACT

Upon reviewing existing literature, it becomes evident that human brain tissue exhibits conflicting material responses under diverse testing modalities. This inconsistency underscores the necessity for a predictive computational model capable of reconciling these disparate findings. A crucial stride in this endeavour involves the integration of the vascular structure into a continuum material model, aiming to address the coupling dynamics between solid and fluid phases within the tissue. This integration holds the potential to elucidate variations observed between in vivo and ex vivo experimental responses.

The incorporation of blood vessels into the linear viscoelastic tissue is grounded in the multiscale immersed method [1]. In this approach, blood pressure is factored into the forcing term, and a multidimensional coupling is implemented using the Reduced Lagrange multiplier method.
Expanding our model to replicate the magnetic resonance elastography (MRE) test setup, we note previous MRE findings that highlight the influence of blood flow on in vivo brain viscoelasticity [2]. MRE enables the extraction of cerebral mechanical parameters across multiple length scales, both ex vivo and in vivo, spanning the entire brain and various anatomical regions. A comparative analysis between the computational model and MRE data emphasizes the importance of integrating vasculature into the brain computational model, particularly when dealing with in vivo and non-invasive experimental setups.

ABSTRACT

The presentation considers the solution of a three-dimensional problem of modeling of all types of seismic waves propagating in real geological environments [1]. The numerical algorithm based on the spectral element method (SEM) [2]. The main advantages of SEM (high order space discretization, explicit time integration scheme) are presented in comparison with the classical approach based on the finite element method (FEM). The features of the massively parallel implementation of the algorithm on modern MultiGPU systems (based on A100 GPU) using CUDA technology are considered. The efficiency of parallelization on hybrid systems with different SEM orders and parameters of the numerical time integration scheme is analyzed. The results of solving a three-dimensional problem of modeling the propagation of seismic waves in a heterogeneous geological environment with faults and sharply varying properties of layers are presented. Analysis of the numerical convergence of SEM for dispersive waves of the Rayleigh type is performed. Local and non-local non-reflective boundary conditions on the artificial boundary of the computational region are considered.

The 3D computational model is constructed using a detailed digital geological model built for one of the Arctic regions. It was converted to an unstructured hexahedral mesh to perform SEM calculations using CAE FIDESYS software [3]. The model is further generalized for typical seismic-geological conditions of Western Siberia, so that on the basis of such modeling it is possible to conduct a wide range of studies on the possibilities of seismic exploration to study the main oil and gas reservoirs in this region. The solution was sought on a hexahedral mesh consisting of 5.5 mln spectral elements of the 5th order with a total number of SEM nodes 1.2 billion. The output results of full-wave modeling are stored in the SEG-Y format, suitable for all types of industrial seismic processing. The analysis of the obtained model seismograms and wave fields is carried out. The conclusion is made about the practical significance of the conducted research.

ON THE ENERGY DECOMPOSITION IN VARIATIONAL PHASE-FIELD MODELS FOR BRITTLE FRACTURE UNDER MULTI-AXIAL STRESS STATES

Francesco Vicentini[*1], Camilla Zolesi[2], Pietro Carrara[1], Corrado Maurini[2] and Laura De Lorenzis[1]*

[1]*ETH Zurich*
[2]*Sorbonne Université*

ABSTRACT

Phase-field modelling of fracture is gaining popularity in the fracture mechanics community, particularly for its ability to generate cracks with arbitrarily complex geometries and topologies in two and three dimensions without the need for ad hoc criteria. The model first introduced in [1] has a clear connection with Griffith's propagation criterion via Gamma convergence tools and recent results [2] have shown that, in addition to propagation, it can quantitatively predict crack nucleation for mode-I loading. However, the initial model cannot reproduce with flexibility the experimentally measured strengths under multiaxial loads. Moreover, a modification is necessary to avoid the interpenetration of crack surfaces in compression and reflect the physical asymmetry of fracture behaviour between tension and compression [3].

In this presentation, staying within the realm of variational approaches, we discuss existing modifications based on energy decomposition, their shortcomings, and the requirements for an effective energy decomposition method to model crack nucleation and propagation. Finally, we introduce a new energy decomposition, the star-convex model, that solves (at least partially) the issues with the existing ones.

ON THE SOLUTION OF UNSTABLE FRACTURE PROBLEMS WITH NON-LINEAR COHESIVE LAWS

Miguel Vieira de Carvalho[*1], Igor Andrade Rodrigues Lopes*[1] *and Francisco Andrade Pires*[2]

[1]*Institute of Science and Innovation in Mechanical and Industrial Engineering*
[2]*University of Porto*

ABSTRACT

The existence of numerical problems related to damage and fracture models is well-known and documented in the literature. In an implicit finite element formulation, the radius of convergence of the Newton-Raphson algorithm reduces to zero in the presence of unstable solution branches. One of the following instabilities may arise: snap-through under load-control or snap-back under displacement-control. In [1], the authors state that these numerical difficulties occur when the internal energy stored in the bulk material is higher than the amount of energy that can be dissipated through crack initiation and propagation. Additionally, the rate at which these energies increase as the size of a sample grows varies, meaning that these challenges are fundamentally tied to the length scale of the problem.

Although this finding has been mainly reported for linear softening traction-separation laws, this work comprehensively explores non-linear softening behaviours and proposes a more general instability criterion [2]. It is demonstrated that, to cope with quasi-brittle or plateau softening behaviours, the criterion has to be formulated in terms of power or energy rate (in temporal terms) instead of total energy. Accordingly, the ratio of cohesive to internal power emerges as a crucial factor. As a result, even scenarios involving a single cohesive element undergoing monotonic loading may exhibit a limit point at any stage of crack propagation, not just during crack initiation.

Furthermore, two strategies for handling fracture problems with instabilities within an implicit solution are discussed: an arc-length technique and an extension of quasi-static formulation into a dynamic regime. A comparative assessment is performed, covering both simple single-element cases and more complex scenarios. Additionally, the study delves into more intricate material responses, including transformation-induced plasticity effects.

INPUT-OUTPUT REDUCED ORDER MODELING FOR PUBLIC HEALTH INTERVENTION EVALUATION

Alex Viguerie[1], Evin Jacobson[1] and Chiara Piazzola[2]*

[1]Centers for Disease Control and Prevention
[2]Technical University of Munich

ABSTRACT

In recent years, mathematical models have become an indispensable tool in the planning, evaluation, and implementation of public health interventions. Regardless of specific mathematical formulation, models must provide detailed information for many distinct levels of population stratification. Such detail comes at a price: in addition to the obvious high computational costs, the number of input parameters and outcomes of interest often number well into the tens of thousands. This leads to difficulty at all stages of the modeling workflow: effective study designs can be difficult to develop and computationally demanding; optimization algorithms are slow to converge, and, due the high number uncertain input parameters, may exhibit (perhaps infinitely) many local solutions. Post-processing of model outputs is also challenging, as the large number of outputs can be difficult-to-interpret, and drawing concrete, actionable conclusions and recommendations from simulation results is not necessarily straightforward. While dimension-reduction techniques often show a low-rank structure in the output space, this is of limited utility for intervention planning as connecting the reduced-order outputs to the input space (the relevant space for intervention planning) is difficult.

In this presentation, we focus on addressing these difficulties. We employ polynomial chaos expansion (PCE) to surrogate our full-scale model over a sparse hypercube of model parameter ranges. We demonstrate that this representation enables for fast and effective uncertainty quantification and sensitivity analysis, allowing us to easily identify important model parameters. This has immediate application in study design, as it allows us to reduce the number of exploratory variables.

We then further show that these techniques can also be employed on a reduced-order output space, and that the sensitivity of reduced-order outputs to specific model inputs can be easily assessed. We then further exploit the structure and regularity of the PCE representation to rigorously map the reduced output-space to a corresponding reduced-order input space with low computational cost, allowing us to associate each reduced-order output with a corresponding reduced-order input. We show this representation allows for fast and effective intervention planning with a minimal loss of information and further, that the reduced-order representations of both the input and output spaces are highly interpretable. While we use our HOPE compartmental model for HIV transmission and disease progression as our working example, the principles and techniques discussed also apply more generally.

A MULTISCALE LAMINATE-BASED MODEL FOR SEMI-CRYSTALLINE POLYMERS

José L. P. Vila-Chã[1], Bernardo P. Ferreira[2] and Francisco Andrade Pires[1]*

[1]*University of Porto*
[2]*Brown University*

ABSTRACT

Semi-crystalline polymer morphology is heterogeneous, hierarchical, and complex. At the microscopic level, there is a crystalline phase, often organized into lamellae, embedded in an amorphous phase. In turn, these lamellae commonly organize into spherulites., approximately spherical arrangements of lamellae [1]. To some degree, all these features contribute to the mechanical response of semi-crystalline polymers. Several authors try to capture some of the effects evident in these experimental results by solely considering the volume fraction of the two phases while neglecting additional information regarding the microstructure of these polymers, e.g., [2]. However, to better understand the microstructure evolution of the polymer and its influence on the macroscopic behavior of these materials, we need to include a more adequate description of the polymer's morphology. Accordingly, various authors propose multiscale formulations that take into account the lamellar nature of the crystalline phase, e.g., [3].
In these models, they consider as phases an appropriate number of simple laminates, reflecting the lamellar structure of semi-crystalline polymers, and obtain the macroscopic behavior of the polymer through homogenization. In particular, mean-field averaging is used, where local-global interaction laws replace real interactions between domains. At the microscopic scale, appropriate constitutive laws describe the two constituents.

This work also considers the lamellar microstructure of semi-crystalline polymers, but it does so in an alternative way.
Instead of selecting a priori some number of simple laminates as the relevant phases to represent the microstructure, their appearance follows from an appropriate decomposition of the RVE domain, followed by the application of a dilute or self-consistent local-global interaction scheme.
This approach enables us to make a more informed choice regarding the number and direction of simple laminates to consider in the homogenization procedure, resulting in efficiency and accuracy improvements.
We discuss the continuum formulation, and its computational implementation, and then present a few numerical results.
We explore the local-global interaction laws selected and the impact of the appropriate choice of the number and direction of simple laminates considered in the accuracy and efficiency of the model.

NON-LINEAR ENCODING FOR MULTI-FIDELITY NEURAL NETWORK SURROGATES

Cristian Villatoro[*1], Gianluca Geraci[2] and Daniele Schiavazzi[1]*

[1]*University of Notre Dame*
[2]*Sandia National Laboratories*

ABSTRACT

The construction of accurate surrogates is a key step in many outer loop tasks, like uncertainty quantification (UQ) and optimization. Neural Networks (NNs), thanks to their expressiveness, have demonstrated great potential to significantly improve the quality of emulators, particularly in high dimensions. Unfortunately, it is recognized that NNs usually require large amounts of data to be reliably trained and to produce satisfactory prediction accuracy. Recently, multi-fidelity approaches have been proposed to tackle this challenge, creating larger datasets leveraging data sources of varying accuracy and computational cost. Using such approaches it is possible, in principle, to leverage larger training datasets to meet required accuracy thresholds for high-fidelity predictions, all while keeping the overall computational cost below to a predetermined budget. In recent work [1], the correlation between data sources is used as the main mechanism to enhance training accuracy in scenarios of limited high-fidelity data availability. Therefore, the performance of such approaches may degrade for realistic applications where the correlation between model outputs could be low as a result of an inconsistent formulation. To this end, in our recent work [2,3], we show that even a simple linear transformation on the inputs can greatly increase the correlation between high- and low-fidelity models while giving a natural way to resolve differences in model parameterization. In the proposed work, we extend linear encoding [2,3] to non-linear encoding and multiple low-fidelity sources, demonstrating their benefits on multiple test cases, including numerical examples and problems inspired by realistic applications.

NONLINEAR REDUCED ORDER MODELING OF A MULTISCALE MODEL FOR MICROCIRCULATION

Piermario Vitullo[1], Nicola Rares Franco*[1] and Paolo Zunino[1]

[1]*Politecnico di Milano*

ABSTRACT

Multiphysics mathematical models of the vascular microenvironment assess the impact of microcirculation in transport phenomena through the tissue. Since the embedded vascular network is characterized by high complexity and multiple scales, the numerical solutions of high-fidelity models are often computationally expensive. We present an alternative strategy that is applied to a 3D-1D computational model for microcirculation [1], based on parametrized partial differential equations. The full order model (FOM) describes blood flow and oxygen transfer from the microvasculature to the tissue and it consists of a 3D model for the tissue combined to a 1D model in the vascular network. We propose a multiscale strategy, decomposing the 3D domain of interest in small voxel components, where local numerical solutions are retrieved. We exploit non-intrusive and nonlinear reduced order models (ROMs) [2] to approximate the parametric map to derive an approximated solution in each voxel. We leverage on proper orthogonal decomposition (POD) methods and we rely on sparse Mesh-Informed Neural Networks [3] to handle the spatial dependencies in the solutions and in the geometrical input data encoding the small scale features of the problem. The adopted ROM is built in a supervised learning framework, hinging on local finite-element approximations. Firstly, it approximates the POD reduced basis coefficients using a neural network that combines dense layers for the physical parametrization with a MINN for the geometrical inputs. Then, a closure model based on the geometrical parametrization is added to augment the first approximation, acting as a fine-scale corrector that retrieves the nonlinear information associated to the high frequencies of the problem in each subdomain. We exploit this result to improve classical homogenization methods for multiscale modeling that neglect smaller scales and capture only the global behaviour in the voxel. Finally, the multiscale simulation is performed deriving suitable multiscale basis functions to assemble the local ROM approximations, solving the multiphysics macro-problem with the embedded complex microstructure.

FLUID-STRUCTURE INTERACTION SIMULATIONS AND MULTI-SCALE APPROACHES FOR NUCLEAR REACTOR APPLICATIONS.

*Daniele Vivaldi**[1]

[1]*Institute for Radiological Protection and Nuclear Safety*

ABSTRACT

Different fluid-structure interaction (FSI) configurations can be encountered in the frame of nuclear reactors. In this presentation, examples of single-phase cross-flow and axial flow local scale (i.e., CFD) FSI numerical simulations are presented and discussed. The configurations simulated consist of experimental campaigns, for which flow (velocity, pressure) and structure (displacement, acceleration) parameters were measured: this allowed to assess the consistency of the numerical set-up and results, a necessary step towards a comprehensive validation of the numerical simulations. The impact of the numerical treatment of turbulence (linear-viscosity models, second-order models or scale-resolving approaches) is discussed: regardless of the configuration, scale-resolving approaches are found to be required to calculate consistent force spectra. The impact of the numerical schemes, of the retained coupling algorithm, of the system damping and other numerical parameters on the calculated results and on the numerical stability is analyzed. Reduced-order models for the finite element simulation of slender structures are assessed and are found to represent an interesting compromise in terms of precision and CPU requirements.

Typical components of nuclear power plants include a huge number of slender structures, such as tubes and rods. It follows that the study of FSI at the local scale is feasible only for limited portions of the systems. A multi-scale approach for such problems is necessary if one aims at applying an FSI analysis at the industrial scale (which represents the final goal). In such approach, porous media simulations can be employed to calculate the average hydraulic (i.e., the fluid flow) system-scale behavior. These component-scale results can provide numerical boundary conditions to apply to local-scale analysis: this allows to zoom over specific regions, where the FSI can be taken into account by the simulation. Nevertheless, the switch from component-scale to more local scales is far from straightforward: parameters such as turbulence intensity and time/length scales are required to apply consistent boundary conditions at the CFD-scale, and are not directly available from component-scale analysis. A discussion of a R&D work plan on multi-scale strategy for FSI in a nuclear reactor core and on possible methods to face down-scaling issues is proposed.

A REDUCED ORDER MODEL CONDITIONED ON MONITORING FEATURES FOR ESTIMATION AND UNCERTAINTY QUANTIFICATION IN ENGINEERED SYSTEMS.

Konstantinos Vlachas[*1], Thomas Simpson[1], Anthony Garland[2] and Eleni Chatzi[1]*

[1]*ETH Zurich*
[2]*Sandia National Laboratories*

ABSTRACT

Reduced Order Models (ROMs) form essential tools in various engineering domains by their function as surrogates for computationally intensive digital twinning simulators.
While data-driven reduction processes exist, physics-based approaches can render ROMs interpretable. However, such techniques typically face challenges when dealing with models that feature multi-parametric dependencies, while further requiring a reliable quantification of estimation confidence. The performance of the ROMs is usually tied to the approach employed in associating the defining parameters' vector with an appropriate local reduction basis. We propose using Conditional Variational Autoencoders (CVAEs) to continuously map the required reduction bases to the parameter vector while additionally allowing for a probabilistic assessment of the predicted Quantities of Interest. A main novelty of this work lies in linking the operational space of the ROM to practical features that are automatically inferred from measurements of monitored systems rather than physics-based, and usually a priori unknown, system parameters. An auxiliary task using a feed-forward neural network is introduced to re-establish the required connection to the physical model parameters. Its prediction is treated as the mean of a suitable distribution, while an additional network is jointly trained using the respective probability density function to estimate the uncertainty involved. In this context, we here propose a generative physics-based ROM, able to quantify the confidence involved in its post-deployment estimations while being conditioned to online delivered sensing-based features. These components contribute to developing a generalized representation, offering significant utility for tasks related to Structural Health Monitoring (SHM). A series of case studies are used for validation featuring damage in the form of stiffness reduction or plasticity/hysteresis under multi-parametric dependencies relating to the system's properties and the traits of the input load.

A LARGE LANGUAGE MODEL AND DENOISING DIFFUSION FRAMEWORK FOR TARGETED DESIGN OF MICROSTRUCTURES WITH COMMANDS IN NATURAL LANGUAGE

Nikita Kartashov[1] *and Nikolaos Napoleon Vlassis**[1]

[1]*Rutgers University*

ABSTRACT

Microstructure's crucial impact on macroscopic properties is widely recognized, with alloy phase distribution affecting mechanical properties, microfeature precision in MEMS dictating device performance, and cellular arrangement in tissue-engineered scaffolds influencing cell growth and differentiation, among countless other domains of study. While advanced ML-based design and generative AI tools exist to explore the forward and inverse relationships between microstructure and macroscopic behaviors, a substantial knowledge and expertise barrier limits their accessibility and broader application in the field. To address this, we introduce a framework that combines Large Language Models (LLMs) and Denoising Diffusion Probabilistic Models (DDPMs) to streamline the design of complex microstructures for users of all expertise levels in mechanics, materials science, and machine learning. By leveraging LLMs, our framework reduces the expertise barrier, allowing users with diverse backgrounds to specify design objectives in intuitive language. The core of this system is an LLM that interprets these inputs, translating them into actionable directives for a DDPM algorithm. This integration effectively democratizes access to complex design processes, making advanced microstructure design more accessible and adaptable. Central to our methodology are DDPMs, generative models that learn to reverse a Markov diffusion process and have been proven to work exceptionally well in text-conditional settings, enabling the generation of synthetic microstructures with specific, fine-tuned properties. This approach allows the manipulation of microstructure topology within the latent space of the training data, ensuring the generation of realistic and viable designs. Demonstrated using the Mechanical MNIST dataset as a benchmark and extending on the work by Vlassis et al, 2023, our framework highlights the capability of DDPMs in performing the inverse design of microstructures with specific nonlinear properties and in understanding the nonlinear structure-property relationships through natural language commands embedded by the coupled LLM. This is critical for exploring the complex interactions among geometry, topology, and macroscopic properties in materials through a user-friendly text interface. This integration of LLMs and DDPMs aims to introduce a paradigm in microstructure design, combining advanced generative machine learning methodologies under a singular, intuitive interface.

COMPARISON OF FULLY RESOLVED AND UNRESOLVED PARTICULATE FLOW SIMULATIONS USING THE LATTICE BOLTZMANN METHOD

Tristan Vlogman[*1], Rob Hagmeijer[1] and Kartik Jain[1]*

[1]*University of Twente*

ABSTRACT

Particulate flows are ubiquitous in nature and industry and numerical simulations are an important tool to understand them. Fully resolved methods are the gold standard in terms of accuracy, but their computational cost makes studying large problems involving many particles prohibitively expensive. Unresolved methods lessen the computational burden by allowing a mesh size larger than the size of the particles at the price of reduced accuracy. In this study we compare fully-resolved and unresolved methods to simulate particulate flows.

We have implemented a coupled lattice Boltzmann and Discrete Element Method solver that is capable of both fully resolved and unresolved simulations of particulate flows in arbitrarily complex geometries. The implementation is parallelized using MPI which allows us to simulate large problems. The fully resolved method is based on the Momentum-Exchange method [1] in which the no-slip boundary condition on the particle surface is explicitly modelled. The unresolved method is based on an LBM implementation of the Volume-Averaged Navier-Stokes (VANS) equations [2].

We investigate the degree to which unresolved simulations can predict the effect of particles on macroscopic quantities like the pressure drop over a porous medium and the rheology of a sheared suspension. We do this by comparing to both the fully resolved method as well as to popular empirical relations. We show how incorporation of the solid volume fraction in the unresolved model is necessary to obtain realistic pressure drops. Regarding suspension rheology, the essential role of short-range hydrodynamic (lubrication) interactions is highlighted. These are naturally accounted for in the fully resolved model, but must be added through a correction term in the unresolved model to obtain realistic values for the apparent viscosity.

Furthermore, we compare the predicted group dynamics of particles using the fully resolved and unresolved methods. First the drafting-kissing-tumbling phenomenon of two interacting sedimenting particles is simulated. Both the fully resolved and unresolved methods reproduce the characteristic dynamics qualitatively. Our ongoing work concerns the capability of the unresolved methods to predict the behavior of larger groups of sedimenting particles in a Rayleigh- Taylor instability.

ROBUST SCALABLE FINITE VOLUME METHOD FOR TWO PHASE FLOW THROUGH POROUS MEDIA USING A NONLINEAR COMPLEMENTARITY PROBLEM APPROACH

Naren Vohra[*1], Konstantin Lipnikov[1] and David Moulton[1]*

[1]*Los Alamos National Laboratory*

ABSTRACT

Multiphase flow through porous media is integral to many applications in geosciences, including oil recovery and carbon sequestration. The governing system of equations presents strong nonlinearities due to advection and solute miscibility, which is accounted for using Henry's law. A popular discretization approach is the use of finite volume schemes, however the presence of nonlinearities requires the use of an appropriate robust solver. In this talk, we present various fully implicit finite volume schemes for two phase flow through porous media using the novel approach of nonlinear complementarity problem (NCP) to handle phase transitions. We consider the linear two point flux approximation (TPFA) to compute the numerical fluxes, and demonstrate the robustness of the semismooth Newton's method as a solver for the nonlinear discrete system. The advantages of the NCP approach over the widely used primary variable switching approach include computational efficiency and increased robustness of the solver, and the choice of TPFA provides an ease of implementation and monotonicity of the solution. We also investigate the effectiveness of appropriate preconditioners, such as ILU and MGR, and provide results on the scalability of our nonlinear solver using physical examples, including the well-known MoMas benchmark problem of gas phase appearance and disappearance. We further discuss the assumptions frequently used in the model equations, such as the existence of the solvent in liquid phase alone with negligible solute concentration, the challenges associated with the extension of the system to three phase flow, and the coupling of multiphase processes in matrix and fracture networks.

WRINKLING OF FLUID DEFORMABLE SURFACES

Axel Voigt[1]*

[1]*TU Dresden*

ABSTRACT

Wrinkling instabilities of thin elastic sheets can be used to generate periodic structures over a wide range of length scales. Viscosity of the thin elastic sheet or its surrounding medium has been shown to be responsible for dynamic processes. While this has been explored for solid as well as liquid thin elastic sheets we here consider wrinkling of fluid deformable surfaces, which show a solid-fluid duality and have been established as model systems for biomembranes and cellular sheets. We use this hydrodynamic theory and numerically explore the formation of wrinkles and their coarsening, either by a continuous reduction of the enclosed volume or the continuous increase of the surface area. Both lead to almost identical results for wrinkle formation and the coarsening process, for which a universal scaling law for the wavenumber is obtained for a broad range of surface viscosity and rate of change of volume or area. However, for large Reynolds numbers and small changes in volume or area wrinkling can be suppressed and surface hydrodynamics allows for global shape changes following the minimal energy configurations of the Helfrich energy for corresponding reduced volumes.

POSITIVE REAL BALANCED TRUNCATION MODEL REDUCTION OF MECHANICAL SYSTEMS

Ines Dorschky[1], Timo Reis[2] and Matthias Voigt[*3]*

[1]ZEISS Semiconductor Manufacturing Technology
[2]Technische Universität Ilmenau
[3]UniDistance Suisse

ABSTRACT

In this talk, a model reduction approach for linear time-invariant second order systems based on positive real balanced truncation is introduced. The method guarantees to preserve asymptotic stability and passivity of the reduced order model as well as the positive definiteness of the mass and stiffness matrices. Moreover, an a priori gap metric error bound is obtained. Besides the theoretical foundations, the numerical challenges will be discussed. The presentation will be concluded by numerical examples illustrating the approach.

DEEP GENERATIVE MODELING FOR DATA-DRIVEN IDENTIFICATION OF NOISY, NON-STATIONARY DYNAMICAL SYSTEMS

Doris Voina[*1], Steven Brunton[1] and Nathan Kutz[1]*

[1]*University of Washington*

ABSTRACT

An important challenge in many fields of science and engineering is making sense of a deluge of time-dependent measurement data by recovering the governing equations in the form of ordinary or partial differential equations. We are interested in finding interpretable, parsimonious models in the form of closed form differential equations for nonlinear, noisy, and non-stationary dynamical systems. To this end, we propose a machine learning method that performs system identification in such systems.

An array of methods so far have addressed noisy and limited data; however, the problem of non-stationarity, when parameters describing the differential equations have explicit time dependence, has received considerably less attention. In this work, we combine a framework for data-driven discovery of stochastic differential equations using hypernetworks and the SINDy (sparse identification of nonlinear dynamics) method with a separate neural network module that identifies switches in the parametric time dependencies. The result is a novel approach – dynamic HyperSINDy – to system identification of stochastic, non-stationary dynamical systems. We test our method on synthetic data using simple canonical systems, including non-linear oscillators with underlying time-dependent parameters, and the chaotic Lorenz system. The aim is to extend dynamic HyperSINDy to a wide range of problems, specifically on dynamic systems where complex parametric time dependencies are expected.

ADAPTIVE PHASE FIELD MODELING OF HYDROGEN ASSISTED CRACKING USING SCALED BOUNDARY FINITE ELEMENT METHOD

Suvin VS[1], Ean Tat Ooi[2] and Sundararajan Natarajan[1]*

[1]*Indian Institute of Technology Madras*
[2]*Federation University Australia*

ABSTRACT

Hydrogen-assisted cracking (HAC) poses a significant threat to the structural integrity of materials, particularly in industries such as petrochemical, aerospace, and energy. The interaction of hydrogen with metals, facilitated by chemical reactions, corrosion processes, or exposure to hydrogen-containing environments, is a crucial factor influencing crack growth.

The relatively small size of hydrogen atoms allows for absorption and diffusion into the metal lattice, accumulating in stress concentration areas and grain boundaries. This accumulation weakens atomic bonds, locally increasing brittleness and causing premature metal failure. Predicting and understanding these catastrophic failures is essential, and existing models, such as those in Finite Element Method (FEM), often face limitations due to the need for highly refined meshes.

This study aims to effectively predict hydrogen-assisted cracking using the Scaled Boundary Finite Element Method (SBFEM) and an adaptive Phase Field Model (PFM). The adaptive quadtree mesh provides computationally faster solutions, with the expense of hanging nodes.

SBFEM, unlike conventional models like FEM, Boundary Element Method (BEM), or eXtended Finite Element Method (XFEM), efficiently handles hanging nodes, making it suitable for polygonal structures. The phase field model is employed for damage prediction, capable of forecasting all stages of crack development, including initiation, propagation, and failure.

In this work, a staggered approach is used to solve elasticity, phase field, and diffusion equations. The elasticity equation is two-way coupled with the phase field equation, as the phase field value influences material stiffness, and strain energy affects the phase field variable. The diffusion equation is one-way coupled to both elasticity and phase field equations, capturing the impact of hydraulic stress on hydrogen concentration and its subsequent effect on the critical energy release rate, altering the phase field value.

Validation of the proposed numerical model is achieved through a single-edge notch tension test and crack growth from an existing pit corrosion. The work is extended for examining failure patterns in a hydrogen storage tank with an initial crack. Results indicate close agreement with existing models in all scenarios, affirming the effectiveness of the proposed framework in predicting hydrogen-assisted cracking.

ESTIMATION OF GRINDING CONTACT STIFFNESS AND DAMPING PARAMETERS FROM DYNAMIC OUTPUT ONLY USING HUNT-CROSSLEY FORCE MODEL AND UNSCENTED KALMAN FILTER

Viet-Hung Vu[1], Quoc-Cuong Nguyen*[2] *and Marc Thomas*[3]

[1]*Royal Military College of Canada*
[2]*Hanoi Architectural University*
[3]*École de technologie supérieure*

ABSTRACT

A new method combining the Unscented Kalman filter and the operational modal analysis is presented for estimating experimentally the stiffness and damping at the contact point of a grinding process by a flexible manipulator. The Hunt-Crossley force model is proposed for the force contact considering the flexibility of the manipulator structure and is rewritten in a state form as functions of the contact stiffness and damping. The Unscented transform is used to linearize the nonlinear measurement functions and therefore the Unscented Kalman filter can estimate and update the stiffness and damping parameters from the state model. The method is applied to a real grinding process using a flexible manipulator where only the dynamic responses are employed to estimate the contact stiffness and damping parameters. This method promises a convenient and practical technique for estimating the operational machining parameters and can be effectively used to develop a vibration control strategy in machining.

A COMPUTATIONALLY EFFICIENT METHOD FOR CONSIDERING A LARGE NUMBER OF NONLINEAR MULTI-POINT CONSTRAINTS WITHIN THE FINITE ELEMENT METHOD

Jens Wackerfuß[1] and Jonas Boungard*[1]

[1]*University of Kassel*

ABSTRACT

The modeling of nonlinear constraints plays an important role in various problems in computational solid mechanics, especially in the context of large elastic and inelastic deformations. Among other things, they can be used for the subsequent consideration of rigid inclusions in a body originally modeled as deformable, without requiring a remeshing of the considered domain and thus contributing to a rapid modeling building. Further examples are the modeling of shear force release in frame structures under large displacements and rotations, or the modeling of deformation-dependent Dirichlet boundary conditions. In the context of the finite element method, the constraints refer to the nodal degrees of freedom; if several nodes are involved, they are referred to as multi-point constraints. One method for considering constraints is master-slave elimination, which, in contrast to Lagrange multipliers and the penalty method, offers the advantage of reducing the dimension of the problem [1]. However, the existing master-slave elimination method is limited to linear constraints.

The presentation introduces a new master-slave elimination method for the treatment of arbitrary nonlinear multi-point constraints [2]. The method is based on a mathematically rigorous derivation, where an optimization problem with constraints is chosen as the starting point. It is transformed into a modified optimization problem without constraints using the implicit function theorem. In order to perform this transformation, the set of slave degrees of freedom must be chosen in such a way that the Jacobian matrix derived from the constraints fulfills several conditions. The derivation is general and is not restricted to specific constraints. As part of the algorithmic implementation, it was possible to separate the presented method itself from the definition of the individual constraints. In the context of several numerical examples, the new method is compared with the existing methods. The results show that the new method is as accurate, robust and flexible as the Lagrange multipliers and is more efficient by reducing the total number of degrees of freedom, which is particularly advantageous when a large number of constraints have to be considered.

ABSTRACT

Accurate simulation-based design optimization (SDDO) of innovative vehicles requires physics-based high-fidelity simulations, such as the Reynolds-averaged Navier-Stokes (RANS) solvers, which are usually computationally expensive. Therefore, simulations are often combined with surrogate models, fitted through the results of a limited number of evaluations. Furthermore, multi-fidelity approaches [1] are used to further reduce the computational effort of the SDDO process, by combining a few accurate but expensive high-fidelity simulations with several less accurate but faster to evaluate low-fidelity ones. Finally, efficient adaptive sampling of the surrogate training set further increases the performance for multi-fidelity surrogate-based SDDO.

The paper addresses the estimation of the uncertainty associated with the surrogate model prediction, which is crucial for driving most of the adaptive sampling approaches and assessing the quality of the surrogate model, in case of training data affected by numerical noise. The key to our approach is to divide the uncertainty into separate contributions from the interpolation, the training data, and the multi-fidelity corrections.

Surrogate models and interpolation uncertainty are reconstructed with Stochastic Radial Basis Functions (SRBF), that use a range of RBF fits with different kernels [2]. In the proposed approach, the noise in the training data is reduced by reconstructing filtered data in the training points, which are then interpolated with standard SRBF. For the filtering, RBF surrogates with a number of kernels smaller than the number of training points are least-squares fitted through the data. The uncertainty due to the noise filtering is estimated as the variance of the reconstructions. Finally, for sparse datasets the prediction uncertainty is modeled as a parabolic function based on the distance to the nearest and the number of available training points.

The method is applied for analytical test problems and the optimization of a lifting hydrofoil, addressing its efficiency. Numerical simulations are performed with the flow solver ISIS-CFD and fidelity levels are obtained with adaptive grid refinement.

EVALUATION OF CRACK PROPAGATION CRITERION USING LOCAL APPROACH UNDER EXTREMELY LOW CYCLE FATIGUE

Yoshitaka Wada[*1]*

[1]*Kindai University*

ABSTRACT

It is important for piping to predict unstable failure in a structure due to excessive cyclic load caused by a huge earthquake. The J-integral is used as a fracture mechanics parameter which is applicable to elastic-plastic deformation. However, J-integral cannot be effective under cyclic loading. Fatigue crack growth rate in the low cycle fatigue is evaluated by Δ J which is defined by the stress and strain ranges in a given cycle. The applicability of ΔJ has not been well verified yet under extremely low cycle loading. A generation phase analysis requires several parameters by experiment during fracture of a compact tension (CT) specimen in the previous study. Crack length and its front are the most important for load and load line displacement evaluation as a local approach. In this study, we evaluate crack propagation criterion, which has been proposed by us, with different crack propagation manners, which are simultaneous propagation of crack front, individual propagation by nodal release on a crack front and individual propagation in the mid-part of specimen under plane strain. The FE models with 1.5 and 2 inch thicknesses are 1/4 of actual CT specimen. Load control is used in experiments, however, displacement control is performed in the generation phase analysis. The approximation curve, which is determined by the experiment and represents the relationship of crack length and load line displacement, is for determinations of nodal release as crack propagation. In the ΔJ evaluation, the best result, which is the lowest deviation from the experiment, is obtained by generation phase analysis.
Critical CTOD can be corrected by stress triaxiality under the monotonic loading [1]. Additionally, stress triaxiality and equivalent plastic strain are reciprocal relations in the cracked pipe fracture [2]. The relationship between stress triaxiality and incremental equivalent plastic strain along a crack front are well examined. The incremental equivalent plastic strain exhibits some critical condition of fracture. As a result of an evaluation, the crack propagation condition is defined by equivalent plastic strain and stress triaxiality as a local approach manner. The effectiveness and applicability of three-parameter approach will be discussed in detail.

MULTISCALE DESIGN OF COATED STRUCTURES WITH SPATIALLY ROTATING LATTICE INFILL

Eddie Wadbro[*12] and Bin Niu*[3]

[1]*Karlstad University*
[2]*Umeå University*
[3]*Dalian University of Technology*

ABSTRACT

This presentation concerns the multiscale topological design of coated structures with spatially rotating lattices as the infill. The lattice comprises a uniform microstructure that is allowed to rotate with respect to the macroscale. The spatially rotating microstructures allow the variation of lattice at the different load-carrying components, which enhances the design freedom. We optimize three key aspects: (1) the design of the structure at the macroscale, (2) the design of a microscope unit cell, and (3) a rotation field that determines, for each point on the macroscale, the relationship (the angle of a rigid rotation) between the microscale and macroscale coordinate systems. A morphology-mimicking nonlinear filtering procedure provides size control at the macroscale and microscale, while a filtering procedure utilizing an elliptic PDE ensures a smoothly varying rotation field. Numerical examples demonstrate the effectiveness and highlight some particular features of the present method with spatially varying rotation of the microstructure.

REDUCED-ORDER DYNAMICS MODELING FOR ADDITIVE MANUFACTURING VIA A PRE-TRAINED TRANSFORMER NETWORK

Zhongsheng Sang[1], Andrew Potts[1] and Gregory Wagner[1]*

[1]Northwestern University

ABSTRACT

Metal Additive Manufacturing (MAM), popular in sectors ranging from aerospace to medicine, excels in creating intricate geometries, merging multiple parts into a single unit, and minimizing material waste. MAM processes typically employ complex thermal and computational fluid dynamics (CFD) models for simulation, which are time-intensive, sometimes taking days or weeks for a single high-fidelity laser track simulation. To address these computational challenges, surrogate modeling has proven crucial for enhancing the predictive and optimization capacities in manufacturing. In this work, we present a novel model hyper-reduction technique that merges the Koopman operator with an autoencoder-decoder framework while including control signal dependencies. After learning the relevant encoding, this approach leverages a transformer neural network trained on detailed physics simulations using dynamic control signals (such as laser power and scan path). This enhancement improves the model's ability to predict and flexibly adapt to changes in controlled dynamical systems, making it highly suitable for additive manufacturing process modeling. Our approach has been validated on various complex systems, including the Lorenz system with varying parameters and multi-fluid lock exchange flow under varying gravitational conditions. A critical application of this methodology has been in simulating thermal transfer in MAM processes. By treating laser path history, laser power, and laser speed as control signals of the system, we have achieved accurate predictions for MAM processes with complex laser pathways and varying laser parameters. Our results indicate that the combined use of the transformer and the Koopman operator-based approach significantly outperforms traditional models that rely solely on linear dynamics. This method demonstrates superior predictive abilities over extended periods with considerably reduced error accumulation, especially in scenarios involving control signals. This advancement marks a step forward in predictive modeling for additive manufacturing, offering a more efficient and accurate alternative to traditional simulation methods.

TOPOLOGY OPTIMIZATION OF CROSS-SECTIONAL PROPERTIES CONSIDERING TORSIONAL AND WARPING BEHAVIOR

Christos Kostopoulos[1], Ameer Marzok[1] and Haim Waisman[1]*

[1]Columbia University

ABSTRACT

This talk introduces a novel efficient topology optimization methodology for beams' torsion using the warping function formulation. The finite element method is used to discretize the cross-section of the beam and an efficient gradient-based optimization problem is formulated to optimize the relevant parameters corresponding to the torsion and warping constants of the beam. As a result, for the first time, one can optimize a beam for problems where the warping behavior is dominant. Density-based optimization is defined where the SIMP approach is utilized to penalize intermediate element densities.

A key challenge of the optimization that arises in the warping function framework is the so-called, updating right-hand side problem. That is, the forcing vector varies during the optimization as it depends on the cross-section boundaries, which are functions of the updating topology. To this end, an efficient differentiable boundary recognition algorithm is proposed. The methodology is applied to design beam cross-sections in which both torsion and warping constants are of interest. While intuitive topologies are obtained in the case of optimized torsion constant, this is not the case for the warping constant. The latter shows unique material distributions and a special dependence on the allowable material density.

A NEW PARAMETRIZATION OF DIRECTED ACYCLIC GRAPHS AND CAUSAL MARKOV KERNELS FOR SCIENTIFIC FEATURE DISCOVERY

Elise Walker[*1], Jonas Actor[1], Carianne Martinez[1] and Nathaniel Trask[2]*

[1]*Sandia National Laboratories*
[2]*University of Pennsylvania*

ABSTRACT

Due to the complexity of multimodal scientific datasets, causal feature detection in these datasets necessitates unsupervised representation learning methods. Physics-informed multimodal autoencoders (PIMA) have recently demonstrated successful unsupervised feature detection with variational autoencoders (VAEs) where multiple scientific modalities and physics constraints act as surrogates for the supervision labels typically needed for successful VAEs. Building upon the successes of PIMA, we present a VAE framework coupled with a trainable directed acyclic graph (DAG) to discover features with plausible causal relationships in multimodal scientific datasets. In particular, we introduce a new parametrization for learning both the edges of a DAG and the causal Markov kernels of the joint distribution of its nodes. We use this parametrization to simultaneously learn a DAG in conjunction with a latent space of a VAE. Our DAG and VAE training is performed in an end-to-end differentiable framework via a single, tractable evidence lower bound (ELBO) loss function. We achieve a single ELBO by placing a Gaussian mixture prior on the latent space and identifying each of the Gaussians with an outcome of the joint distribution of the DAG nodes. We demonstrate the efficacy of our DAG parametrization, and we test our joint VAE and DAG framework on both a synthetic and a scientific dataset. Our results demonstrate the capability of learning a DAG on discovered key features in an exploratory scientific setting.

EXPLORING MOMENTUM ENHANCEMENT IN EULERIAN AND LAGRANGIAN COMPUTATIONS OF HYPERVELOCITY IMPACT INCLUDING THE DART-DIMORPHOS IMPACT

James Walker[1], Sidney Chocron[1], Stephen Beissel[1], Christopher Sorini[1], Donald Grosch[1], Daniel Durda[1] and Simone Marhci[1]*

[1]*Southwest Research Institute*

ABSTRACT

The recent DART spacecraft impact into the asteroid moonlet Dimorphos demonstrated the phenomenon referred to as momentum enhancement (Ref. 1). The phenomenon is that in hypervelocity impact a large amount of material is liberated from the impacted body, hence providing more momentum transfer to the impacted body than just from the impactor itself. Over the years it is proven quite difficult to model this effect. The liberated ejecta material is in motion, moving in the opposite direction to the incoming impactor, and the ejecta has speeds that range orders of magnitude. Not only is it necessary through the modeling to correctly determine how much of the material is liberated from the impacted body, but also its speed at time of liberation. The crater left in the impacted body has a volume corresponding to liberated material as well as displaced (but still attached) material in the impacted body. The challenges in modeling are clarified by experiments that show various behaviors in such impacts. Experiments have been performed in speeds ranging from 2 to 6 km/s (the DART impact was a 6.14 km/s) with a variety of impacted materials and show interesting impactor-size-dependent behavior in both the amount of ejecta material (normalized by impactor mass) and momentum enhancement (normalized by impactor momentum, referred to as β, Refs. 2, 3). Computations have been performed with the Eulerian hydrocode CTH and the Lagrangian impact code EPIC. Sophisticated material models were placed in these codes to model the metal and rock materials. The results of the two different computational approaches will be compared with themselves and with experiments. Subsequent experiments have been per-formed with crushed basalt targets to try to simulate the asteroid surface impacted by DART. Computations will also be compared to these experiments. It is important to understand the mechanisms in these computations and how they contribute to the observed effects for there to be reasonable confidence in extrapolating the DART results to other asteroid impact situations.

A MIXED-DIMENSIONAL MULTIPHASE MODEL FOR COUPLING AIR FLOW, BLOOD FLOW AND GAS EXCHANGE IN HUMAN LUNGS

Lea J. Köglmeier[1] and Wolfgang Wall[1]*

[1]Technical University of Munich

ABSTRACT

Despite the clear benefits of mechanical ventilation, it can also cause ventilator-induced lung injury, especially for critically ill patients suffering from Acute Lung Injury/ARDS. The main obstacles to more protective and individualized ventilation strategies are still insufficient knowledge and understanding of complex lung mechanics in healthy and diseased states, mainly due to the limited ability for in vivo measurement and imaging on the most relevant alveolar level. Even the most powerful computational approaches, however, only focus on investigating the effect of ventilation on air distribution, tissue strains/stresses, while coupling to the pulmonary circulation is mostly neglected. This is even though the lungs' main function, namely gas exchange, occurs through a dense network of pulmonary blood vessels in the alveolar walls. Hence, the coupling between respiratory system and pulmonary circulation is crucial for getting more insight into the main purpose of ventilation: adequate oxygen supply and carbon dioxide release while keeping the tissue in a healthy state.

This contribution presents a physics-based, coupled, multi-dimensional, and multiphase poroelastic approach to computationally model airflow, blood flow, and gas exchange in human lungs. Motivated by the structure of the lungs, larger airways, and blood vessels are modeled as discrete 0D networks that are embedded into a 3D, three-phase (air, blood, and tissue) porous medium, representing the smaller airways, smaller blood vessels and lung tissue in a homogenized manner. Further, the respiratory gases, oxygen, and carbon dioxide are modeled as chemical subcomponents of air and blood with a suitable exchange model in the porous domain. To connect the homogenized and the discrete representations of airways and blood vessels, respectively, a 0D-3D coupling method is used, which allows a non-matching spatial discretization of both domains. The method couples fluid flow and species transport in these phases via an outflow condition from the tips of the discrete networks into the 3D porous medium and vice versa.

Such a comprehensive approach allows us to study the complex interplay of tissue deformation and perfusion and its effects on oxygenation and carbon dioxide release. Further, the underlying multiphase model can easily be extended to include additional phases to study pathological conditions such as water accumulation in pulmonary edema in future model stages.

[5]*University Savoie Mont Blanc, ISTerre*

ABSTRACT

The paper investigates a major challenge in the modeling of multiphase flow in unsaturated soils where the solid skeleton deforms as water and air occupy the pore space in various proportions. One can distinguish four water saturation regimes in soil: (1) pendular state where particles are cohesively held by liquid bridges, (2) funicular state where the liquid engulfs only a few particles with air largely occupying the remaining void space, (3) capillary state where liquid with some air occlusions invades the entire void space, and (4) the fully saturated condition with liquid exclusively in the void space.
While the pendular regime is well understood, the funicular and capillary regimes require further analysis. Existing models primarily focus on the pendular regime, leaving a gap in understanding the complexities of funicular regimes due to challenging geometries of water clusters and air [1]. Thus, there is a need for a novel approach to cover transitions across all capillary regimes.

To address these challenges, this study proposes a numerical model coupling the Lattice Boltzmann Method (LBM) and the Discrete Element Method (DEM). The LBM simulates capillary bridge dynamics, solving Navier-Stokes and Allen-Cahn equations for multiphase flow in intricate pore geometries. Meanwhile, DEM, based on an elastic-plastic contact law, handles the kinematics of spherical grains [2]. This coupled approach successfully captures features such as water retention as well as mean capillary stress evolution during wetting and drying processes. The mean capillary stress, equivalent to capillary (apparent) cohesion, is calculated by subtracting grain-to-grain contact stress from the total stress applied to a granular assembly. The numerical simulations involve an initial assembly of spherical particles subjected to drying and wetting processes. A hysteresis is observed in the mean capillary stress and suction, showing the model's potential in predicting unsaturated soil behavior across various saturation regimes.

In conclusion, the proposed coupled DEM-LBM model is a promising tool for understanding unsaturated soils at the micro-scale, considering all saturation regimes, especially when upscaling the results to examine the stability of geostructures (dikes) under changing environmental conditions.

DIRECT FINITE ELEMENT TECHNIQUE FOR UNCERTAINTY QUANTIFICATION FOR STOKES FLOWS

Chien-Kai Wang[*1] and Po Ting Lin*[12]

[1]*National Taiwan University*
[2]*Academia Sinica*

ABSTRACT

In the experimentation of microfluidic devices, uncertainties arising from human operation or environmental conditions often lead to discrepancies between the expected and actual velocity and pressure fields within the system. Uncertainty analysis becomes a crucial research focus in the design of microfluidic devices to predict field information and control device quality. the research work in presentation successfully developed a direct finite element analysis technique applicable to incompressible Newtonian fluids. The technique accurately evaluates extreme velocity and pressure field responses in uncertain Stokes flow under random boundary stimulus conditions. This innovative analysis technique seamlessly integrates the computational principles of traditional Galerkin finite element method with the continuum mechanics theory of load-response correlation. With the aid of mesh element model information, it efficiently predicts the extreme motion behaviors of fluids under uncertain conditions through an analytical approach.

Using a microfluidic cell culture chamber as an example, this study applies the newly proposed direct analysis technique for demonstration. To highlight the high accuracy of the predictive technology, the results are compared with numerous repeated simulations using traditional finite element methods under randomly configured stimulus conditions. The findings indicate our ability to directly and accurately analyze the statistical characteristics of uncertain flow velocity in the cell culture chamber under stochastic external pressure stimuli. This includes the average value, standard deviation, and correlation coefficient between random external pressure and the target flow velocity variable. The extreme value response of the target flow velocity is also obtained. Through multiple repeated simulations and the direct analytical approach in this study, the results show less than four-thousandths of a discrepancy. By employing this innovative mechanics theory and corresponding analytical technique, substantial savings in experimental resources and computational costs required for uncertainty analysis can be achieved. Therefore, this breakthrough significantly opens a door for overcoming limitations in the analysis and design of systems with stochastic conditions.

ENERGETICS OF FLEXIBLE CHANNEL FLOW

Danyang Wang[*1], Xiaoyu Luo[2], Zishun Liu[1] and Peter Stewart[2]*

[1]Xi'an Jiaotong University
[2]University of Glasgow

ABSTRACT

There are many flexible vessels in human body, such as artery, air way and urethra. When these vessels subject to a negative transmural pressure (internal minus external) while conveying flow, self-excited oscillations can occur. We explore the mechanism of self-excited oscillations in a two-dimensional rigid channel conveying laminar high-Reynolds number flow. One segment of the upper rigid wall is replaced by a flexible wall under external pressure. In particular, we construct a general framework for analyzing the energy budget of self-excited oscillations about a non-uniform basic state. We then apply this general framework to consider two particular models for the flexible wall, namely a fluid-beam model [1] and simple fluid-membrane model [2] with an external pressure gradient.

For fluid-beam model, a modified constitutive law is used to ensure the elastic beam is energetically conservative. We solve both the steady and unsteady systems using finite element method with adaptive mesh. The steady system shown multiple steady configurations: an (inflated) upper branch and a (collapsed) lower branch, connected by a pair of limit point bifurcations to an unstable intermediate branch. Both upper and lower steady branches can each become unstable to self-excited oscillations. In addition, detailed energy budget over a period of oscillation was calculated, where we shown that both upper and lower branch instabilities require an increase in the work done by the upstream pressure to overcome the increased dissipation.

For fluid-membrane model, numerical simulations indicate that the baseline state (with Poiseuille flow and a flat wall) exhibits two unstable normal modes: the Tollmien–Schlichting (TS) mode and a surface-based mode which manifests as one of two flow-induced surface instabilities (FISI), known as travelling wave flutter (TWF) and static divergence (SD), respectively. We find that both FISI are primarily driven by the working of normal stress on the flexible wall, lower-branch SD has negative activation energy, while upper-branch SD approaches zero activation energy in the limit of large wall damping.

ON THE CONVERGENCE OF LUMPED MASS GALERKIN MESHFREE METHODS

Dongdong Wang[*1], Saisai Fu[1], Like Deng[1] and Zhiwei Lin[1]*

[1]*Xiamen University*

ABSTRACT

The lumped mass matrices have been widely used in Galerkin meshfree methods with explicit time stepping due to their simplicity and efficiency. However, owing to the complexity of meshfree approximants, i.e., the moving least squares or reproducing kernel shape functions, there still lacks a theoretical assessment of the accuracy of lumped mass Galerkin meshfree formulation. This work presents a rational theoretical estimate on the frequency accuracy of lumped mass Galerkin meshfree methods [1]. The proposed methodology is completely based upon the reproducing or consistency conditions of meshfree shape functions and their gradients, which successfully circumvents the fundamental difficulty associated with the use of complicated expressions of meshfree shape functions. The frequency error measures are attained for the lumped mass Galerkin meshfree formulation, which show an important odd/even basis degree discrepancy feature. More specifically, the lumped mass Galerkin meshfree formulation using a pth degree basis function yields (p+2)th order of accuracy when p is even, and (p+1)th order of accuracy in case that p is odd. In addition, it is shown that the results of lumped mass Galerkin meshfree methods are polluted by non-physical spurious modes, which on the other hand can be suppressed through replacing the conventional non-interpolatory shape functions by the interpolatory shape functions [2] in meshfree formulation. The theoretical findings are well confirmed by numerical results.

A NOVEL 3D TOPOLOGICAL METAMATERIAL FOR POLARIZATION-DEPENDENT MULTILAYER ELASTIC WAVE CONTROL

Guifeng Wang[1], Muhammad Muhammad[2] and C.W. Lim[1]*

[1]*City University of Hong Kong*
[2]*University of Galway*

ABSTRACT

The achievement of high-quality wave concentration and manipulation has always been considered as state-of-the-art technologies, especially for integrated photonics, acoustics, and mechanics. The exploration of topological phase of matter provides abundant design tools for robust waveguiding that is immune to back scattering at small defects and sharp bends. Recent research has extended the elastic wave manipulation from 2D edge waveguiding to 3D planar waveguiding. However, most of the designs are limited to single-modal and single-frequency wave propagation along the designed plane. This paper introduces a novel 3D topological metamaterial structure whose geometric parameters are intentionally configured to obtain dual-modal topological states at distinct frequencies. A comprehensive parametric study is presented to demonstrate bandgap controllability and to establish a design principle with unwanted mode prevention capabilities. Topologically protected interface modes with either large group velocity or near-zero group velocity along the z-direction are determined. Full-scale finite element simulations are employed to uncover the elastic wave propagation behaviors. The interesting layer-locked and layer-unlocked waveguiding based on excitation polarization and frequency for a straight path and a zig-zag path are demonstrated. The outcome of this work suggests abundant potential applications related to elastic wave control such as wave filters, energy harvesters, mechanical computers, etc. This work may also help inspire future research for more complex multi-modal waveguiding in 3D space.

ABSTRACT

Normally, the diameter of a mature typhoon is generally more than 100km, with different areas in meteorological characteristics. During the life cycle of a typhoon, its location and structure will change significantly, leading to dramatic changes in the wind speed field of the LOWT at a fixed site. The scales and physics involved in turbine-typhoon interaction is a typical multi-scale mechanical problem, where typhoons are mesoscale phenomena while the destruction of wind turbines occurs on the microscale. Investigating the spatiotemporal typhoon impacts on the inflow wind speed field is paramount for solving this multi-scale mechanical problem. This comprehensive understanding will facilitate the identification of design ultimate loads and enable more reliable service cycle performance. The current project aims to qualitatively and quantitatively analyze the spatiotemporal typhoon impacts on offshore wind turbines in China waters for the worst-case regarding the spatiotemporal effect. This comprehensive understanding will facilitate the identification of design ultimate loads and enable more reliable service cycle performance.

The manuscript is organized as follows: Section 2 introduces the eventual worst-case scenario in China waters. The information of LOWT and offshore wind farm (OWF) is detailed in Section 3. Then, Section 4 presents an analysis framework for spatiotemporal typhoon effects on wind speed field, which is based on a data-driven typhoon wind speed field model developed and the extreme value estimation method used in data analysis. On these bases, Section 5 presents the typhoon-induced wind speed field of different LOWTs at the same time, addressing the influence of spatial impacts on the inflow wind speed field. Section 6 presents the typhoon-induced wind speed field of different times for the same LOWT, addressing the influence of temporal impacts on the inflow wind speed field. The paper ends with a discussion of spatiotemporal typhoon impacts on the inflow wind speed field for the worst-case assessment regarding offshore wind power in China waters.

MESH DEFORMATION METHOD BASED ON DISPLACEMENT NORMAL PROPAGATION AND DUAL QUATERNION FOR ORTHOGONALITY PRESERVATION AND HIGH EFFICIENCY

Huadong Wang[1], Zhidong Guan[1], Xiangyu Liu[1] and Xiaodong Wang[1]*

[1]*Beihang University*

ABSTRACT

Mesh deformation technique is commonly used in CFD simulations with moving boundaries because of its high efficiency and mesh consistency, such as unsteady flow, aeroelasticity, and aerodynamic shape optimization, whose deformed mesh quality and efficiency are of great importance. For the purpose of orthogonality preservation and deformation efficiency improvement, this paper introduces a new mesh deformation method based on displacement normal propagation and dual quaternion.

The translational and rotational motions at the boundary points are measured in a uniform way using dual quaternions. Then their total displacements are propagated to the corresponding volume points along the normal under the control of the damping function. Compared to the popular radial basis function (RBF) method[1], this method couples the displacements in all directions, preserving the orthogonality and maintains normal distribution of the near-wall mesh, preventing element inversion. And compared to the traditional quaternion method[2], it eliminates the dependence of deformation effect on rotation center selection and avoids complex interpolation.

In order to expand the application scenarios, the proposed method are combined with the RBF method into a hybrid method to cope with topologically complex mesh. The former is dedicated to dealing with the points inside the boundary layer, which always has normal correspondence whether the surface mesh is structured or unstructured. And the latter handles the points outside, whose support points are chosen from the points in the outermost layer. The pure RBF method in the whole domain needs abundant support points to guarantee the accuracy near the boundary and prevent element inversion failure, which is computationally expensive. But benefiting from valid processing of the near-wall elements, the hybrid method requires much fewer support points to ensure the mesh validity outside the boundary layer only, reducing the calculation costs and improving deformation efficiency greatly.

Two typical test cases with different mesh features and deformation modes, fluctuation deformation in fish cruise and bending deformation of a missile, are carried out to demonstrate the superiority of the proposed method in mesh quality and deformation efficiency. The influence of the damping radius and the necessity of quaternion smoothing are also discussed.

THE FORCE-FREQUENCY RELATIONSHIP OF THE THICKNESS-STRETCH VIBRATIONS OF QUARTZ CRYSTAL PLATES

Ji Wang[1], Jia Lou[1], Bin Huang[1], Hui Chen[1] and Chuanzeng Zhang[1]*

[1]*Ningbo University*

ABSTRACT

Quartz crystal resonators are one of the widely used sensitive elements of force sensors with increasingly broad applications, particularly in robotics. Current quartz crystal force sensors are made with AT-cut quartz crystal resonators vibrating at the thickness-shear (TSh) vibration mode, and the force-frequency relation is a typical hyperbolic curve. A thorough examination of the vibration equations of quartz crystal plates reveals that the thickness-shear vibration mode is coupled with the applied force in stresses indirectly because usually the force is exerted in the wave propagation direction and not a quantity varying along the thickness. As a result, the coupling with the thickness-shear vibration is not direct, and the effect is complicated and weak as can be seen from the hyperbolic relation between the force and frequency. To be able to obtain the frequency shift as known with the Sauerbrey equation of the quartz crystal microbalance, a new vibration mode has to be selected for possible direct coupling with the stress resultant from the applied force, and a linear relation between the stress and frequency can be obtained. A further examination of the coupled thickness-shear vibrations of an infinite quartz crystal plate shows that while the plane stresses are coupled indirectly with the thickness modes, the thickness stress perpendicular to the plate surface is directly coupled to the thickness-stretch (TSt) vibration mode. Consequently, the force-vibration relationship will be linear with the applied stress, and the sensitivity is also proportional to the ratio of stress and corresponding elastic constant. Of course, the vibration frequency will be doubled from the thickness-shear vibration mode. The vibrations of the coupled thickness-stretch mode of an AT-cut quartz crystal plate are analyzed for frequency and sensitivity to enable the design and optimization of a force sensor application. It is believed such an exploration will improve the current technology in force sensor development to satisfy increased demands for sensitive and reliable devices in fast-growing industries with intelligent features. The thickness-stretch vibration mode is not utilized in resonators for oscillators and filter applications, but it is possible to be the core element of a force sensor with the unique force-frequency relation to improve current design and deliver novel products amid the strong demands for technology development.

CONDITIONAL NEURAL FIELD-BASED LATENT DIFFUSION MODEL FOR STOCHASTIC GENERATION OF SPATIOTEMPORAL TURBULENCE

Pan Du[1], Meet Hemant Parikh[1], Xiantao Fan[1], Xin-Yang Liu[1] and Jianxun Wang[1]*

[1]University of Notre Dame

ABSTRACT

Turbulent flows, characterized by their chaotic and stochastic nature, present significant challenges in predictive computational modeling. Traditional eddy-resolved numerical simulations, though detailed, require extensive computational resources, limiting their applicability in various engineering scenarios. In response, deep learning-based surrogate models have emerged, providing data-driven solutions. However, these models frequently struggle to capture the intrinsic chaotic and stochastic behaviors characteristic of turbulent dynamics, primarily due to their deterministic frameworks.

This study introduces the Conditional Neural Field-Based Latent Diffusion Model (CNF-LDM), an innovative generative framework employing probabilistic diffusion models for the versatile generation of spatiotemporal turbulence across diverse conditions. The CNF-LDM synergistically integrates a conditional neural field (CNF) encoding with a latent diffusion model, facilitating memory-efficient generation of spatiotemporal turbulence. This method also leverages Bayesian conditional sampling, enabling the unconditional model to directly accommodate a broad spectrum of conditioned turbulence generation scenarios without the need of re-training. We have rigorously evaluated CNF-LDM through a series of numerical experiments, demonstrating its versatility and efficacy in generating turbulent flows. The outcomes of these experiments highlight the transformative potential and substantial progress represented by CNF-LDM in the domain of turbulence generation. This model not only overcomes the limitations of existing deterministic deep learning approaches but also offers a more efficient and adaptable method for simulating complex turbulent phenomena.

ANALYSIS OF SPH ALGORITHM FOR ELASTIC-PLASTIC LARGE DEFORMATION

Jiayi Wang[*1], Fei Xu[1] and Zhen Dai[1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

SPH (smoothed particle hydrodynamics) is a gridless Lagrangian technique that is attractive as a possible alternative to the numerical technique used to analyze large deformation events. The high-velocity impact problem is successfully simulated by introducing the strength of material into the SPH method by considering deviatoric stress and simple elastic-plastic constitutive equation. However, there are still many problems in applying the SPH method to the large deformation analysis of solid problems in relatively low-velocity impact. In the conventional SPH method, numerical fracture due to the loss of interactions among particles, which annoys the ability and the accuracy of the SPH method. Additionally, for elastic-plastic deformation of metals in low-velocity impact, the constitutive equation is essential to describe the stress state of the structure accurately. Therefore, the incremental theory of plasticity is adopted to establish the stress-strain relationship for elastic-plastic large deformations of structures in low-velocity impact.

To prevent the numerical fracture, we introduce the artificial stress and conservative smoothing method in the SPH algorithmic framework. The influence of parametric of the two methods for removing numerical fracture is analyzed. In addition, an alternative method for improving numerical fracture, the spatially adaptive particle splitting method, is suggested. The two-dimensional impact case of metal sphere on thin metallic plate is simulated by finite element and improved SPH method, and the results of such two methods are basically consistent. The validity of the improved SPH algorithmic framework has been proved and the approach achieves certain achievements in removing numerical fracture. The stress response of the plate at different impact velocities is also discussed using the improved SPH method. The result indicated that the improved SPH method removes the numerical fracture, and it avoids the influence of parameters. It is an optimal alternative compared to the artificial stress and conservative smoothing method. The conclusions obtained provide reference for the description of the large deformation behavior of elastic-plastic solid material and have great significance in further promoting the application of the SPH method in the field of solid dynamics.

PARAMETER OPTIMIZATION OF MJC MODEL AND SIMULATION OF HULL BEAM STRUCTURE FRACTURE

Jiuqiang Wang[*1], Dongyan Shi[1] and Bo Huang[2]*

[1]Harbin Engineering University
[2]18045176756

ABSTRACT

Due to the excellent anti blast and impact properties of Q345 high-strength steel, it is often used in key components such as deck structures of ships. The study of its dynamic material properties has practical guiding significance. This article is based on the testing results of a universal material testing machine and a separated Hopkinson compression bar system, and obtains the material properties under different strain rates, temperatures, and stress states, respectively. At the same time, a series of related experimental studies were conducted under shear conditions to analyze the fracture performance under low stress triaxiality. In order to improve the accuracy of MJC constitutive relations and fracture criteria, six parameters including temperature terms were recalibrated for the above two indicators by combining experimental measurement methods and numerical simulation results. Afterwards, in order to verify the effectiveness of parameter calibration in the MJC model, the Q345 steel Taylor rod impact rigid target plate test results based on the first stage light gas gun system were analyzed, and a numerical model of Taylor impact test was established. The MJC model has good prediction performance under low-speed conditions, but there is a significant error in the prediction of Taylor pier diameter under medium to high-speed conditions. To reduce prediction errors, in-depth analysis is conducted from multiple perspectives such as yield plateau, strain rate sensitivity coefficient, and transformation of high strain rate plastic deformation mechanism. Research has found that the yield plateau has little effect on the predicted results; Although the strain rate sensitivity coefficient effectively reduces the prediction error of cross-sectional area, it cannot accurately predict the shape characteristics of Taylor rods; Considering the high strain rate plastic deformation mechanism, the predicted results are converted, and the conversion results are closer to the experimental results. Simulate the damage effect of ship hull beams under underwater explosive explosion conditions, and compare the damage differences between the constitutive relationship obtained in this paper and the traditional constitutive relationship. To provide a theoretical basis for the comprehensive consideration of the transformation of high strain rate plastic deformation mechanisms in performance analysis under high strain rates.

ABSTRACT

The anti-explosion ability of ship grillage structure is an important index to evaluate the vitality of ships. Its model test is a low-cost and effective method to evaluate the vitality of ships and guide the design of ship anti impact structures. In view of the nonlinear and non-stationary process of underwater explosion damage to ship grillage, this paper breaks through the nonlinear effect of transient explosion impact that is not considered in the traditional scale model design, focuses on the one-dimensional nonlinear impact response of ship grillage structure, and carries out the characterization study of the similarity between model experiments and real ships. Considering that the vertical motion of the prototype and the model grillage structure in the model test obey the random walking model, the vertical impact response of the deck grillage is characterized as one-dimensional nonlinear non-stationary Brownian motion, which is described by Hurst index. Based on the classical similarity law, the similarity transformation relationship between the range R and the mean square deviation S is derived, and the Hurst index of the model and the prototype meets the equal relationship; Take a section of grillage structure on a real ship and conduct prototype, 1/2, 1/3, 1/4 and 1/5 one-dimensional nonlinear explosion impact scale simulation tests respectively. The numerical response results show obvious nonlinear characteristics, and the Hurst index of displacement, velocity and acceleration response of the model within the pulse width range is less than 5% compared with the prototype. According to the scale invariance of fractional Brownian motion, the similarity conversion relationship of multiple parameters (displacement, velocity, acceleration and mean square response) is obtained. With the mean square response as the characteristic parameter, the response value of the prototype is converted through this relationship, and compared with the model simulation results, the multi parameter response error under each scale ratio is less than 20%. It provides theoretical and technical support for conducting similar experiments on nonlinear response of underwater explosion shock of ships.

MULTIPHYSICS MODEL OF HYPERVELOCITY IMPACT INDUCED PLASMA: SIMULATION AND EXPERIMENT

Shafquat Islam[1], Paul Asimow[2], John Michopoulos[3] and Kevin Wang[1]*

[1]Virginia Polytechnic Institute and State University
[2]California Institute of Technology
[3]U.S. Naval Research Laboratory

ABSTRACT

During hypersonic collisions between materials, kinetic energy rapidly dissipates through various pathways. This process generates strong shock wave fronts and extreme thermodynamic states, not only within the solids involved but also in the surrounding gas. These states often lead to material ionization, forming a highly non-ideal plasma. The physical mechanisms of plasma formation and its source and composition are not yet fully understood and remain as open questions. We introduce a computational model of hypervelocity impact dynamics, accounting for fluid-solid interaction and predicting material ionization across all subdomains: the projectile, target, and ambient fluid. Our model combines the compressible Navier-Stokes equations with the non-ideal Saha equations. The Navier-Stokes equations are solved by employing a high-resolution finite volume method in the Eulerian reference frame. The material boundaries are tracked by solving two level-set equations. Since the subdomains share the same velocity field, spurious overlaps of materials are avoided. The Navier-Stokes equations are complemented by appropriate equations of state for each subdomain to account for their material behavior. As such, the metallic projectile is modelled using Mie-Gruneisen, the silicate target using Nobel-Abel stiffened gas, and the ambient fluid using perfect gas. We apply the model to the case of soda-lime glass shocked by a metallic projectile during a hypervelocity impact event. We carried out an experimental campaign to characterize pressure, density, temperature, and sound speed along the principal Hugoniot of soda-lime glass. The experimental data are used to calibrate the numerical model and a validation study is performed. The challenge of computing the numerical fluxes across material boundaries with significant discontinuities has been a topic of significant focus in the literature. We overcame this challenge by using the Finite Volume with Exact Riemann (FIVER) method, which has been validated for several multiphase flow applications. The plasma characteristics were computed by solving the non-ideal Saha equations along with conservation of electrical charge and nuclei, using a safeguarded root-finding algorithm. To demonstrate the developed computational model, we investigate the impact of a tantalum projectile onto a soda-lime glass target in an argon environment. The transport of energy between the materials during the impact event is measured and analyzed. Furthermore, the composition of the impact induced plasma, especially in the soda-lime glass, is investigated. Our results indicate that the alkaline metals (principally Na) in the glass account for the majority of the charged particles in the impact induced plasma, due to their low ionization potentials.

A STEPWISE PHYSICS-INFORMED NEURAL NETWORK FOR SOLVING LARGE DEFORMATION PROBLEMS OF HYPOELASTIC MATERIALS

Lei Wang[*1] and Zikun Luo*[1]

[1]*Hohai University*

ABSTRACT

Physics-informed neural network (PINN) has been widely concerned for its higher computational accuracy compared with conventional neural network. The merit of PINN mainly comes from its ability to embed known physical laws or equations into data-based neural networks. However, when dealing with the rate-dependent nonlinear problems, such as elasto-plasticity with loading and unloading and hypoelastic large deformation, the conventional PINN cannot obtain satisfactory results. In this paper, a stepwise physics-informed neural network (sPINN) is proposed to solve large deformation problems of hypoelastic materials. The whole process of sPINN can be divided into a series of time steps. In each time step, the rate constitutive equation expressed by Hughes-Winget algorithm and momentum governing equation are incorporated into the loss function as physical constraints. The displacement and stress fields can be resolved by completing the training process of each time step. Three numerical examples are designed to validate the proposed method by comparing with the solutions of FEM. The results show that sPINN can accurately resolve the displacement and stress fields in path-dependent large deformation problems. Furthermore, the performance of the sPINN on small data sets are also discussed, which illustrates that sPINN is more capable of predicting the global solution on small data sets as compared with conventional artificial neural network.

STABILIZED LAGRANGE INTERPOLATION COLLOCATION METHOD: A MESHFREE METHOD INCORPORATING THE ADVANTAGES OF FINITE ELEMENT METHOD

Lihua Wang[*1] and Zheng Zhong*[2]

[1]*Tongji University*
[2]*Harbin Institute of Technology*

ABSTRACT

Since most approximation functions in meshfree methods are rational functions which do not possess the Kronecker delta property, how to achieve exact integration and accurately impose the essential boundary conditions are two typical difficulties for meshfree methods. In this paper, a new stabilized Lagrange interpolation collocation method (SLICM) is proposed in which the Lagrange interpolation (LI) is employed for the approximation in a meshfree method. This method can satisfy the high order integration constraints which can conserves the high order consistency conditions in the integration form. This property leads to the exact integration in the subdomains and optimal convergence for the proposed method. Meanwhile, performing the integration in subdomains can also reduce the condition number of discrete matrix, which improves the stability of the algorithm. Since the Lagrange interpolation approximation has Kronecker delta property, the essential boundary conditions can be simply and exactly imposed like the finite element method, which further improves the accuracy of this method. Convergence studies present that the same convergence rate can be attained for utilizing the odd and even order LI shape functions, while the convergence rate is reduced if the odd order basis function is employed in the reproducing kernel (RK) approximation. Numerical examples validate the high accuracy and convergence as well as good stability of the presented method, which can outperform the direct collocation method and the stabilized collocation method based on RK approximation.

FACTORIZATION-BASED ONLINE VARIATIONAL INFERENCE FOR PARAMETER-STATE ESTIMATION OF PARTIALLY OBSERVABLE NONLINEAR SYSTEMS

Liliang Wang[*1] and Alex Gorodetsky*[1]

[1]*University of Michigan*

ABSTRACT

In many application areas such as robotics, financial prediction and computational neuroscience, the online procedure which estimates the parameters and states of a nonlinear system as the system is evolving is among the most crucial tasks. A good online inference method is expected to be efficient, robust and scalable to provide estimation rapidly, guarantee safety and handle different problems. However, estimating the states with nonlinear systems known in a fully online manner can be a difficult task in many cases. The requirement of learning the states and system parameters simultaneously online makes the procedure even more challenging. In recent years, some inference methods have been developed for online parameter-state estimation. However, many of these methods either are unreliable or scale poorly with high-dimensional problems. There exist a limited number of effective and scalable methods but they are normally computationally expensive, which makes them ill-suited for real-time tasks.

In this talk, we introduce an efficient and flexible variational inference scheme for online parameter-state estimation. Our method provides an approximate joint posterior distribution of the parameters and current states of a nonlinear system at every time step by assimilating data incrementally. At each time step, only the newly received data is processed to update the joint distribution. This keeps the computational cost for each step constant and avoids the requirement of storing historical data. Our method factorizes the variational joint posterior distribution as the product of marginal distribution of parameters and conditional distribution of current states given parameters. This enables our method to avoid assumptions of the joint posterior distribution structure, therefore providing a significantly more accurate posterior approximation. The marginal distribution over parameters can be learnt using an arbitrary representation family. Moreover, the conditional distribution of current states given known parameters can be obtained by any existing filtering approaches. The functional representation of hyper-parameters for the variational conditional distribution, can also be chosen arbitrarily. The choices of representation family of distributions, filtering approaches and functional representation of variational hyper-parameters can be made to achieve the speed or performance required by different tasks. The effectiveness of the method will be demonstrated by applications on low- and high-dimensional problems arising in various application areas.

A GRAND-POTENTIAL BASED MULTI-PHASE-FIELD MODEL FOR SIMULATING THE EVOLUTION OF INTERMETALLIC PHASES IN CR-COATED ZRY-4 ALLOYS

Menghui Wang[*1] and Chen Lin*[1]

[1]*Sun Yat-sen University*

ABSTRACT

Chromium (Cr)-coated zirconium alloys are considered a promising candidate material for accident-tolerant fuel (ATF) cladding in nuclear reactors due to their excellent high-temperature oxidation resistance under accident conditions [1]. However, a diffusion-induced intermetallic ZrCr2 layer would be formed at the coating/substrate interface at high temperatures, which significantly affects the microstructure and mechanical properties of the coating [2]. To quantitatively understand the effects of interdiffusion on the microstructure and mechanical properties of Cr-coated Zry-4 alloys, a novel method that incorporates successfully diffusion potential dependent-properties of bulk multicomponent phases into a grand-potential based multi-phase-field model is proposed, which captures the complex interplay among diffusion, interfacial morphology evolution, and stress variation in a high-temperature process. Results showed the variation of the simulated thickness of the Cr coating and the Cr-Zr interlayer with time was in good agreement with the experimental results. Moreover, many experimentally observed but insufficiently understood phenomena can be well explained through this numerical model. Specifically, the numerical simulations quantitatively revealed the influence of the grain size (or the number of grain boundaries), the initial thickness of the Cr coating, and the stress caused by the intermetallic ZrCr2 layer on the microstructure and mechanical properties of Cr-coated Zry-4 alloys. These numerical findings provide theoretical references for understanding the effects of interdiffusion and improving the material properties of zirconium-based alloy cladding used in nuclear power plants.

INVERSE DESIGN TOWARD EXACT STATIC AND DYNAMIC BEHAVIORS

Kshiteej Deshmukh[1], Yunya Liu[1], Fei Chen[1], Bolei Deng[2] and Pai Wang[1]*

[1]University of Utah
[2]Georgia Institute of Technology

ABSTRACT

We report a comprehensive roadmap for the inverse design of periodically architected materials. The primary focus is to achieve desirable linear static (i.e., elasticity tensor) and linear dynamics (i.e., dispersion relation [1]) properties with analytical precision. Both eigen-analysis-based methods and data-driven approaches will be examined. In addition, we also introduce our ongoing investigations based on recent breakthroughs in the inverse design for visco-elastic [2] and hyper-elastic [3] behaviors.

STATIC BENDING RESPONSE OF SANDWICH COMPOSITE PLATES BY USING C0 ELEMENT BASED ON HIGHER-ORDER REFINED ZIGZAG THEORY

Pei-Yu Wang[*1] and Chung-De Chen[1]*

[1]National Cheng Kung University

ABSTRACT

This study aims at investigating static bending response of sandwich composite plates based on higher-order refined zigzag theory (HRZT). Recently, the authors developed the HRZT for static bending response of sandwich composite beams. This study is an extension of the application of HRZT to sandwich beams, which has been developed by authors recently. For plate applications, the inplane displacements are assumed to be higher-order zigzag functions, which allow this theory accurately modeling free-stress on the free surfaces and shear stress continuity at interfaces between layers.

The four-node quadrilateral element is developed to solve the displacements, deflections and stresses under linear static lateral loads. There are 9 degree-of-freedoms (DOFs) at each node, including two inplane uniform deformations, two rotations due to bending, two rotations due to zigzag, two average inplane strains and one deflection. There are totally 36 DOFs in one element, which is abbreviated as C0-4N-36. The stiffness matrix of C0-4N-36 can be derived by variational principle with introducing Lagrangian interpolation functions as the shape function to interpolate the DOFs with the element. A shear locking testing reveals a slow convergence speed of C0-4N-36 for large span-thickness ratio (thin plate).

In order to solve the shear locking phenomenon occurred in C0-4N-36, a modified element is created by adding four extra nodes, each of which is placed at the middle of the element edges. The extra nodes have the DOFs of deflection only, resulting 40 DOFs in the modified element. Thus, it is abbreviated as C0-4N-40. With extra DOFs, C0-4N-40 can effectively avoid shear locking problem for both thick plate (e.g. span-thickness ratio=5) and thin plate (span-thickness ratio=100). By considering some demonstration examples of sandwich plates with various material properties, geometric parameters and boundary conditions, the deflections, inplane displacements and stresses calculated by the present approach are compared with the 3D FEM models solved by commercial software ANSYS. It has proved that the solutions based on HRZT are reliable to linear static analysis for sandwich plates.

The main advantage of HRZT is that the calculated shear stresses along the thickness are continuous at interfaces between two adjacent layers. Both the deflections and inplane displacements solutions calculated by HRZT are much more accurate than those by Mindlin-Reissner plate theory, especially for the cases of thick sandwich plates. The formulations and results of HRZT plate developed in this study are applicable to aerospace engineering, naval engineering, civil engineering and mechanical engineering, etc.

UNDERSTANDING STRAIN HARDENING BEHAVIOR OF SEAWATER SEA-SAND ENGINEERED CEMENTITIOUS COMPOSITE (SS-ECC) WITH RECYCLED SILICA NANOPARTICLE (NSP)

Xiu-mei Gao[1], Wei-wen Li[1], Peng Wang[1], Lin-yu-wen Ke[2], Jia-ying Wei[2] and Christopher K. Y. Leung[2]*

[2]The Hong Kong University of Science and Technology

ABSTRACT

Seawater sea-sand engineered cementitious composite (SS-ECC) has emerged as an available alternative to conventional cement composites with the employment of tap water and river sand. Given this, SS-ECC exhibits significant potential in marine infrastructure applications, not only safeguarding embedded glass fiber reinforced polymer (GFRP) bars against water-induced degradation [1-3] but also addressing concerns regarding the depletion of natural resources. To enhance the tensile performance of SS-ECC and expand its practical utility, amorphous silica nanoparticles (nSP) derived from recycled GFRP powder are introduced into the cementitious matrix. The inclusion of nSP is anticipated to facilitate the formation of additional nuclei for calcium silicate hydrate (C-S-H) gels, thereby reinforcing the bond between polyvinyl alcohol (PVA) fibers and the cementitious matrix. However, the influence of nSP particle size and incorporation ratio remains uncertain, warranting comprehensive investigation encompassing both experimental and numerical approaches.
First, SS-ECC matrices are modified with nSP of varying particle sizes (a few to hundreds of micrometers) and incorporation ratios (0 to 5 wt% nSP/binder ratios). Subsequently, bench-scale experiments involving single fiber pullout tests and dog-bone tensile tests are conducted. Furthermore, molecular dynamics (MD) simulations are employed to model the interactions between nSP and the cementitious matrix, as well as between the cementitious matrix and PVA fibers. The findings obtained from this integrated approach are anticipated to shed light on the underlying chemical and mechanical mechanisms governing nSP-based SS-ECC.

MULTISCALE TIP SOLUTION OF HYDRAULIC FRACTURE WITHIN HETEROGENEOUS DOMAIN

Quan Wang[*1], Hao Yu[1] and HengAn Wu[1]*

[1]*University of Science and Technology of China*

ABSTRACT

Numerical methods have become one of the most important approaches for analyzing hydraulic fractures, which are common in the oil and gas production industry. Due to the nonlinear fluid-solid coupling, the tip solution of hydraulic fracture contains multiscale characteristics, resulting in various limit propagation regimes (such as viscosity- and toughness-dominated regimes) [1]. Regarding the more realistic and complex geological materials, layered heterogeneity plays a crucial role in fracture propagation. This work aims to reveal the multiscale tip asymptotics under the influence of heterogeneous interfaces between two different materials and provide some applications for modeling hydraulic fractures [2]. Firstly, the displacement and stress solutions are independently analyzed in each domain using Fourier transform, and then combined through continuous boundary conditions at the interface. Then, the integral form of the balance equation is derived, with an additional term in the kernel function that is singular at the interface. A semi-infinite hydraulic fracture is considered to investigate the multiscale tip solution, a specific space mapping and a middle variable is proposed in the solving algorithm. A remote force is defined to account for the influence of the heterogeneous interface, and its effects at the near-tip, intermediate, and far-field scales are analyzed through asymptotic analysis and validated using numerical solutions. It is indicated that the solution at the intermediate scale displays the unique characteristic of the heterogeneous domain. When the crack tip is located in front of the interface, there exists an implicit solution form that depends on the interface property at the intermediate scale instead of a matching solution for both near-tip and far-field solutions. Once the crack tip passes through the interface, an additional interface solution is integrated with interaction from the transition solution. It is pointed out that two propagation aspects of hydraulic fracture should be modified because of the asymptotic behavior, one is the failure criteria and the other is the limit propagation regime in the adjacent region of the heterogeneous interface. This work provides a fundament knowledge for hydraulic fracture in layered structures and has potential application in numerical modeling through specific tip-enhanced algorithms.

MULTIPHYSICS MODELING FOR LASER ABLATION BEHAVIOR OF COMPOSITE STRUCTURE SUBJECTED TO HIGH-SPEED AIRFLOW

Ruixing Wang[*1]*

[1]*The Institute of Mechanics, Chinese Academy of Sciences*

ABSTRACT

When the composite structure is subjected to high-power laser irradiation and high-speed airflow, its ablation behavior presents significant localized characteristics and strong coupling effect. In this work, a coupled fluid-thermal-ablation model is developed to quantitatively investigate the localized coupling effects. Here a loosely coupled scheme with second order temporal accuracy is utilized to improve the coupling efficiency, and a high-quality mesh reconstruction method combining the Arbitrary Lagrange-Euler (ALE) algorithm and Radial Basis Function (RBF) interpolation algorithm is established to capture the moving boundary of the localized ablation pit with large deformation. The model is validated by simulating the laser ablation behavior of C/SiC composite plate subjected to the hypersonic airflow, and the predicted ablation pit profile shows a good agreement with the available experimental result. Analytical results show that as the evolution of the localized asymmetric ablation pit induces transformation of the flow regime from a closed pit flow to an open pit flow. Moreover, the flow regime transition would remarkably alter the localized flow characteristics, including the local static pressure and dynamic pressure, which in turn significantly affects the sublimation and mechanical erosion rates of C/SiC composite plate, respectively.

EXPLORING AN EMMS DRAG MODEL WITH TWO-PHASE FLUCTUATIONS

Jingwei Geng[1], Yujie Tian[1] and Wei Wang[1]*

[1]Institute of Process Engineering, Chinese Academy of Sciences

ABSTRACT

Gas-solid fluidization is characterized by pervasive, dilute-dense two-phase flow structures, which need mesoscale drag modeling to account for their subgrid effects. The classic formulation of the energy-minimization multi-scale (EMMS) drag modeling requires a semi-empirical correlation of cluster diameter. To avoid using such a phenomenological description of mesoscale structures, in this work, we propose a two-level averaging approach: First, the mean drag in a fine-grid cell is defined as a weighted sum of the drag force in both the dilute and dense phases; Then, the second-level averaging is performed at the coarse-grid scale, where the unified EMMS drag is defined, and determined by performing a series expansion with respect to the phase-mean points of both the dilute and dense phases, respectively. The unified EMMS drag is validated with comparison to fine-grid simulation in a periodic domain and coarse-grid simulation of realistic fluidized beds, both showing fair agreement.

NUMERICAL INVESTIGATION OF THE INFLUENCE OF HIGH TEMPERATURE GAS ENVIRONMENT ON OXIDATION AND MECHANICAL DEGRADATION OF THERMAL BARRIER COATINGS

Weidong Wang[*1], Yazhi Li[1] and Biao Li[1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

Failure process of thermal barrier coatings (TBCs) involves combined effect of hot gas and coolant. In this paper, we synthesize the analysis of conjugated heat transfer (CHT) and the modified chemo-mechanical theoretical model to clarify significant influence of high-temperature vapor and coolant on the oxidation of TBCs. Sensitivities of a number of factors to stress distributions and oxidation depth are investigated via. numerical simulation. The results show that:
(1) Computational fluid dynamics (CFD) model and modified oxidation model can describe the CHT and oxidation of TBCs under different conditions, representing a combination of CFD and finite element method (FEM) can well predict the complex corrosion by oxygen.
(2) The oxidation and failure of TBCs are jointly influenced by gas and coolant parameters. The initial oxidation rate increases exponentially with the increase of the gas temperature, velocity, total pressure, angle of attack, coolant temperature or the decrease of coolant velocity. The oxidation rate decreases rapidly at the early stage, resulting in an approximate parabolic thickening curve of the oxide. The oxidation curve is linear only when the gas temperature, velocity, angle of attack, total pressure and coolant temperature are small and the coolant velocity is large.
(3) During heat preserving, the out-of-plane stresses show tensile relief and compressive enhancement with the increase of gas temperature, velocity, attack angle, total pressure, coolant temperature or the decrease of coolant velocity. However, the volume fraction of oxygen has little effect on the stresses. The peak of thermally grown oxidation/bond coat (TGO/BC) interface and the valley of top coat/thermally grown oxidation (TC/TGO) interface are the locations prone to initiate cracks, and the final residual stresses at these positions after cooling also increase with the increase of the fluid parameters other than the coolant velocity, which is different from the effect of temperature holding stage. It is also noteworthy that when gas temperature is high up to 1773K or coolant velocity is lower than 50m/s, the residual stress near the peaks of TGO/BC interface decreases rapidly.
(4) The coatings can be designed by accounting for the critical stress and critical TGO thickness conditions. The design diagrams are conceived according to the numerical results, showing that increasing the Young's modulus of the TC layer and reducing the roughness of the upper surface of the BC layer according to the design curve in the diagrams is able to alleviate the stress concentration and improve the durability of TBCs.

ABSTRACT

1. Problem
Our study investigates physics-informed machine learning (PIML) for solving the time-dependent 2D compressible Navier-Stokes equations in astronomy. Specifically, the evolution of rotating accretion flows within protoplanetary disks. Gravitational perturbations from planets introduce sharp, time-dependent spatial features, complicating the solution. We aim to approximate these problems using PIML, training neural networks on physical laws without labeled numerical data.
2. Contribution
Deriving numerical solutions for these equations is notably resource-intensive. Recent strides in Machine Learning (ML) have accelerated solving these equations significantly. Nonetheless, this advancement is hampered by the ML models' heavy reliance on extensive training data. To address this, the field is shifting towards PIML, which involves training neural networks with PDEs to approximate solutions. PIML promises accurate modeling with minimal data dependency. However, it struggles with complex fluid dynamics, particularly in modeling unstable fluid flows. Our research explores the application of PIML to a complex fluid dynamic problem in an astronomical setting. Also, we introduced strategies to speed up the training process and improve accuracy.
3. Method
Our initial trials with standard Physics-Informed Neural Networks (PINNs) were unsuccessful in capturing the system's evolution, particularly the development of sharp spatial features. A detailed analysis revealed several shortcomings of the standard PINN: slow convergence, limited long-term solution fitting, cumulative deviation from physical laws, and poor performance in capturing sharp features. To overcome these, we introduced enhancements: a self-scalable activation function, an adaptive time-marching strategy with multiple networks, a biased loss function, and a spatial-temporal adaptive PDE sampling method.
4. Results
We evaluated our enhanced PIML model against traditional numerical solutions. Despite higher computational costs and increasing prediction errors over time, our model demonstrated markedly better efficiency. It achieved significantly smaller prediction errors compared to standard PINNs and successfully reproduced most spatial sharp features without requiring labeled data. This study provides a crucial reference for applying PIML to similar fluid dynamics challenges.

AUTOMATED DISCOVERY OF HYPERELASTIC MODELS FOR THE HUMAN BRAIN CORTEX THROUGH SYMBOLIC REGRESSION

Jixin Hou[1] *and Xianqiao Wang**[1]

[1]*University of Georgia*

ABSTRACT

We introduce a novel data-driven framework capable of automatically identifying interpretable and physically valid hyperelastic models in terms of sparse experimental data. Leveraging symbolic regression, an evolution algorithm that explicitly generates parsimonious mathematic expressions for accurate data fitting, our approach enforces crucial hyperelasticity constraints, such as polyconvexity, to ensure physical plausibility and enhance model generalizability beyond the training data regime. Our exploration spans three distinct hyperelastic contexts: invariant-based, principal stretch-based, and normal strain-based, unveiling the versatility of symbolic regression. Validation of our methodology involves benchmark tests with synthetic data derived from five classic hyperelastic models. Subsequent application to experimental data, including three loading modes and targeting an optimal hyperelastic model for the human brain cortex, demonstrates the algorithm's efficacy. Results indicate that our symbolic regression algorithms adeptly discover accurate models with succinct mathematic expressions in invariant-based, stretch-based, and strain-based scenarios. Notably, the strain-based model exhibits superior accuracy, and all models, except for the invariant-based ones, effectively capture the inherent nonlinearity and asymmetry in human brain cortex under uniaxial tension and compression. Further polyconvexity examinations affirm the strict convexity within the training data regime and satisfactory extrapolation capabilities outside this regime for all models. However, the stretch-based and stain-based hyperelastic models might pose concerns regarding convexity violations under large deformations. Finally, robustness tests using synthetic data with noise prescriptions underscores the reliability of our proposed symbolic regression algorithms. Our study confirms the applicability and accuracy of symbolic regression in the automated discovery of hyperelatic models for the human brain cortex, highlighting promises in future applications in soft tissue modeling endeavors.

CONTINUUM MODELLING AND ANALYSIS OF DISCRETE ELASTIC METAMATERIALS

Xiaodong Wang[*1]*

[1]*University of Alberta*

ABSTRACT

Elastic metamaterials are typically periodic materials possessing unit cells with engineered architecture, which make this type of metamaterials discrete in nature. Most current studies of the dynamic behaviour of these metamaterials are based on the evaluation of the property of unit cells or directly conducting analysis and simulation of the original discrete systems. Obviously, it is desirable to develop suitable continuum models capable of accurately capturing the overall dynamic property of these metamaterials. The current paper discusses the development of new two dimensional continuum models for a class of discrete elastic metamaterial systems with local rotation. For typical discrete metamaterials, the equations of motion can be obtained by making use of their geometries and material properties. In the current work, the continuum models are developed directly from the established equations of motion of the original discrete metamaterial systems. New constitutive relations are proposed, which contain new rotational degrees of freedom, in addition to traditional displacements. Evaluation of the new material properties indicates that the rotational and translational displacements are inherently coupled in this type of materials. The new continuum models are then used to study harmonic wave propagation in these materials. The resulting dispersive behaviour of the waves is discussed and compared with that from the original discrete metamaterial systems, showing an excellent agreement at least for relatively low frequencies. The general behaviour of wave propagation in the new continuous media is further studied and compared with the behaviour of traditional elastic waves. The current results show clearly the feasibility of using continuum models to describe the general dynamic behaviour of discrete elastic metamaterials.

CHARACTERIZING AND MODELING THE WIDE STRAIN RATE RANGE BEHAVIOR OF AIR-FILLED OPEN-CELL POLYMERIC FOAM

Xinghao Wang[*1] and Zhanli Liu*[1]

[1]*Tsinghua University*

ABSTRACT

Modeling the compression behavior of air-filled open-cell polymeric foams under large deformation across a wide strain rate range remains a challenge, as the air pressure is dominated by viscous effect or inertial effect at different strain rates. In this study, a visco-hyperelastic constitutive model is developed to describe the response of air-filled open-cell polyurethane (PU) foam under large deformation across strain rate range from quasi-static to dynamic. The time-independent response is characterized by an Ogden form strain energy potential, capturing the nonlinear behavior of the PU foam's cellular structure. For the time-dependent response, in contrast to existing studies, two time-dependent contributions are considered. The first contribution, representing the viscoelastic response of the polymer matrix, is modeled using a hereditary integral-based approach. And the second contribution from airflow resistance is quantitatively modeled through finite difference methods across a wide strain rate range. The model is validated and calibrated through experiment results. It shows that at high strain rates, the air pressure can constitute up to forty percent of the stress and thirty percent of the energy absorption contribution, while it is relatively negligible at quasi-static strain rates. Furthermore, a simplified semi-empirical formula is proposed to rapidly estimate the air pressure in open-cell foams at high strain rates. This formula demonstrates the mechanical response transition from open-cell to closed-cell foams with increasing strain rates. The study is meaningful for understanding the dynamic response and the energy absorption capabilities of gas or fluid filled open-cell foam.

DIAMOND NANOTHREAD AS PROMISING 1D NANOADDITIVE: TOPOLOGY-CONTROLLED THERMOMECHANICAL PROPERTIES FOR POLYMERIC COMPOSITES

Xing-Quan Wang[*1] and Denvid Lau*[1]

[1]*City University of Hong Kong*

ABSTRACT

Diamond nanothread (DNT) has garnered significant interest as a carbon-based nanoadditive for polymeric materials due to its exceptional mechanical properties. DNT has been found to possess superior properties compared to other carbon additives, primarily in two aspects. Firstly, due to the strong interfacial shear force inside DNT bundle, there is no sliding problem between DNTs. This indicates that even if DNT is not well-dispersed, it will not affect the composite's performance. Since DNT is composed of sp3 carbon and lacks graphene surfaces, long-term ultrasonic treatment does not impact its performance. Therefore, more powerful treatment techniques can be used to achieve better dispersion effect on DNTs, and the mechanical dispersion technology has fewer restrictions. Secondly, the hydrogenated surface of DNT can prevent the introduction of structural defects during functionalization, resulting in a reinforced nanocomposite with superior performance. However, the exact influence of DNT in enhancing thermomechanical properties remains unclear. In this study, molecular dynamics simulation was used to identify the role of DNT with various topological structures on the glass transition temperature (Tg) of polymeric materials and to uncover the underlying mechanism of glass-rubber transition. The interaction mechanism was investigated through density functional theory, revealing the impact of DNT topological structures on the instantaneous dipole at the interface between DNT and adjacent polymer chains. Our results show that DNT with different topological structures exhibit variability in enhancing thermomechanical properties of polymeric materials, which is related to their rigidness, the dihedral angle between DNT and aromatic ring in the polymer chain, and their mechanical interlock. The transition from glass to rubber is induced by increases in intermolecular motions due to increases in free volume at the interface, which is governed by van der Waals interaction. Furthermore, we found that DNT significantly improves Tg of epoxy nanocomposite more than other carbon-based nanoadditives. These findings shed light on the thermal degradation mechanism of polymeric composite and provide guidance for improving the reinforcing efficiency of nanomaterials in engineering applications. Our research is expected to offer state-of-the-art theoretical approaches for designing new nano-additives tailored to different reinforcement needs of polymeric composite.

VARIATIONAL QUANTUM ALGORITHMS FOR TOPOLOGY OPTIMIZATION

Jungin E. Kim[1] and Yan Wang[1]*

[1]Georgia Institute of Technology

ABSTRACT

Topology optimization (TO) is the process of optimizing the distribution of materials within a spatial domain. Despite its wide scope of applications, TO is computationally expensive because of two causes. One is the large number of design variables corresponding to the design choices, and the other is the simulation that is used in evaluating the performance of each design. As the alternative computational paradigm, quantum computing can tackle the computational challenge of TO by leveraging the properties of quantum mechanics [1]. In this work, a novel variational quantum algorithm, quantum approximate Bayesian optimization algorithm (QABOA) [2,3], is developed and applied to solve TO problems. In QABOA, mixers are designed to achieve the exploration-exploitation balance for optimization. The equilibrium equations are solved with the QABOA quantum circuit consisting of phase-separating and mixer Hamiltonian operators in the alternating fashion. The rotation angles of the operations are optimized by Bayesian optimization, which is a surrogate-based global optimization scheme. The proposed variational quantum algorithms are demonstrated with truss structure optimization.

APPLICATION OF MACHINE-LEARNED INTERATOMIC POTENTIALS IN ATOMIC-SCALE SIMULATIONS AND BEYOND

Yangshuai Wang[*1] and Christoph Ortner*[1]

[1]*University of British Columbia*

ABSTRACT

This presentation will explore recent advancements in the field of machine-learned interatomic potentials (MLIPs), their impact on molecular simulations, and their potential for enhancing our understanding of materials behavior at the atomic scale and beyond. Starting with an overview of the Atomic Cluster Expansion (ACE) method, we will delve into its construction, recent advancements, and its role in molecular dynamics simulations. We will then discuss the generalization error analysis of ACE for simulating crystalline defects, focusing on defect equilibrium studies. Furthermore, we will explore various applications of MLIPs in materials science at the atomic scale. Finally, we will introduce MLIPs-assisted coarse-grained molecular dynamics, a method that extends simulation scales in both temporal and spatial domains using the state-of-the-art ACE method.

ACCELERATING MATERIALS DESIGN VIA COMPUTATION AND MACHINE LEARNING COMBINED APPROACHES

Yanming Wang[*1]*

[1]*Shanghai Jiao Tong University*

ABSTRACT

A long-standing challenge for materials design is to clarify materials microscopic features, and discover their linkage to macroscopic properties and processing parameters. With the recent development of computing equipment and algorithms, modeling and simulations, assisted by artificial intelligence techniques, have become a promising means to tackle the above problem. In this presentation, computation-based strategies for accelerating materials design will be discussed, through the demonstration of three examples from different aspects on combining modeling and machine learning. In the first example, an effective ensemble learning framework was proposed, for automated identification on atomic crystal structures from molecular dynamics trajectories, as a generalizable tool to extract materials descriptors. In the second example, Bayesian optimization guided coarse-grained molecular dynamics simulations were performed, to systematically investigate the effects of molecular level material properties on lithium-ion transport in polymeric material systems, for promoting an efficient screening of solid polymer electrolytes. In the last example, a three-dimensional generative-adversarial-networks-based model was established, as an attempt toward inverse design of composite materials with complex structures and multiple optimization objectives.

UNVEILING A NOVEL FLUID-STRUCTURE INTERACTION MODEL AND 3D HEXAGONAL CHANNEL NETWORK FOR ARTIFICIAL PANCREAS OPTIMIZATION

Yifan Wang[*1] and Suncica Canic[2]*

[1]*Texas Tech University*
[2]*University of California, Berkeley*

ABSTRACT

An artificial pancreas is a medical device designed to mimic the functions of the natural pancreas, which is responsible for regulating blood sugar by producing and releasing insulin. The significance of this endeavor is underscored by the potential to revolutionize diabetes treatment. Inspired by the artificial pancreas design from our collaborator at UCSF, which involves a bioartificial organ scaffold architecture encapsulating insulin-producing cells, we embarked on developing a fluid-structure interaction model to comprehensively analyze the flow dynamics within the device, which directly influences the effectiveness of oxygen and nutrient transport crucial for optimal device performance. To capture the intricacies of this system, we employed the incompressible Navier-Stokes equations to model blood flow through the device. Simultaneously, the elasticity of the cell scaffold was described using the Biot equation. The coupling of these two problems took place at the fluid-structure interface, highlighting the intrinsic connection between fluid dynamics and structural behavior within the device. Addressing this coupled system, we introduced a decoupling approach based on Niche's scheme, followed by a solution utilizing the finite element method. Our primary focus is on presenting a novel 3D hexagonal channel network, derived from insights gained in our previous 2D study, which demonstrates remarkable superiority in design. In this presentation, we will delve into the details of our model and numerical approach, emphasizing the effectiveness of the decoupled approach. Furthermore, we will discuss the exceptional design benefits achieved through the implementation of the 3D hexagonal geometry for the artificial pancreas device.

INTEGRATED MODELING OF PROCESS-MICROSTRUCTURE-PROPERTY RELATIONS IN WIRE ARC ADDITIVE MANUFACTURING

YiFei Wang[*1] and Zhao Zhang*[1]

[1]*Dalian University of Technology*

ABSTRACT

In order to study the anisotropic mechanical properties of materials in wire arc additive manufacturing (WAAM), the temperature field during the wire arc additive manufacturing process is simulated using a double ellipsoid heat source model in this paper. A Monte Carlo model is established to simulate the microstructural changes in additive layer. The modified dislocation dynamics model is used to reveal the anisotropic mechanical behavior based on grain morphology of additive manufactured Ti-6Al-4V. The obtained results are consistent with experimental data. The mechanical performance of additive manufactured Ti-6Al-4V in the build height direction is significantly lower than arc scanning direction. When the ratio of grain size between the build height direction and the arc scanning direction reaches 3.51mm/0.5mm, the yield strength ratio reaches 857.6Mpa/905.1Mpa. Titanium alloys exhibit obvious material softening at temperatures above 600°C due to grain spheroidization. The yield strength is decreased with the increase of scanning speed, which is due to the decrease in average grain width of columnar grains.

DOUBLE-VARIABLES SECOND-ORDER EXPLICIT PRECISE INTEGRAL (DSEPI) AND ITS ERROR THEORY

Yu Wang[1], Xiangrong Fu[2], Pu Chen[1] and Huipeng Liu[3]*

[1]*Peking University*
[2]*China Agricultural University*
[3]*Guangzhou University*

ABSTRACT

Abstract
In this paper, a new kind of double-variables explicit second-order precise integration method (DSEPI) is proposed. In order to obtain a stable numerical solution from the phase field equation of structural dynamics, we adjust the second order Taylor expansion of the general solution of the motion equation with two factors. The two factors are then determined by stability and energy conservation condition, as well as the absence of global stiffness matrix inversion. Thus, we obtained DSEPI. In fact, as an algorithm DSEPI uses nodal displacement and velocity as independent variables, and might be a rising competitor to the well-known central difference method (CDM). DSEPI has the same stable integration time step as CDM but provides a more precise solution inside the stable time step. From the perspective of engineering applications, DSEPI is of advantage compared with the CDM, because velocity is introduced as an independent variable, eliminating the need to assume initial velocity as required in CDM. The algorithm demonstrates enhanced coordination steps by steps. Both DESPI and CDM feature zero numerical damping within the stable time step. It is found that DSEPI deliver accurate free vibration displacement magnitude under sudden load, since energy conservation in the form of displacement and velocity is exact in the recurrence. Both theoretically and numerically, DSEPI demonstrates superior accuracy compared to CDM for harmonic load. Particularly, when the time step approaches critical values, the accuracy obtained by DESPI is much higher than that of CDM. Preliminary numerical tests show that DSEPI is a potential integration method for structural dynamics. Its suitability for practical engineering applications makes it a noteworthy consideration.

FORCE TRANSMISSION DESIGN METHOD OF STIFFENED THIN-WALLED STRUCTURES BASED ON A UNIFIED MODEL

Yu Wang[1], Lingzhi Jin[1] and Peng Hao[1]*

[1]*Dalian University of Technology*

ABSTRACT

Stiffener design plays a critical role in achieving lightweight design for stiffened panels. In this study, we propose a force transmission design method of stiffened thin-walled structures, utilizing a unified modeling-analysis-optimization model. The foundation of this model is the nested spline model, where stiffeners are represented as curves on the surface of the panel. These curves are embedded into the parameter space of the surface, resulting in a nested geometric model. The design of force transmission is divided into two steps [1]. Firstly, clear force flow members (FFM) are generated based on the principal stress direction. Secondly, a nodal variable-based sizing-topology optimization is introduced to further enhance the lightweight design. To generate precise principal stress trajectories on free-form surfaces, we employ an iterative tracing technique to generate dense principal stress trajectory families and extract FFM using hierarchical clustering. The challenging task of generating high-precision principal stress trajectories is effectively addressed by the nested spline model. For the lightweight design of FFM, we propose a nodal variable-based sizing-topology method. The heights of FFM control points are designated as design variables, and we employ the Sigmoid function to penalize these variables and steadily eliminate pseudo-heights. Additionally, we propose an isogeometric analysis method for stiffened thin-walled structures based on nested spline models to achieve integration of modeling and analysis [2]. The nested spline model is used simultaneously in the modeling-analysis-optimization process, ensuring a unified model throughout the entire design process and avoiding the need for model conversion. We demonstrate the effectiveness and robustness of the proposed method through various benchmarks and examples with industrial backgrounds. The present design framework exhibits significant potential for application in the lightweight design of stiffened panels.

STRUCTURE DESIGN AND MECHANICAL PROPERTIES ANALYSIS OF MULTI-FUNCTIONAL OPERATION PLATFORM

Zeyi Wang[*1], Dongyan Shi[1], Fugang Zhai[2] and Jiuqiang Wang[1]*

[1]*Harbin Engineering University*
[2]*Yanshan University*

ABSTRACT

Aerial work platform is an important mechanical equipment for aerial work. It is an indispensable tool in the fields of high-rise building maintenance, fire rescue work, power maintenance and installation, which greatly improves the timeliness and safety of high-rise building maintenance and fire protection work. Based on the structural characteristics of the telescopic arm type working platform and the scissor type working platform, this paper designs a spider type curved arm aerial working platform. Through the analysis of the mechanical characteristics of the working platform, combined with the force of the structure when the position of the curved arm changes, the integrated design of the curved arm boom system and the wheeled outrigger chassis structure is carried out. Through the finite element simulation technology, the reliable design of the spider-shaped curved arm aerial working platform is realized. The results show that the curved arm boom system can realize multi-point operation such as rotation, expansion and vertical lifting, and has the advantages of wide operation range, high operation efficiency and small retractable space. At the same time, the wheeled chassis with legs improves the mobility and stability of the operation platform. It has important application value in new working environments such as forest farms, stations and docks.

[3]*Ecole des Ponts ParisTech*

ABSTRACT

Accurate permeability prediction in porous media flow is crucial in geotechnical engineering and material science, with applications spanning the oil and gas industry, hydrology, and hydrogen fuel cells. However, conventional laws such as the Kozeny–Carman equation do not capture the influence of pore structure disorder on permeability. In this study, we numerically investigate the permeability in porous media under varying degrees of pore structure disorders and porosity using the lattice Boltzmann method. Notably, our findings reveal a twofold impact of the disorder on permeability, dependent on the porosity of the media. For media with high porosity, the permeability increases with increasing disorder; whereas for media with low porosity, an increase in disorder corresponds to greater flow resistance. To provide insights into how the solid structure affects permeability, an effective tortuosity parameter that accounts for both disorder and porosity is derived. Our results demonstrate that the modified Kozeny–Carman equation successfully predicts the permeability of porous media across a wide range of disorders and porosity.

A SIMULATION-DRIVEN DESIGN METHOD FOR GRADED LATTICE STRUCTURES WITH COMPLEX BOUNDARY CONSTRAINTS

Zhujiang Wang[*1], Xinwei Du[1] and Bin Zhai[1]*

[1]*Guangdong Technion-Israel Institute of Technology*

ABSTRACT

Graded lattice structures (GLS) are used widely in the areas of 3D printed sensors, personalized wearable devices, robotics, energy absorption, etc., and have a prospective future in the field of personalized medical devices. The implementation of GLS-based personalized wearable medical devices necessitates a GLS design method that can effectively tackle the challenges stemming from diverse boundary surface constraints and nonlinear contact loads, due to patient-specific care needs. In this study, the proposed GLS design approach, grounded in an automatic seed generation algorithm, emerges as a prospective solution to facilitate the broad deployment of GLS-based personalized medical devices. The proposed GLS design approach is founded on the following key elements: (a) the application of PIMesh, an automatic point cloud generation algorithm, to create nonuniform seed distributions within domains of any shape; (b) subsequent generation of raw GLS based on the seed distribution; (c) the further optimization of the raw GLS geometry based on finite element analysis. As the seed distributions are customized to adhere to the specified boundary shapes of the target GLS, and the graded mechanical properties are fine-tuned via finite element analysis, the resulting GLS ensures adherence to boundary constraints and graded mechanical prerequisites. The GLS geometry optimization method, rooted in finite element analysis, adeptly manages the non-linear contact loads commonly encountered in wearable medical devices. Several demonstrations, including a 3D-printed shoe sole and an energy absorber, have been conducted. The results affirm the efficacy of the proposed GLS design and optimization method.

A MOVING LEAST SQUARES IMMERSED BOUNDARY METHOD FOR SPH WITH THIN-WALLED OR SLENDER STRUCTURES

Zhuolin Wang[*1], Yi Zhang[2], Zichao Jiang[1], Bohua Huang[1], Xuan Luo[1] and Qinghe Yao[1]*

[1]Sun Yat-sen University
[2]Guilin University of Electronic Technology

ABSTRACT

This study presents a moving least squares immersed boundary method for smoothed particle hydrodynamics (SPH), aiming to simulate thin-walled or slender structure immersed in fluid. Based on the direct forcing immersed boundary method, the proposed method improves the velocity interpolation using the moving least squares method. In comparison to traditional SPH wall boundaries (e.g., ghost particles, fixed particle method, etc.), this method eliminates the need for multiple layers of particles, making it particularly suitable for thin-walled or slender structures. The proposed method reduces oscillations and achieves higher accuracy while retaining the advantage of immersed boundary method.

Results of three-dimensional numerical tests are presented, including impulsively started plate, flow past a cylinder, and flow past a sphere, comparing to results of other commonly used immersed boundary schemes. Compared to the diffusive direct forcing immersed boundary method, the proposed method shows more accurate lift and drag coefficients, effectively avoids mutual interference on both side of the boundary. In comparison to the direct forcing immersed boundary method using linear interpolation, the proposed method sustains more accurate computational results while effectively decreasing pressure oscillations. Furthermore, the proposed method is applied in flexible fibers fluid-structure-interaction (FSI) problems, successfully simulating the shape and movement of flexible fibers with different stiffness in three-dimensional shear flow.

MICROPLANE CONSTITUTIVE MODEL FOR TENSILE AND COMPRESSIVE DAMAGE IN BRITTLE POLYMERS

Sanket Vinod Wardhekar[*1], Garret Smith[1] and Kedar Kirane[1]*

[1]*Stony Brook University*

ABSTRACT

This work presents a novel adaptation of the microplane constitutive model for tensile and compressive damage in brittle polymers. The salient feature of the model is the “microplane” which is an imagined plane within the material microstructure. At each material point several microplanes of various orientations are assumed to exist and various tensile and compressive damage mechanisms are formulated in terms of stress-strain vectors acting on these microplanes. The macroscopic strain tensor is projected on these microplanes to yield several strain vectors. Through the damage laws, these yield corresponding stress vectors, which are homogenized via the principle of virtual work to obtain the macroscopic stress tensor. Four damage laws are considered at microplane level, driven by the normal, deviatoric, volumetric, and shear strains, each intended to capture specific observed damage mechanisms in the highly nonlinear tensile and compressive stress strain laws of polymers. These include tensile microcracking, shear microplasticity, micro-crack friction, and far post-peak compression hardening. The model incorporates a volumetric-deviatoric (V-D) split at the microplane level, which is necessary for materials with Poisson ratios above 0.25. The model is calibrated through experimental data and is demonstrated to reproduce the intricate damage behaviours of polymers, through relatively simple damage laws. It is also shown that while the uniaxial tensile behaviour can be reproduced with single material point analyses, a specimen level (multiple material points) model is required to capture the uniaxial compressive behaviour due to the marked localization of shear damage. The model is also compared to Mohr Coulomb and Drucker Prager plasticity models and is found to exhibit better agreement with experiments.

MICROMECHANICAL CONSTITUTIVE MULTISCALE MODELING OF RATE-DEPENDENT EFFECTS IN FERROELECTRICS: A COMPREHENSIVE APPROACH

Andreas Warkentin[*1] and Andreas Ricoeur*[1]

[1]*University of Kassel*

ABSTRACT

Ferroelectrics exhibit many interesting effects, both linear and nonlinear, which is why these materials are widely used in science and industry. Moreover, it is noteworthy that the majority of these effects, particularly those which are nonlinear, are strongly rate-dependent, rendering the modeling of these intricate materials with multiple material scales quite challenging. The rate dependence is contingent on the material scale at which these distinct effects occur, yet they are all reflected in the macroscopic material behavior. Furthermore, nonlinear effects are irreversible and are accompanied by energy dissipation, which generally leads to a temperature rise of the material. For modeling the distinctive nonlinear rate-dependent effects of ferroelectric materials, there are numerous options, including microphysical and phenomenological models.

Aspects of different rate-dependent effects, as well as mutually coupled dissipative processes in ferroelectrics, in particular ferroelectric domain switching and viscoelasticity, are investigated theoretically, based on a microphysical motivated thermo–electromechanical multiscale constitutive framework. For this purpose a hybrid micromechanical–rheological constitutive model is developed and embedded in the framework of a multiscale modeling approach [1, 2, 3]. The mathematical theory is consistent against the background of rational thermodynamics and deals with two types of internal variables. The advanced modeling approach is inter alia applied to identify novel energy harvesting cycles exploiting dissipative effects, resulting in a major electric work output.

ENABLING PROBABILISTIC MICROWEATHER PREDICTIONS THROUGH DEEP GENERATIVE MODELING AND OPERATOR LEARNING

James Warner[*1], Geoffrey Bomarito[1], Patrick Leser[1] and Paul Leser[1]*

[1]NASA Langley Research Center

ABSTRACT

Motivated by NASA's pursuit of safe, reliable, and weather tolerant urban air mobility (UAM) solutions, this work develops a framework for rapidly and probabilistically assessing microweather conditions. The approach leverages recent advances from the deep learning field to make efficient wind predictions as a continuous function of space/time while also capturing natural random variability (e.g., wind gusts). In particular, a denoising diffusion probabilistic model [1] is trained to produce realistic samples of wind speed on the periphery of a UAM operational space to serve as boundary conditions. A deep operator network (DeepONet) [2] then learns the nonlinear operator that maps samples of winds on the boundary to the microweather wind conditions throughout an area of interest (e.g., a landing zone). The framework bypasses the need for expensive computational fluid dynamics predictions and is shown to provide accurate uncertainty quantification (UQ) that can enable reliable UAM operations.

POLYMORPHIC UNCERTAINTY QUANTIFICATION, SENSITIVITY ANALYSIS AND BAYESIAN MODELING IN MULTISCALE AND MULTIPHYSICAL FEM MODELS

Navina Waschinsky[*1] and Tim Ricken*[1]

[1]*University of Stuttgart*

ABSTRACT

The complexity of numerical simulations, especially in multiscale and multiphysical modeling, highlights the need for polymorphic uncertainty quantification (PUQ) methods. These are vital for a comprehensive understanding of input parameters, improving model efficiency, and contributing to the optimization of complex systems. Our presentation aims to highlight various aspects of PUQ analysis using different engineering examples based on the Finite Element Method (FEM), focusing on examples from the automotive and aircraft industries, as well as examples from soil mechanics and biomechanics.

In our workflow, we start by creating a parameterized FE model along with an essential metamodel, which is particularly important for complex models to save computational time. Uncertain parameters are modeled as either aleatoric or epistemic uncertainties based on available information. Subsequently, PUQ is derived to obtain a probability of the solution of interest or to perform reliability analysis.

Key aspects to highlight include Bayesian analysis, employed to generate a metamodel. Numerical simulations provide additional knowledge to optimize estimated parameters within the surrogate model. Furthermore, the Bayesian approach refines estimated uncertainties of input parameters. When experimental data is available, Bayesian approaches can update prior assumptions for input uncertainties, thereby improving output uncertainties.

Another focus is on Variational Sensitivity Analysis (VSA), which can analyze the local impact of input parameters and can be embedded in an efficient metamodel, a so-called Gradient Enhanced Kriging model.

Additionally, we aim to highlight the relevance of a polymorphic approach, whereby both aleatoric and epistemic uncertainties can be considered. Aleatoric uncertainty requires additional information for a probability distribution of parameters, whereas epistemic uncertainty is viewed as information with missing knowledge, addressed through a fuzzy approach.

THE GEOMETRICALLY EXACT BEAM IN A QUATERNION FORMULATION WITH AN ENERGY-MOMENTUM CONSERVING INTEGRATOR

Paul Wasmer[*1] and Peter Betsch*[1]

[1]*Karlsruhe Institute of Technology*

ABSTRACT

In various engineering domains, beam models play a pivotal role in simulating slender structures efficiently. The most important model for large deformations is the so-called geometrically exact beam also often referred to as Simo-Reissner beam. The configuration manifold of the beam model is given by special Euclidean group as it describes the position of the centerline as well as the orientation of the beam's cross-section. The partial differential equations describing the behavior of the beam is usually solved with the help of the Finite Element Method (FEM). So it becomes necessary to discretize the special orthogonal group in a finite element sense.

However, discretizing the special orthogonal group proves challenging due to its non-abelian, non-additive matrix group nature under multiplication. An intriguing alternative is the use of unit quaternions for the parametrization of the special orthogonal group. Employing a Hu-Washizu-like approach for the beam enables us to mitigate locking effects. To establish a stable time integration, our objective is to devise an energy-momentum conserving scheme. By integrating the Liven’s principle into this mixed approach, we simplify the development of an energy-momentum conserving time integration scheme.

Existing literature frequently highlights the advantages of Isogeometric Analysis (IGA) over traditional FEM using Lagrangian elements, particularly in addressing dynamic challenges. We thus apply the IGA to the Hu-Washizu-like quaternion formulation of the geometrically exact beam.

CHARACTERIZATION OF LOCAL MECHANICAL PROPERTIES OF METALLIC MICROSTRUCTURE USING INSTRUMENTED INDENTATION TEST

Ikumu Watanabe[*1], Toshiro Amaishi[2] and Ta-Te Chen[3]*

[1]National Institute for Materials Science
[2]JSOL Corporation
[3]Nagoya University

ABSTRACT

Instrumented indentation test is an extension technique of hardness test, in which the load-depth relationship is measured. Based on the material test, various approaches have been proposed to estimate the stress-strain curve corresponding to a tensile test. Among them, a single indentation approach based on pile-up height of the impression[1,2] has preferable feature to characterize the heterogeneity of mechanical properties in a structure such as an additive-manufactured sample[3]. In this approach, a finite element model can be constructed based on the estimated heterogeneity. Besides, the instrumented indentation test has multiscale extensibility similar to hardness test; i.e., it can be applied to micro-scale evaluations by setting a small load. In this study, the single indentation approach based on pile-up height is applied to estimation of mechanical properties in a metallic microstructure. Here, a simple constitutive model for single crystal is defined and its material constants are determined on the basis of a correlation between experiments and simulations of instrumented indentation tests. Subsequently, the applicability and limitations are discussed.

EFFECTS OF ROTATING CYLINDRICAL ROUGHNESS AND ITS ROTATING DIRECTION ON CROSSFLOW-VORTEX TRANSITION OF SWEPT-FLAT-PLATE BOUNDARY LAYER

Yuto Watanabe[*1], Kosuke Nakagawa[1], Ryo Araki[1], Takahiro Ishida[2] and Takahiro Tsukahara[1]*

[1]*Tokyo University of Science*
[2]*Japan Aerospace Exploration Agency (JAXA)*

ABSTRACT

The turbulent transition on the swept wing of an aircraft is triggered by the crossflow instability near the leading edge and/or the Tollmien-Schlichting (TS) instability in the downstream [1]. Also, the crossflow instability promoted by the presence of manufacture-induced surface roughness turns the entire wing surface of existing aircrafts into turbulent. Discrete roughness elements, such as cylinders, have been adapted to the wing in order to delay the turbulent transition [2]. However, despite the advantage of being the passive control, this method has not been applied to actual aircraft due to its low robustness to flight attitude such as angle of attack, i.e., flow field in the boundary layer. Recently, Wu et al. [3] studied the effect of rotating cylindrical roughness on the TS instability of the two-dimensional boundary layer, without the crossflow instability.

In this study, we study the turbulent transition process in the downstream of the rotating cylindrical roughness in a three-dimensional boundary layer by direct numerical simulations. To this end, we employ the Falkner-Skan-Cooke similarity solution to model the swept-flat-plate boundary layer and the rotating cylindrical roughness is implemented by the immersed boundary method. We compare two adjacent cylinders rotating in either the same (co-rotating) or opposite (counter-rotating) directions by varying their height and angular velocity. The gap between the adjacent cylinders is set to the most unstable wavelength at which the crossflow instability grows most rapidly.

With zero angular velocity, a crossflow vortex emerges in the downstream, leading to the turbulent transition. The co-rotating cylinders alter the vortex generation process. Under limited conditions, this alteration of the vortex structure causes a transition delay, and we find that a faster rotation eventually promotes the transition. The threshold of delay/promote also depends on the roughness height. In the co-rotating condition, the friction coefficient is higher than in laminar flow before the transition, but the transition position is delayed. In the counter-rotating condition, the friction coefficient is similar to that of the laminar flow before the transition, but the transition position is not delayed as in the co-rotating condition. In the presentation, we will further discuss how the rotating cylinders modify the crossflow vortex structures, and how they determine the turbulent transition point.

SIMULATION OF FLUID-STRUCTURE INTERACTIONS USING MULTI-VELOCITY DESCRIPTION COMBINING DISCONTINUOUS GALERKIN FINITE ELEMENT METHOD AND MATERIAL POINT

Jiajia Waters[*1] and Duan Zhang*[1]

[1]*Los Alamos National Laboratory*

ABSTRACT

Accurate description and determination of material interfaces are important tasks for any numerical method intended to study fluid-structure interactions. Many interface tracking and reconstruction methods have been proposed and studied for this purpose.

Here, we introduce a numerical approach for fluid-structure interactions using a multi-velocity description of the materials with the combination of Discontinuous Galerkin finite element method (DGFEM) and the material point method (MPM). In this approach, no special interface tracking method is needed. All simulated materials are described by their own velocity fields. The solid materials will be simulated by MPM while the fluid materials will be handled with DGFEM. For fluid structure interaction, at each spatial location there are two velocities values, one for the fluid and one for the solid. The solid material is represented by the Lagrangian material points, which moves with the deforming solid. The positions of these material points describe the region occupied by the solid in the computational domain, which includes information about the boundaries or interfaces between the solid and fluid. The interaction of the two materials, regardless of fluid-fluid, solid-solid or fluid-solid, is modeled as the interaction force, such as drag, in the mixed cell containing any amount of materials. In our formulation, all the materials are allowed to have their own density, velocity, energy, and stress fields. The density of a material is calculated according to its own evolution equation subjected to the continuity constraint. The stress (or pressure) evolves independently according to the constitutive relation (or equation of state) of the material.

In this presentation, we will discuss the application of multi-velocity to only fluid materials interaction, only solid materials interaction and fluid structure interaction. The algorithms needed for applying the material point method to multi-velocity calculations will be discussed. Numerical examples will be provided to show validity of the method.

[1]*Technical University of Munich*
[2]*Altair Engineering*

ABSTRACT

The Lattice-Boltzmann method (LBM) stands out in versatile and highly parallel fluid mechanics simulations. However, increasing computational demands with finer resolution and larger domains motivate the exploration of quantum computing potential in computational fluid dynamics applications.

The LBM can be divided into two significant algorithmic steps: collision and streaming. Quantum algorithms for the LBM using amplitude encoding techniques allow the formulation of the streaming step by a unitary evolution of the state vector. Given its inherently non-unitary nature attributed to the diffusive component, the collision step cannot be directly implemented within a quantum algorithm. Hence, a Linear Combination of Unitaries (LCU) algorithm is employed to statistically implement the linearized collision step. The collision process is successful when an ancillary qubit is measured in the ground state and fails otherwise [1].

We introduce a novel hybrid quantum algorithm for the LBM, encompassing initialization, collision, and streaming as unitary quantum operators. The zeroth and first moments of the distribution functions are computed by digital post-processing at each time step. Subsequently, a unitary evolution enables linear collision, removing the necessity for the LCU algorithm. This is achieved by incorporating the quantum measurement as part of the collision operator, resulting in a fail-safe collision operator. Finally, established algorithms implement the streaming step.
Our algorithm agrees with a digital reference implementation utilizing an analytical state vector simulator. Additionally, we assess the performance of our algorithm through noise-free sampling simulators, revealing a faster convergence rate with fewer required shots. Algorithms utilizing the LCU method often demonstrate mass loss due to under-sampling errors. In contrast, our algorithm fully conserves mass for the linearized collision operator.

The Carleman linearization approximation can incorporate non-linear effects to address the collision operator's inherent non-linearity [2].
Our framework facilitates the computation of the non-linear dependence of the collision operator by leveraging the non-linear measurement process. Consequently, we can implement the non-linear collision operator without using approximate linearization techniques.

ABSTRACT

Particles suspended in fluids continue to pose a challenge in various fields of science and engineering, especially for particles in the micrometer range, due to the high complexity and cost of computational models and experimental techniques. For microparticles, the particle Reynolds numbers are usually well below one, and the local flow around the particle can be described by Stokes flow, [1]. Although surface tension results in a predominantly spherical shape for microscopic droplets and bubbles, several types of deformable microparticles are nonspherical and can be deformed by the action of the fluid flow, which significantly increases the complexity of particle tracking. Examples in this area are liquid capsules, vesicles and biological cells. In recent years, these soft particles have gained considerable importance in science, especially in the pharmaceutical field, e.g. in the targeted delivery of drugs.

In this talk, we will focus on our novel computational model for tracking the motion and deformation of a large number of micrometer-sized, soft, i.e. deformable, non-spherical particles in dilute fluid flows using Lagrangian particle tracking. In this context, we use the point-particle approach since it is a common technique for modelling a large number of microparticles and has comparatively low computational requirements. Furthermore, we assume affine deformation and creeping flow around the particle, [1].

We compare the novel approach in the limit of quasi-rigid as well as for soft deformable particles with analytical and numerical results from the literature, [2], and obtain good agreement with the references. The model is further applied to simple flows such as Couette and Poiseuille flows, here we especially focus on the tank-treading phenomenon displayed by flow-immersed soft particles. Future steps include the application to technologically relevant flows, such as in realistic human lung replicas.

PARAMETERIZED HYPERELASTIC MATERIAL MODELING AND MULTISCALE TOPOLOGY OPTIMIZATION WITH PHYSICS-AUGMENTED NEURAL NETWORK

Oliver Weeger[*1], Felix Püsch[1], Dominik K. Klein[1], Fabian J. Roth[1] and Kurt Maute[2]*

[1]*TU Darmstadt*
[2]*University of Colorado Boulder*

ABSTRACT

In the last decades, a vast amount of highly specialized metamaterials has been developed and, with advancing requirements in engineering applications, the trend is growing. Often comprised of complex microstructures with parametrized geometry, these materials can be tailored for each specific application. Examples include lattice-metamaterials with varying radii or fiber-reinforced elastomers where the volume fraction of the fibers might vary. Since such materials behave highly nonlinear, their mechanical description is challenging. Thus, we envision the use of physics-augmented neural networks (PANNs), circumventing the current limitations of analytically formulated multiscale material models.

In [1], we apply neural networks to formulate parametrized hyperelastic constitutive models. The models fulfill all common mechanical conditions of hyperelasticity by construction. In particular, partially input convex neural network (pICNN) architectures are applied based on feed-forward neural networks. Receiving two different sets of input arguments, pICNNs are convex in one of them, while for the other, they represent arbitrary relationships, which are not necessarily convex. In this way, the model can fulfill convexity conditions stemming from mechanical considerations without being too restrictive on the functional relationship in additional parameters, which may not necessarily be convex. Two different models are introduced, where one can represent arbitrary functional relationships in the additional parameters, while the other is monotonic in the additional parameters. As a first proof of concept, the model is calibrated to data generated with two differently parametrized analytical potentials, whereby three different pICNN architectures are investigated. In all cases, the proposed model shows excellent performance.

Furthermore, in [2], we apply hyperelastic PANN constitutive models for topology optimization (TO). Using a level-set TO approach, the applicability of hyperelastic PANN constitutive models in 2D and 3D optimization scenarios is demonstrated. The optimized designs received with the PANN constitutive model are in excellent agreement with the ones received with their ground truth counterparts. Furthermore, a parametrized PANN from [1] is applied for multiscale TO. In the optimization process, both the geometry of the macroscale and microstructural parameters are optimized, where the TO with the PANN model again shows excellent results.

AN IMPROVED MULTI-LEVEL HP FINITE CELL METHOD FOR EFFICIENT THERMO-VISCOPLASTIC ANALYSES

Oliver Wege[*1], Jan Niklas Schmäke[1] and Martin Ruess[1]*

[1]*Hochschule Düsseldorf*

ABSTRACT

Efficient numerical integration of the weak formulation of the governing equations plays a key role in the finite cell method [2]. The challenge is even more severe for non-linear problems relying on iterative solution schemes. Higher order interpolation spaces and the geometric and structural complexity of the analysis models usually require a significant number of quadrature points to capture the analysis domain with sufficient accuracy and to ensure an adequate convergence behavior of the analysis. A remedy to an over-excessive need of quadrature points from the established recursive bi-section approach is the use of the recently proposed non-negative moment fitting quadrature approach [1, 3] which is demonstrated in this presentation in the framework of thermo-viscoplastic analyses. Instead of the conventional cell partitioning approach [2], we use non-negative moment fitting quadrature to find a priori an optimal set of quadrature points that provides the desired properties. The performance of this novel quadrature method is tested in the framework of viscoplastic analyses with a multi-level hp refined finite cell method. We present the proposed approach for smooth and non-smooth solution fields and show an extension to a thermo-viscoplastic analysis of industry-relevant models [3].

MODELING GROWTH AND MECHANICAL FEEDBACK IN ELASTIC BIOLOGICAL TISSUES

Chaozhen Wei[*1], Nonthakorn Olaranont[2], John Lowengrub[2] and Min Wu[3]*

[1]*University of Electronic Science and Technology of China*
[2]*University of California, Irvine*
[3]*Worcester Polytechnic Institute*

ABSTRACT

The inhomogeneity of cell proliferation, apoptosis, and myosin-dependent contraction can generate elastic stress and strain in living tissues, which may be dissipated by internal rearrangement through cell topological transition and cytoskeletal reorganization. Moreover, cells and tissues can change their sizes in response to mechanical cues. We develop a continuum model based on finite elasticity and growth theory to describe the coupled tissue growth and mechanics in the Eulerian frame. We incorporate the tissue rearrangement by introducing a tissue rearranging rate and propose energy-dissipative mechanical feedback on growth. By linearizing the model, we show that the stress follows the Maxwell-type viscoelastic relaxation. The rearrangement rate, which we call tissue fluidity, sets the stress relaxation time, and the ratio between the shear modulus and the fluidity sets the tissue viscosity. We apply the model to study the tumor spheroid growth and mechanics in the context of differential growth induced by the growth-promoting factor field undergoing a reaction-diffusion process. We investigate the key parameters in the model by fitting experimental data of tumor spheroid growth. We aim to demonstrate the roles of the tissue material properties and mechanical feedback regimes on its size and mechanics regulation.

HOW MATHEMATICAL AI IS TRANSFORMING BIOSCIENCES

*Guowei Wei**[1]

[1]*Michigan State University*

ABSTRACT

Mathematics underpins fundamental theories in physics such as quantum mechanics, general relativity, and quantum field theory. Nonetheless, its success in modern biology, namely cellular biology, molecular biology, chemical biology, genomics, and genetics, has been quite limited. Artificial intelligence (AI) has fundamentally changed the landscape of science, engineering, and technology in the past decade and holds a great future for discovering the rules of life. However, AI-based biological discovery encounters challenges arising from the intricate complexity, high dimensionality, nonlinearity, and multiscale biological systems. We tackle these challenges by a mathematical AI paradigm. We have introduced differential geometry, algebraic topology, and combinatorial theory to significantly enhance AI's ability to tackle biological challenges. Using our mathematical AI approaches, my team has been the top winner in D3R Grand Challenges, a worldwide annual competition series in computer-aided drug design and discovery for years. By further integrating mathematical AI with millions of genomes isolated from patients, we uncovered the mechanisms of SARS-CoV-2 evolution and accurately forecast emerging dominant SARS-CoV-2 variants.

ADVANCING MULTISCALE MODELING IN POLYCRYSTALLINE MATERIALS: A NOVEL DEEP MATERIAL NETWORK APPROACH

Ting-Ju Wei[1] and Chuin-Shan Chen*[1]

[1]*National Taiwan University*

ABSTRACT

This study introduces an enhanced Deep Material Network (DMN) model specifically designed to analyze and model polycrystalline materials. Our method builds on the original DMN concept by Liu et al. [1]. It incorporates the interaction-based mechanisms proposed by Noel et al. [2], significantly improving polycrystalline materials' simulation efficiency and accuracy. The core of our approach involves adapting the DMN architecture to capture the complex geometry of polycrystalline materials, allowing for a more accurate representation of the interactions among different phases and, thus, better representing their textural characteristics. Furthermore, our model includes an active learning strategy to efficiently sample diverse material properties, enhancing the dataset and the model's predictive capability and robustness. This ensures that all critical data points are comprehensively covered, effectively navigating the vast material property space. A notable feature of our model is its ability to accurately and efficiently capture the polycrystalline texture during the online prediction phase. This capability is further enhanced by integrating crystal plasticity within the DMN framework, which aligns well with direct numerical simulation (DNS) results and showcases the model's high efficiency. In summary, our enhanced DMN model marks a significant advancement in the analysis and modeling of polycrystalline materials. Combining an enhanced DMN architecture and crystal plasticity makes our model a powerful tool in multiscale modeling. It offers accuracy, efficiency, and a physically meaningful interpretation of polycrystalline materials, paving the way for applications in material design and performance optimization.

OPENQUAD: A SEMI-AUTOMATIC AND SCALABLE UNTRIMMING PIPELINE FOR TRIMMED NURBS

Xiaodong Wei[*1] and Zheng Wei*[1]

[1]*Shanghai Jiao Tong University*

ABSTRACT

In engineering design, one of the most daunting problems in the design-through-analysis workflow is the dealing with trimmed NURBS, which often involve problematic topological information and lead to inevitable gaps and overlaps in the geometric model. Given the dominance of the trimming technology in the CAD community, fixing such a model with a watertight representation is highly desired. While remarkable progress has been made in recent years, especially with the advancement of isogeometric analysis, there still lack a fully automatic and scalable tool to achieve this reconstruction goal. To address this issue, we present a semi-automatic and scalable untrimming pipeline based on a scalable, field-aligned meshing tool QuadriFlow. On top of it, we add support for open surfaces to deal with engineering shell structures, and we perform sophisticated patch simplification to remove undesired slender patches. As a result, we obtain a watertight multi-patch NURBS with a nice semi-regular layout. Through several challenging models from industry applications, we will show that the manual intervention is minimal (i.e., tuning only a single parameter when necessary) and the pipeline can handle large-scale models within minutes.

ADVANCED FLUID-STRUCTURE INTERACTION SIMULATION OF A HUMANOID BIOREACTOR SYSTEM FOR OPTIMIZED TISSUE ENGINEERING

Yuyang Wei[1], Pierre Mouthuy[1], Sarah Waters[1] and Antoine Jerusalem[1]*

[1]*Oxford University*

ABSTRACT

The integration of computational mechanics in tissue engineering has opened new avenues for optimising bioreactor designs as faster and more cost-effective alternatives to traditional trial-and-error experiments. In particular, the incorporation of the biomechanical environment in tissue (re)generation models can leverage recent progress made in multiphysics computational sciences. This study presents a fluid-structure interaction (FSI) simulation of a bioreactor subjected to in vivo-like conditions. This bioreactor, which integrates a flexible scaffold within a dynamic mechanical stimulation setup, mimics the complex biomechanical environment of human tissues. Our FSI simulation framework aims at predicting the impact of the flow of culture medium on cell seeding and growth. We then compare these simulation results with the cell distributions from in vitro models to optimise the bioreactor design and operation. Our FSI approach couples our solid solver (MuPhiSim) with a fluid dynamics solver (OpenFoam) using Precice. Ultimately, the proposed simulation framework aims to identify optimal operating conditions and system properties, including scaffold geometry, material properties, and fluid dynamics parameters such as perfusion velocity, to promote cell proliferation and achieve uniform seeding distribution. A distinctive feature of this research is the validation of the FSI model against in vitro experimental data. We employ fluorescence imaging to quantify cell distribution on the scaffold and compare it with simulated shear stress and pressure distributions. This comparison between fluid dynamics within the bioreactor and cell distribution patterns will provide valuable insights into the mechanical stimuli influencing cellular activities, which are crucial for designing more effective tissue engineering bioreactors.

DEEP MATERIAL NETWORKS FOR UNIFIED COMPUTATIONAL MULTI-SCALE MODELING OF THE HIGHLY NON-LINEAR BEHAVIOR OF SHORT FIBER-REINFORCED POLYMERS

Fabian Welschinger[*1], Argha Protim Dey[1], Matti Schneider[2] and Thomas Böhlke[3]*

[1]*Robert Bosch GmbH*

[3]*Karlsruhe Institute of Technology*

ABSTRACT

In competitive industrial environments, fast development processes for products with high reliability requirements are key to success. This is achieved by virtualizing the product development process to a high degree. Designing reliability of complex systems in early phases of the product development process in the absence of physical prototypes requires the use of precise simulation methods. For components made of short fiber-reinforced polymers, accurate modeling and simulation is a non-trivial task since the manufacturing-induced microstructural configuration of the material impacts the thermo-mechanical behavior of the macroscopic component. Conventional anisotropic modeling approaches typically used for these tasks do not accurately resolve the microstructure-property relation and require a time and cost intensive material parameter identification. Numerous experiments are required with different combinations of load directions versus material orientations. The recently developed deep material networks (DMNs) [1, 2] have the potential to relieve this pain by either generating virtual data for calibrating classical anisotropic models [2] or by being used as a material model in finite element analyses on component level directly [3]. DMNs are extremely fast and accurate surrogate models for high-precision fast Fourier transformation-based simulations (FFT) on realistic 3D microstructures. In an offline phase, numerous micromechanical FFT simulations are performed to generate linear elastic training data. Once trained, the DMN is used in an online phase to inversely identify the constitutive parameters of the non-linear individual phases in the composite based on sparse experimental data. The calibrated DMN either allows to enrich real experimental data by virtual data and then to identify model parameters of anisotropic models or to carry out component simulations directly [3]. This work outlines the application of DMNs for highly non-linear deformation problems in the context of short glass fiber-reinforced polymers to industrially relevant problems.

DATA-DRIVEN MULTISCALE FINITE ELEMENT SIMULATION AND ITS APPLICATIONS IN LITHIUM IONS BATTERIES

Jici Wen[1], Qingrong Zou*[2] and Yujie Wei[1]

[1]*Chinese Academy of Sciences*
[2]*Beijing Information Science and Technology University*

ABSTRACT

As lithium-ion battery technology advances, a thorough comprehensive understanding of its performance and safety becomes increasingly imperative. This study focuses on a data-driven multiscale finite element simulation approach aimed at modeling and analyzing the intricate behavior of lithium-ion battery systems. To shed light on the multiscale interactions within the battery more comprehensively, we leverage experimental data to construct a data-driven constitutive model for electrode materials with considering the inhomogeneous effects of micro composite structures, capturing electrochemical-mechanical coupled behaviors. By integrating these models into a multiscale finite element framework, we can simulate and analyze the behavior of the battery across different scales, ranging from the particle to the macroscopic cell level. This holistic simulation approach facilitates a deeper understanding of the multiscale and multiphysical processes occurring within the battery. This study provides profound insights for the further optimization and enhancement of lithium-ion battery technology, holding significant implications for the future of renewable energy storage.

AN AUGMENTED LAGRANGIAN TRUST-REGION METHOD TO ACCELERATE CONSTRAINED SHAPE OPTIMIZATION PROBLEMS USING MODEL HYPERREDUCTION

Tianshu Wen[*1] and Matthew Zahr*[1]

[1]*University of Notre Dame*

ABSTRACT

We present an augmented Lagrangian trust-region method to efficiently solve side-constrained optimization problems governed by large-scale nonlinear systems of equations. A globally convergent, hyperreduced trust-region framework is embedded in the nested optimization to ensure the global convergence of the overall framework towards the critical point. The trust-region framework constructs a hyperreduction model via empirical quadrature procedure (EQP) on the fly, which completely avoids an offline training phase. Two numerical experiments are performed on the shape optimization problem to verify and demonstrate the efficiency of the proposed work.

PARAMETRIZATION OF PHASE-FIELD MODELS FROM ATOMISTIC SIMULATIONS AND MECHANO-THERMAL CHARACTERIZATION

Frank Wendler[*1], Dilshod Durdiev[1], Michael Zaiser[1], Takahiro Tsuzuki[2], Hikaru Azuma[2], Shuji Ogata[2], Ryo Kobayashi[2] and Masayuki Uranagase[2]*

[1]Friedrich-Alexander University of Erlangen-Nürnberg
[2]Nagoya Institute of Technology

ABSTRACT

Phase-field models are applied since more than three decades to a vast spectrum of microstructure related problems in materials science and engineering. The length scale spans the range of microscopic order parameters that decribe deformation and defects like twinning and dislocations on an atomic scale, over mesoscopic models for interface motion in grain growth or solid state transformation up to the scale of a polycrystalline sample, where coarse grained phase fields can be used.
In the talk we highlight the importance of a consistent parametrization for physically valid predictions for two problems on separate length scales:

For ferroelectric barium titanate (BTO), microscopic phase-field models based on the Landau-Ginzburg-Devonshire theory offer a bottom-up approach, where a comprehensive energy landscape can be generated from molecular dynamics simulations (MD). This proves particularly valuable for quantitatively incorporating defects into the continuum approach. Essential material parameters, including elastic and piezoelectric properties, kinetic coefficients, and domain wall characteristics, are extracted from MD data to refine the anisotropic gradient energy.
The polarization switching process in BTO involves localized nucleation and subsequent domain growth under the influence of an applied electric field. MD data establishes the significant role of thermal activation in domain nucleation, resulting in a notable scatter in observed parameter like the coercive fields. Utilizing this data, we develop a statistical method to calculate the activation parameters governing polarization switching at coercive fields, providing crucial insights into domain wall energy. This information is then used to parameterize the phase-field model.

On the device scale (~ mm) we present a model for martensitic transformation in shape memory alloys that is computationally tractable by coarse graining of the underlying crystallographic phases into volume fractions and tensorial eigenstrain. The model is based on continuum theory for mechanics and thermal transport implemented within a finite element framework, and a transition state theory approach for thermally activated kinetics. The mechanical part of the Gibbs free energy is formulated as a continuous multi-well potential that is calibrated with data from mechanical characterization experiments, digital image correlation and calorimetric characterization.

For both models parametric optimization techniques are applied to find a best fit for the overall thermo-mechaníc (-electric) behavior. We sketch how interfacial energies and fluctuations of the transformation barriers can serve as a link between the scales.

A MULTISCALE FINITE ELEMENT MODEL OF CARDIAC GROWTH AND BAROREFLEX REGULATION

Hossein Sharifi[1], Mohammad Mehri[1], Kenneth Campbell[1], Lik Chuan Lee[2] and Jonathan Wenk[1]*

[1]University of Kentucky
[2]Michigan State University

ABSTRACT

The heart functions within a complex system that adapts its function to alterations in loading via several mechanisms. For example, the baroreflex is a short-term feedback loop that modulates the heart's function on a beat-to-beat basis to control arterial pressure. On the other hand, cardiac growth is a long-term adaptive response that occurs over weeks or months in response to changes in left ventricular loading. In this study, we investigate the impact of a baroreflex feedback loop on left ventricular growth in simulations of valve disease. To achieve this, we integrated the effects of a short-term baroreflex feedback loop and a long-term growth algorithm into a beating multiscale finite element model of the left ventricle. The baroreflex loop modulates the system from the molecular-level function of myofilaments up to system-level parameters, such as heart rate, to control arterial pressure [1]. Meanwhile, the growth algorithm responds to the altered stress level of the myocardium to drive long-term changes in the geometry of the left ventricle. Specifically, eccentric growth (chamber dilation) is driven by time-averaged passive stress in the myofibers, while concentric growth (wall thickening) is driven by time-averaged total stress along the myofiber direction over the cardiac cycle. Our integrated model replicates clinical measures of left ventricular growth in two types of valvular diseases - aortic stenosis and mitral regurgitation - at two different levels of severity for each case. Furthermore, our results showed that incorporating the effects of baroreflex control in simulations of left ventricular growth not only led to more realistic hemodynamics, but also impacted the magnitude of growth. Specifically, our results highlighted the role of regulating venous compliance (vasoconstriction) by the baroreflex immediately after the onset of valvular diseases, which has a significant role on the extent of LV growth in the long term.

ADAPTIVE CHOICE OF NEAR-OPTIMAL INTERPOLATION POINTS FOR STRUCTURE-PRESERVING MODEL REDUCTION

Steffen W. R. Werner[1] and Quirin Aumann*[2]*

[1]*Virginia Tech*

[2]*Max Planck Institute for Dynamics of Complex Technical Systems*

ABSTRACT

For the efficient generation of accurate reduced-order surrogate models, interpolation-based techniques are well-established, effective approaches. Typical challenges for such methods are the automatic choice of good or even optimal interpolation points as well as a suitable size for the reduced-order model. An approach that tackles the first problem for linear, unstructured systems is the Iterative Rational Krylov Algorithm (IRKA), which computes optimal interpolation points by iterative updates solving small, linear eigenvalue problems resulting from the projection of the original system quantities. Considering the case of systems with internal (differential) structures, one could think of a similar iterative approach. However, the eigenvalue problems resulting from the projection of the corresponding transfer functions are nonlinear such that the number of potential new interpolation points exceeds the order of the reduced model. In our work, we propose StrAIKA (Structure-preserving Adaptive Iterative Krylov Algorithm), an IRKA-inspired iterative interpolation method for structured systems to compute near-optimal interpolation points as well as a suitable size for the reduced-order model. Thereby, the iterative updates of the expansion points are chosen to yield accurate approximations in specified frequency ranges of interest.

SUMMATION-BY-PARTS FINITE-DIFFERENCE OPERATORS FOR SINGULAR COORDINATE SYSTEMS

Jonatan Werpers[*1]

[1]*Swedish Defence Research Agency*

ABSTRACT

We present a general scheme for using existing summation-by-parts (SBP) finite-difference (FD) \cite{svard2014review} operators with singular coordinate transformations. The scheme preserves the accuracy and SBP properties of the original operators and permits simple implementation into existing codes.

The scheme allows taking advantage of the many previously constructed SBP-FD operators and developments when solving problems involving coordinate singularities. This greatly simplifies the design of the numerical method by avoiding re-constructing operators for the given coordinate system.

The operators are modified by viewing them in a weak form and eliminating the degrees of freedom associated with the coordinate singularities. By then returning to a strong form formulation an operator for the reduced grid is achieved which can be handled as any other SBP-FD operator.

Using the scheme we derive a stable and high-order accurate finite-difference method for underwater acoustic wave propagation in an axisymmetric domain. The method handles range and depth-dependent material properties, including discontinuous jumps. The accuracy and stability properties of the method are proven and corroborated using numerical experiments.

IPSC-DERIVED ENDOTHELIAL MULTI-CELL NETWORKS SYNERGISTICALLY MODIFY THEIR BASAL CONTRACTILITY MACHINERY AND EXTRACELLULAR MATRIX IN 3D

Toni West[1], Jiwan Han[1], Gabriel Peery[1], Robin Tuscher[1], Janet Zoldan[1] and Michael Sacks[1]*

[1]*The University of Texas at Austin*

ABSTRACT

INTRODUCTION: We have seen within 3D matrices that newly differentiated endothelial cells (ECs) from induced pluripotent stem cells (iPSCs) migrate towards each other and form networks of connected cells which configure into hollow tubes that resemble capillary networks, (Crosby et. al. 2019 Tiss Eng Part A). Understanding how the mechanical attributes of these cell networks change and affect their microenvironment is key to developing efficacious stem cell therapies for microvascular diseases. In our current work, we hypothesize that measurements from 3D traction force microscopy (3D-TFM) experiments can be implemented to develop inverse models to determine how networks of endothelial cells differentially affect their 3D microenvironment (through degradation and collagen deposition) and how their cytoskeletal structure organization is distinct compared to individual cells.

METHODS: We have previously developed a Gaussian process model to determine how basal cell contractility affects displacement of the surrounding 3D matrix through traction force microscopy (3D-TFM) and have developed an inverse computational model to depict localized cell-induced modification of the matrix modulus and an inverse computational continuum model of the internal stress fiber structure of single cells, (Sacks et. al. 2020 Biophys J; Khang et. al. 2023 J Biomech Eng). Our models therefore account for localized differences in modulus that previous 3D-TFM models assumed were homogenous. Since cells degrade extracellular matrices to grow and move in them while also depositing stiff matrix substances such as collagen, factoring the variation in matrix modulus into our calculations allows us to determine the cell-generated traction forces with much less error. Here we have further developed our models to determine the mechanical properties of nuclei, cells, and the microenvironment of 3D multi-cell networks from experimentally measured displacements that occur because of basal contractility.

RESULTS: From our computational models, we found that multi-EC networks, when compared to individual ECs, have roughly four times the strain energy per cell volume, an increase in extracellular matrix modification per cell volume, and differing stress fiber orientation that affects basal nuclear shape. These results suggest that networks of iPSC-EC cells synergistically work together mechanically to form capillary beds. The increase in strain energy per unit volume indicates that the cells are more energy dense as clusters. Further research into the mechanical properties of iPSC-derived ECs will enable understanding of how these cells are able to maintain structural integrity as they highly modify their environment, paving the way for development of stem cell therapies for microvascular diseases.

HYGROMECHANICAL MODELING OF FIBER REINFORCED POLYAMIDE ON MICRO- AND MACROSCALE

Paul Wetzel[*1], Benjamin Schneider[1], Jan-Martin Kaiser[1], Anna Katharina Sambale[2] and Markus Stommel[23]*

[1]Robert Bosch GmbH
[2]Leibniz-Institut für Polymerforschung Dresden e.V.
[3]Technische Universität Dresden

ABSTRACT

In this study, the anisotropic hygromechanical behavior of short fiber reinforced polyamide 66 is modeled using numerical homogenization. For this, a solver based on the Fast Fourier Transform (FFT) is deployed on the microscale while finite elements are used on the macroscale.

On the microscale, the deformation behavior, including thermal and hygroscopic expansion, as well as the moisture diffusion process in the polymer matrix are studied. Based on micro-computed tomography (µCT) scans, representative volume elements (RVEs) of the 3D microstructure consisting of short glass fibers and a polyamide 66 matrix are generated. Next, an FFT-based solver operating directly on 3D voxel images is deployed [1]. Uniaxial tensile tests, thermomechanical analysis (TMA) as well as moisture sorption and swelling experiments are performed and used to calibrate the constitutive model of the polymer matrix [2]. After calibration, the present RVE simulations are capable of reproducing the key experimental findings.

On the macroscale, an anisotropic constitutive model is applied in finite element simulations. The model parameters are identified in advance using further RVE simulations that enrich the experimental test results with virtual test data for further loading directions and microstructure variations. The mechanical model features anisotropic elastoplasticity as well as thermal and hygroscopic expansion coefficients given as a function of the local moisture content, temperature and the state of fiber orientation. To solve the hygromechanical field problem, sequential coupling is used, i.e., first, the moisture diffusion problem is solved independently of the state of mechanical loading, and next, the resultant moisture concentration field is prescribed in the mechanical simulation. The capabilities of the macroscale model are shown in simulations of a demonstrator part which are verified against additional experiments.

UNCERTAINTY PROPAGATION FOR MULTI-PHYSICS SIMULATION IN GAS TURBINE DESIGN

Andrew White[*1], Alexander Karl[1] and Jason Schmucker[1]*

[1]Rolls-Royce

ABSTRACT

The use of modeling and simulation in gas turbine design has increased substantially over the last few decades. However, computing key quantities of interest in gas turbine systems typically remains beyond the abilities of a single governing multi-physics simulation. Thus, 'analysis chains' must be linked together by separate specialty teams to obtain these outputs. This makes uncertainty propagation difficult, both technically and organizationally, often requiring judicious simplifications by technical experts to keep the computations to a tractable level. This talk considers steps towards epistemic uncertainty propagation in this setting, a model-centric treatment of uncertainty sources, and highlights the differences in separating sources of uncertainty through single and double-loop sampling.

Applications of shape optimization in complex engineering problems

SHAPE OPTIMIZATION OF HYDRODYNAMIC EXPERIMENTS

Daniel White[*1], Dane Sterbentz[1] and Charles Jekel[1]*

[1]*Lawrence Livermore National Laboratory*

ABSTRACT

We are interested in shape optimization of hydrodynamic experiments, where the term “hydrodynamics” refers to the motion of solids and/or fluids under extreme conditions. Typically, the materials are solid at time t=0, but due to extreme pressure, temperature, and deformation the solid materials become fluid at later time. Examples of hydrodynamic experiments include high velocity impact, laser induced deformation, or explosively driven problems. A common theme in many hydrodynamic experiments is the existence of instabilities such as Rayleigh-Taylor (acceleration driven) or Richtmeyer-Meshkov (shock driven). The overall goal of our research is to answer the question: is it possible to optimize the shape of a material interface to either enhance or suppress a Richtmyer-Meshkov instability? In this work the material interface is parametrized by a few (< 10) parameters. The physics simulations are performed using a high-performance Arbitrary Lagrangian Eulerian (ALE) finite element code BLAST [1]. Since our ALE physics code cannot provide exact design derivatives, several alternatives were investigated: surrogate-based design optimization using neural network surrogate models, trust region Bayesian optimization, and gradient-based optimization using finite difference gradients. These algorithms were applied to the design of high-velocity impactor experiments [2] and explosively-driven shaped charges [3]. The advantages and disadvantages of these algorithms will be discussed in detail. Finally, physical experiments were performed to validate the designs.

REDUCING UNCERTAINTY IN DIGITAL TWIN MODELS: USING DATA CONSISTENT INVERSION TO BUILD POPULATION-INFORMED PRIORS FOR BAYESIAN INFERENCE

Rebekah White[*1], John Jakeman[1], Tim Wildey[1] and Troy Butler[2]*

[1]*Sandia National Laboratories*
[2]*University of Colorado, Denver*

ABSTRACT

Bayesian inference is essential to building predictive digital twins of physical assets as it incorporates information from observational data to reduce uncertainties. However, it is challenging to reduce digital twin uncertainty when relying solely on data from an individual asset. Consequently, this work presents an approach for utilizing data from a population of related assets to construct informative Bayesian priors that reduce uncertainty in individual digital twin asset. Specifically, we use data consistent inversion to construct population-informed priors using data on the population of related assets. We demonstrate this approach for a material mechanics model representing additively manufactured structures. Our numerical examples show that utilizing population-informed priors significantly increases the Kullback–Leibler divergence, i.e. the information gain, from the posterior to the prior in comparison to standard prior specification. These results are complemented with theory for linear-Gaussian inference that establishes the conditions under which using our approach is guaranteed to improve posterior estimates of uncertainty.

SPACE-TIME GALERKIN FINITE ELEMENT DISCRETIZATION AND ERROR CONTROL FOR COUPLED PROBLEMS

Thomas Wick[*1], Philipp Junker[1], Jan Philipp Thiele[2] and Julian Roth[1]*

[1]*Leibniz University Hannover*
[2]*Weierstrass Institute Berlin*

ABSTRACT

In this talk, we discuss space-time discretizations with Galerkin finite elements for coupled problems. Therein, the temporal direction is discretized with discontinuous finite elements, while continuous finite elements are adopted for the spatial part. For us, space-time modeling is used to design goal-oriented error control with adjoint sensitivity weights, the same, as used for numerical optimization. Therein, a partition-of-unity is employed for error localization. For both, space-time discretizations and error control, we present recent advances in the treatment of nonstationary, coupled PDE systems.

EVOLUTION OF BIOMECHANICAL SIMULATIONS: VIRTUAL RECONSTRUCTION OF GENERATED FRACTURES

Kerstin Wickert[*1], Michael Roland[1], Annchristin Andres[1] and Stefan Diebels[1]*

[1]*Saarland University*

ABSTRACT

Within the area of orthopedics and trauma surgery, precise classification and understanding of fractures play a crucial role in the development of effective treatment plans and favorable patient outcomes. The AO classification system has been categorized fractures based on anatomical location, severity, and specific fracture patterns [1]. Leveraging the AO classification method, we create virtual fractures, broadening the scope of biomechanical simulations and enhancing our insights into treatment options and healing processes. Crucial to the outcome of a biomechanical simulation is the bone model itself. Clinical image data is scarce or of poor quality, significantly are impacting the results of the simulations. To circumvent this issue, Geomagic FreeformTM software is used. Furthermore, one could extend the virtual reconstruction and use a statistical shape model as a base and implement the fracture pattern. Our approach aims to foster a comprehensive understanding of fracture patterns, their biomechanical implications, and the potential of virtual reconstruction to enhance diagnostic and therapeutic strategies. The workflow comprises the following steps: (1) Utilizing freeform software and its specialized modeling tools to generate various fracture types in pre-existing bone model from clinical image or generate the fracture in a statistical shape model. The bone is now divided into three bone segments: distal and proximal bone segments and the fracture itself. (2) Assigning material parameters to individual segments and passing the bone to a high-quality finite element mesh generator. (3) Biomechanical simulation involves defining subject-specific boundary conditions and applying the joint force to the according bone segment. The required joint force is derived from our monitoring database. Braun et al.[2] outlines the procedure for a distal tibial shaft fracture. Similarly, the calculation of arbitrary joint forces can be approached. By blending virtually generated fractures with subject-specific boundary conditions, we can create a diverse array of pertinent biomechanical simulations, thereby enriching our understanding of the fracture's biomechanics. The use of freeform software for biomechanical simulations open new dimensions for research, promising a deeper understanding of fracture geometries and their clinical implications.

DATA-ADAPTIVE MODELING OF HYPERELASTIC CONSTITUTIVE LAWS: APPLICATION TO EXTREMELY SOFT MATERIALS

Simon Wiesheier[*1], Miguel Angel Moreno-Mateos[1] and Paul Steinmann[1]*

[1]*Friedrich-Alexander-Universität Erlangen-Nürnberg*

ABSTRACT

The traditional approach to modeling the non-linear constitutive behavior of soft materials at finite strains relies on hyperelasticity, a paradigm that inherently involves uncertainties in phenomenological constitutive modeling. This method often results in information loss since experimental data is not directly integrated into calculations, and the engineer's selection of a suitable strain energy function heavily depends on experience.

In contrast, data-driven approaches present a promising alternative. We recently introduced an innovative data-adaptive approach for modeling hyperelastic materials at finite strains [1] allowing for more efficient inclusion of experimental data. The proposed modeling procedure ensures adherence to crucial constraints such as thermodynamic consistency, material objectivity, frame indifference, and material symmetry a priori.

The fundamental concept involves formulating an approximation of the strain energy function using a sum of basis functions multiplied by parameters. The basis functions are expanded over the space of invariants, and support points, where the parameters are defined, are distributed in the invariant space. These parameters are determined through a nonlinear optimization problem, minimizing the 2-norm of the residual vector, representing the difference between measured and computed displacements and reaction forces. Importantly, our approach does not depend on measured stresses, setting it apart from many existing data-driven and model-free methods.

In our initial investigation, we demonstrated the efficiency and flexibility of our method based on numerical experiments and linear finite-element-like basis functions. The focus of this contribution is on the applicability to real experimental data obtained from Digital-Image-Correlation and basis functions with higher continuity. Specifically, we concentrate on a substantial experimental database encompassing various soft materials, particularly ELASTOSIL, VHB, and DOWSIL, with the aim of identifying a set of strain energy functions characterizing these materials in a fully automated and reliable manner.

UTILIZING SUPERVISED MACHINE LEARNING TO ENABLE DYNAMIC ADAPTIVE SUBGRID MODELING FOR MULTISCALE HYBRIDIZED FORMULATIONS

Tim Wildey[*1]*

[1]*Sandia National Laboratories*

ABSTRACT

Multiphysics systems are often strongly coupled, highly nonlinear and characterized by multiple physical phenomena that span a large range of length- and time-scales. Performing direct numerical simulation of such systems that resolves all the relevant length and timescales is often prohibitive, even on the modern leadership-class computing platforms. Nevertheless, these fine-scale variations often impact the behavior of the system on a much larger scale in non-negligible ways. Thus, one often seeks to model or approximate the subgrid scale phenomena to accurately and efficiently capturing their impact on the coarse scale solution. Multiscale formulations based on non-overlapping domain decomposition methods can be viewed as variational multiscale methods and have the additional benefit of allowing different physical models and numerical discretizations in different regions. However, determining the optimal subgrid model within a coarse scale region that effectively balances accuracy and computational expense can be challenging for transient nonlinear multiphysics applications.

In this presentation, we describe our theoretical and computational frameworks that are based on a generalization of hybridized discretizations and are designed to exploit heterogeneous computational architectures to enable concurrent multiscale modelling on a range of transient nonlinear multiphysics applications. We will also describe our utilization of dynamic adaptive subgrid modelling and how we are utilizing supervised machine learning strategies to determine the appropriate subgrid model for an element in the coarse scale partition. We will provide demonstrations on applications motivated by subsurface flow and mechanics in porous media and additive manufacturing.

HP-ADAPTIVE SPARSE GRID COLLOCATION METHODS FOR UNCERTAINTY QUANTIFICATION IN GAS NETWORKS

Hendrik Wilka[*1] and Jens Lang*[1]

[1]*Technische Universität Darmstadt*

ABSTRACT

In this talk, we present a newly developed hp-adaptive method for uncertainty quantification which arises in the simulation of gas transport problems on networks. In short-term optimal control problems, the isothermal Euler equations are used in combination with uncertain boundary data caused by varying demands of consumers. Here especially the pressure is of interest since it should stay in given bounds with a high probability [1]. In recent works, global sparse grid methods have been applied to overcome the curse of dimensionality when approximating functions in high-dimensional probability spaces [2]. As investigated in [3], kinks can arise in important quantities of interest, e.g. for the maximum pressure over a time interval. This leads to well known difficulties when global polynomials of higher order are used. To also approximate non-smooth functions, we have developed a novel sparse grid collocation approach that uses local polynomials with a restricted support as basis functions. This allows us to place additional collocation points in regions where the error is over a predefined threshold. In contrast to previous works, our method is hp-adaptive: In smooth regions, the polynomial degree of the basis functions is increased (p-refinement), while low-degree polynomials are used near kinks (h-refinement). We present two refinement strategies. The first one is a greedy approach which chooses those basis functions having the smallest interpolation errors at new collocation points. A second strategy uses a kink detection algorithm to limit the polynomial degree in non-smooth regions. We discuss academic problems from the Genz test function package as well as examples for gas networks where kinks in pressure functionals are present. We compare our method with other approaches.

VERIFYING DISCRETE ELEMENT MODELS THROUGH MICROMECHANICAL ANALYSIS OF FORCE AND TRACTION CHAINS

Daniel N. Wilke[1], Johannes C. Joubert[1] and Patrick A. Pizette[2]*

[1]*University of Pretoria*
[2]*IMT Nord Europe*

ABSTRACT

Discrete Element Modeling (DEM) has emerged as a tool for understanding and predicting granular materials' behaviour and micromechanical state in various engineering and scientific contexts. This study extends an innovative approach to calibrating DEM simulations by utilising micromechanical concepts [1], specifically focusing on verifying models from force and traction chains within granular assemblies. The verification process involves a detailed statistical analysis of force chains, providing a robust framework for assessing deterministic and non-deterministic DEM codes.

At the core of this approach is the examination of force chains, which are networks of interconnected particles transmitting forces through contact points in granular materials. These chains form the fundamental structural backbone of granular assemblies, dictating their mechanical response under different loading conditions. By analysing the properties and distribution of these chains, we can gain insightful information about the micromechanical state of the material. This method quantifies key characteristics such as chain length, orientation, intensity, and spatial distribution. Traction chains offer insights into the surface interactions between particles. They are critical in understanding the frictional and adhesive forces at play, which are essential in the realistic modelling of granular materials. The analysis of traction chains complements that of force chains by providing a more comprehensive understanding of the micromechanical interactions within the material.

Statistical tools are included to analyse micromechanical elements within DEM simulations. This statistical approach accommodates deterministic and non-deterministic codes, allowing for evaluating models with inherent randomness due to random execution with limited numeric precision. The statistical analysis involves comparing theoretical and numerically verified and validated models against theoretical and validated ones, thereby assessing the accuracy and reliability of the DEM simulations. This verification process serves as an ‘acceptance testing' strategy for DEM codes, ensuring that the fundamental micromechanical behaviours are accurately captured before applying the model to more complex scenarios. Such rigorous testing is crucial for enhancing confidence in DEM simulations, which are increasingly used to predict material behaviour in applications ranging from pharmaceuticals to civil engineering.

FROM TICOM TO THE ODEN INSTITUTE: THE VISIONARY LEADERSHIP OF J. TINSLEY ODEN

*Karen Willcox**[1]

[1]*The University of Texas at Austin*

ABSTRACT

In 1973, J. Tinsley Oden joined the faculty of The University of Texas at Austin. Over a series of conversations with colleagues, he saw the opportunity to use computing to solve engineering problems and he saw the need to pull people together. He said: “One day it hit me, this is where the world is going - concepts in computers and solving problems in physics, mathematics, and mechanics. I saw the need to pull them all together into a unified approach.” That led him to establish the Texas Institute for Computational Mechanics (TICOM) in 1973. Under Oden's leadership, TICOM played a critical role in the founding and advancement of the field of computational mechanics. Fifty years later, TICOM has grown to become the Oden Institute for Computational Engineering and Sciences. From TICOM to the Oden Institute, this talk will give a brief history of J. Tinsley Oden's 50-year visionary journey of leadership, mentorship, and service at UT Austin.

TOWARDS A MULTISCALE COMPUTATIONAL FRAMEWORK FOR SIMULATING FLOW-MEDIATED CRYSTALLIZATION BASED ON PHASE-FIELD CRYSTAL FORMALISMS

Larry Willis[*1], Rekha Rao[2] and Leo Liu[1]*

[1]FAMU-FSU College of Engineering
[2]Sandia National Laboratories

ABSTRACT

Liquid-solid phase transitions into crystalline solids are ubiquitous in industries ranging from additive manufacturing to pharmaceutics to surface coating processes. One system, in particular, CsPbI_3 perovskites, exhibits disparate solar harvesting properties under different crystal structures. Crystal microstructural control and defect prevention during processing is a huge challenge with further complexities arising from coating flows of solar cells for mass production.

With limited experimental techniques to observe flow-mediated crystallization in situ, it is paramount to gain insight from first-principle aware simulations for understanding and controlling crystallization kinetics and phase stability mediated by flows. In this work, we demonstrate the development of a multiscale and multiphysics computational framework for simulating flow-mediated crystallization based on phase-field crystal (PFC) formalisms. Compared to traditional molecular dynamics, which are limited to small spatiotemporal scales, and phase-field methods (e.g., Allen-Cahn), which neglect crystal-level information, we aim to develop a multiscale computational framework that connects crystal-level information to macroscale phase behavior in the presence of flow.

We validate our model by reproducing existing perovskite crystal structures under varying conditions from experiments and course-grained molecular dynamics. We then introduce how we incorporate the effect of flow on crystal structure. Strategies for controlling the crystal microstructure through computation-driven processing conditions will also be discussed in the spirit of digital manufacturing.

AN ASSESSMENT OF THE APPLICABILITY OF MODERN RKPM METHODS TOWARDS SIMULATION OF CONCRETE UNDER EXTREME EVENTS

Dominic Wilmes[1], Michael Hillman[1] and Joseph Magallanes[1]*

[1]*Karagozian and Case, Inc.*

ABSTRACT

Due to its widespread usage in a variety of vital structural applications and infrastructure, the safety and performance of concrete under extreme events, such as impact or blast, is essential to understand and be able to calculate in a predictively. Towards this end, a number of constitutive models have been developed which seek to capture the wide range of behaviors present in concrete such as those related to hardening, softening, rate effects, fracture, etc. However, these material models only comprise a portion a of a given physics-based numerical analysis as they generally represent a discrete material point in a larger numerical framework. As a consequence, capturing large scale discontinuous phenomenology of concrete response such as fracture, fragmentation, scabbing, and spall are often dependent on the numerical framework the material model is embedded in.

In this work, the advantage of utilizing meshfree methods to provide this robust numerical framework for treating concrete under extreme events will be demonstrated using problems which demonstrate a wide range of concrete phenomenology. A series of concrete benchmark problems will be compiled which seek to show several types of phenomenology found within problems involving concrete materials. A modern RKPM [1] numerical code, KC-FEMFRE, will be applied to each of these benchmarks and the results and efficiency from running these benchmarks will be documented compared against previous results taken from open literature, widely-used commercial solid mechanics codes, and experimental results, when applicable. To ensure fair comparison between existing solvers, the K&C Concrete model [2] will be leveraged as a VUMAT in all simulation codes utilized in this study. This will alleviate any differences that might be constitutive model implementation specific and demonstrate applicability of meshfree for this problem domain against comparable options.

ACCUMULATED EPISTEMIC UNCERTAINTIES AND THE CHALLENGE TO QUANTIFY THEM IN MULTIPHYSICS PREDICTIONS

Brandon Wilson[*1]*

[1]*Los Alamos National Laboratory*

ABSTRACT

Epistemic uncertainties are inherent to computational physics and can be introduced at every level of the computational model development process. Sources include systematic errors in experimental measurements, model-form errors, errors due to algorithmic and numerical choices, and interpretation of the active mechanisms in a multiphysics process. Epistemic uncertainties can arise from a lack of understanding of the physics – both mathematically or phenomenologically - or out of the necessity to reduce computational expense.

Epistemic error sources can be particularly challenging to diagnose with common statistical methods because of their non-probablistic nature. This is particularly true for predictive multiphysics simulations for which many epistemic errors accumulate in integral multiphysics simulations and quantities of interest. This conglomeration of correlated, uncorrelated, and/or, possibly, mutually exclusive epistemic uncertainties is observed across computational physics disciplines and necessitates collaborative consideration of approaches across disciplines.

In this talk, I will discuss specific epistemic uncertainties observed at Los Alamos National Laboratory, specifically focusing on the concept of accumulated epistemic uncertainties. These examples will be used to 1) motivate the discussion of epistemic uncertainty management and 2) encourage the need for collaboration across computational disciplines toward engineering and statistics methods for quantifying epistemic uncertainties.

ABSTRACT

Researchers are successfully exploring the concept of differentiable simulators that solve the governing equations of fluid mechanics [1]. Differentiable simulators are gaining prominence due to their applicability across various scientific fields, ranging from the design of data-driven numerical models to reinforcement learning and novel concepts hybridizing simulation and machine learning (ML) workflows. They exploit that numerical methods frequently involve computing the output of discretized operators, which can be divided into sequentially linked elementary units akin to the sequential design of numerous ML architectures. The key features of differentiable simulators include their ability for gradient calculation via automatic differentiation, the integration of ML within simulation workflows, and enhanced computational efficiency when executed in ML frameworks equipped with powerful acceleration features.
We present a PyTorch-based implementation of the Lattice-Boltzmann method (LBM). The LBM is a highly flexible and reliable solution for challenging computational fluid dynamics simulations, renowned for its exceptional parallel efficiency. Our implementation leverages modern software design principles to compose the LBM algorithm from sequentially connected modules. This design ensures seamless compatibility with programming paradigms of PyTorch and allows efficient usage of GPU accelerators. The application programming interface of the solver relies on principles commonly used by ML libraries to fully streamline hybrid workflows.
Based on this modular code design, we provide algorithmic building blocks for various velocity sets, collision models, and boundary conditions that can be interchanged flexibly without losing performance. Additionally, we provide modules for simulating complex multi-phase flow phenomena.
We illustrate the smooth interplay of numerical simulator and ML building blocks by constructing surrogates for complex flow problems using state-of-the-art ML models such as Fourier Neural operators. These models are particularly attractive for their discretization invariance and capability to facilitate zero-shot super-resolution. Also, we present a hybrid approach that merges learned operators capturing the dynamics of the simulation with the numerical simulation. Our approach advances parts of the overall simulation using the learned operators instead of the numerical schemes. Thereby, we drastically reduce the computational cost of the simulation.
The results demonstrate the immense potential of integrated ML simulation workflows, especially in enhancing the efficiency of numerical simulations using the Lattice-Boltzmann method. The careful design of our software framework eases the rapid development and deployment of such novel methodologies.

ABSTRACT

In coastal inundation simulations based on numerical solution of shallow water equations, faithfully representing topography and bathymetry at high enough grid resolution is known to be a crucial factor in obtaining accurate results. However, in practice, a compromise in the grid resolution is often needed to made to a certain level because of a constraint in computing time. As a result, a predictive capability of the model may suffer especially in inundation and recession zones of flow in previously-dry and wet areas. In this work, we present an implementation of subgrid techniques accounting for unresolved topography in a single layer mode of the Model Prediction Across Scales-Ocean (MPAS-O), a finite-volume based method on staggered arbitrarily-structured C-grids. Numerical experiments using a set of test cases with wetting and drying, ranging from an idealized test problem with an analytical solution to a realistic test case of storm surge, demonstrate that the subgrid method can substantially improve the predictive capability of the MPAS-O coarse-grid simulations with only a minor increase in the computing time.

GENERALIZED DATA-DRIVEN MATERIAL MODEL OF 3D-PRINTED BIAXIAL WEAVES USING TRANSFER LEARNING

Marc Wirth[*1] and Kristina Shea*[1]

[1]*ETH Zurich*

ABSTRACT

3D-printed weaves are versatile structures due to their unique combination of pliability, strength and tunability by design. The 3D-printing process enables tuning the weaves mechanical properties by modifying aspects of the weave design, such as the interlacing structure, the yarn geometry and the yarn material. This allows for the tuning of both the overall mechanical properties of the fabric and the local mechanical properties within the structure. For computational design of 3D-printed textiles with locally tuned mechanical properties, a rapid simulation utilizing a design-sensitive material model is key. Previous work has shown a model-free simulation approach of 3D-printed biaxial weaves approximated as planar truss structures utilizing a neural network as a surrogate model. The neural network is trained on the constitutive manifold of a discrete set of input samples varying in their weave design. Despite the versatility in depicting the mechanical behavior of weaves with different designs, the surrogate is limited in the generalization capabilities by the samples provided in the input set. This is a limitation to overcome, since 3D-printed architected structures are prone to change in their structural behavior due to variations in the manufacturing process, such as the manufacturing device and material batch used, and changes in the sample design. Here, we show the capability of the neural network based surrogate model to generalize for unseen samples by transfer learning. We enhance the constitutive manifold by samples varying from the initial input set in their design and printer type used for production and re-train the neural network on the new manifold. We evaluate the performance of the network when used for the simulation of samples having gradually varying designs and samples with designs not included in the manifold. We evaluate the performance when both interpolating and extrapolating in the design space of the samples constituting the constitutive manifold. We show the capability of a neural network utilized as a surrogate in model-free FE simulations to be beneficial in generalizing to new cases, which is especially useful when introducing new design variables and new 3D-printing methods, which would usually require extensive material characterization. With these results, we show the usage of a generalized material model for a large range of 3D-printed biaxial weaves, which enables the computational design of architected textiles.

GENERALISED FINITE VOLUME METHODS - TAYLORED TEST SPACES FOR INTERFACE PROBLEMS

Susanne Höllbacher[1] and Gabriel Wittum[*1]*

[1]King Abdullah University of Science and Technology

ABSTRACT

We present a fully-implicit and stable finite element and finite volume scheme for the simulation of freely moving particles in a fluid. The developed method is based on the Petrov-Galerkin formulation of a vertex-centered finite volume method on unstructured grids. Identification with a corresponding finite element bilinear form finally enables the derivation of a finite element method for particulate flow. Appropriate extension of the ansatz and test spaces lead to a formulation comparable to a fictitious domain formulation. In contrast to most fictitious domain methods no additional Lagrange multipliers or artificial external forces need to be introduced for the fluid-solid coupling. The interface forces are implicitly imposed through the original bilinear form for the fluid. The surface integrals of the finite volume scheme enable a natural incorporation of the interface forces. The extended scheme treats the particles as rigid fluid and the resulting system of equations does not possess saddle-point structure. As a result, only one single solve for the derived linear system for the fluid together with the particles is necessary and the proposed method does not require any fractional time stepping scheme to balance the interaction forces between fluid and particles. For the linear Stokes problem we will prove the stability of both schemes. Moreover, for the stationary case the conservation of mass and momentum is not violated by the extended scheme, i.e. conservativity is accomplished within the range of the underlying, unconstrained discretisation scheme. The scheme is applicable for problems in two and three dimensions.

ABSTRACT

Sustainable aviation has become a very active field of research. One promising approach are hydrogen-powered commercial aircraft. Many concepts for such aircraft have been published (e.g. [1]), but crashworthiness aspects are often neglected in the early concept phase.

Our research focuses on conventional configuration aircraft. As the volumetric energy density of hydrogen is only approximately one fourth of kerosene, the needed fuel volume is much higher. Most concepts therefore propose cryogenic liquid hydrogen (LH2) tanks inside the fuselage to provide the needed capacity. These large tanks close to the passenger cabin can pose a serious safety hazard in case of uncontrolled leakage or damage. A crashworthiness assessment is therefore viable to the whole concept, to meet the required high safety level of modern aircraft.

In the early design phase with its large parameter space, numerical simulations are an established possibility to investigate the behaviour during survivable crash scenarios. The challenges of performing such simulations with the available data are already discussed in literature (e.g. [2]). Current approaches mainly focus on the physical integrity of the passengers due to the accelerations during impact. Technically, they create high-fidelity finite element models from preliminary aircraft data, enriched by knowledge from existing aircraft constructions. Due to the high non-linearity and the large deformations during crash events, the models need to be granular enough to capture the major physics but also efficient enough to be applicable in an early design phase.

We want to present our progress in using such approaches to evaluate a crashworthiness concept build out of discrete crash absorbers to ensure the structural integrity of LH2-tanks during a crash scenario. One challenge is the different airframe architecture of fuselage sections with LH2-tanks. Due to the size, the cargo-deck and passenger-crossbeam are missing, rendering classical crashworthiness concepts used for passengers inapplicable. As the tanks are located close to the bottom, the fuselage kinematics must be influenced in a way that structural parts do not pierce the tanks.

ABSTRACT

Therapeutic cell therapies, such as CAR-T therapy, are a rapidly progressing methodology for treatment of tumors, and have shown broad success in "liquid" cancers. While theoretically effective for the treatment of solid tumors, many practical barriers exist, preventing widespread success of the method. This is especially the case for neurological tumors, where the blood brain barrier prevents uptake of therapeutic cells by the tumor. To overcome this challenge, some CAR-T trials have adopted the strategy of intratumoral delivery, placing cells directly in the treatment site using a surgical catheter. This strategy, while allowing for a higher dose of therapeutic cells in the target region, does not allow for subsequent placement of the catheter for repeat doses. As such, it is important that the catheter is placed optimally to ensure each dose of therapeutic cells provides as much benefit to the patient as possible. In this work, we present an image-informed model of therapeutic cell transport, capturing directed cell migration along fluid streamlines, and predator-prey-like dynamics. Spatial transport parameters are informed by the novel analysis method for dynamic contrast-enhanced MRI, known as LCFR. Cell growth dynamics are informed by a multi-species predator-prey-like model discovered by Brummer et al. (2023) using the SINDy methodology. Using this spatio-temporal multi-species model of therapeutic cell dynamics, we then optimize the delivery location and timing strategy for delivery of therapeutic cells for individuals, testing multiple temporal delivery strategies, and spatially optimizing catheter placement. This is done to encourage spread into invasive tumor margins, where non-enhancing tumor may be present, but undetectable by MRI. In preliminary study, we performed a forward simulation, sampling delivery locations at each 500 um in the x and y directions. We find that optimizing the delivery location within the 2D plane increases the total amount of tumor cells killed by a factor of 2.4 (maximum tumor cell kill/mean tumor cell kill), and simultaneously maximizes the total number of CAR-T cells present in the tumor between doses by a factor of 2.8 (maximum temporally-averaged CAR-T population/mean temporally-averaged CAR-T population). Using this strategy, we aim to give each individual patient an optimal surgical procedure, maximizing the potential efficacy of this treatment strategy.

DIFFERENTIABLE PROGRAMMING OF SMOOTHED PARTICLE HYDRODYNAMICS: COMPRESSIBILITY AND SHOCKS

Michael Woodward[*1], Joshua Coleman[1], Jason Koglin[1] and Daniel Livescu[1]*

[1]*Los Alamos National Laboratory*

ABSTRACT

Many formulations of Smoothed Particle Hydrodynamics (SPH) have been developed for modeling compressible flows involving plasma, such as those seen in astrophysics and engineering applications. Often, these formulations are first tested and developed on simple flows, such as 1D and 2D shock problems in order to validate the modeling and numerical implementations. However, the parameters of these formulations are usually adjusted by trial and error. In this work, we explore the physics informed machine learning methods for finding these parameters. Thus, we develop a compressible SPH formulation consistent with differentiable programming in order to first learn the standard SPH parameters and then to find new parameterized terms such as smoothing kernels, artificial viscosity, and heat conduction, with the goal of improving the SPH framework with respect to accuracy and performance.

The approach is first validated and analyzed for the 1d Sod shock and 2D Taylor-Sedov blast wave problems, i.e. learn-able and parameterized compressible SPH formulations are fit to the analytical solutions using gradient based optimization. Next, we extend the SPH formulation to model the spatio-temporal evolution of plasma plumes generated from rapid thin-target heating by 20 MeV electron beams. The generation of plasma plumes during such heating processes can significantly impact various high-energy physics experiments, making accurate prediction of their behavior crucial for experimental design and analysis. The plasma plumes of interest evolve in vacuum, making the SPH framework a natural choice for modeling at the coarse grained scales of interest. Furthermore, the complex physics involved motivates the use of machine learning to fill in the gaps with exploring new parameterized terms within SPH. We employ experimental data to develop a hierarchy of SPH models, using pulsed bunches of approximately 10^{15} electrons to heat a range of thin targets to temperatures above 1 eV. The shadowgraph and interferometer measurements provide spatially resolved snapshots of the expanding plume's electron density and temperature distributions at discrete time points.

EFFICIENT HIGH-ORDER ENTROPY-STABLE DISCRETIZATIONS OF THE EULER AND NAVIER-STOKES EQUATIONS ON SIMPLICIAL ELEMENTS

Zelalem Arega Worku[*1], Jason Hicken[2] and David Zingg[1]*

[1]*University of Toronto*
[2]*Rensselaer Polytechnic Institute*

ABSTRACT

The summation-by-parts (SBP) framework enables construction of high-order entropy-stable discretizations of the Euler and Navier-Stokes equations. Although they have been shown to be more robust, these discretizations are substantially more expensive than the divergence form implementations of the equations, particularly on simplicial elements, which are favored for mesh generation around complex geometries. Their larger computational cost can be attributed to two-point inviscid flux computations, interpolation and change of variables, and computation of viscous flux Jacobian terms. The number of nodes in an element and their placement play an important role in the efficiency of entropy-stable discretizations, and any set of nodes amenable for construction of SBP operators must define a sufficiently accurate positive-weight quadrature rule. We seek operators that have as few nodes as possible for a given degree and with a subset of nodes placed at the element boundaries to facilitate efficient computation of numerical fluxes. In light of this, we present novel quadrature rules for construction of SBP diagonal-E operators offering, in many cases, fewer nodes than existing rules. We combine the Levenberg-Marquardt and particle swarm optimization algorithms to solve the quadrature accuracy conditions, addressing the challenges of finding good initial guesses and slow convergence rates. Positive weight and nodal symmetry constraints are enforced to find fully symmetric positive-weight quadrature rules. Furthermore, the range of suitable quadrature rules for SBP diagonal-E operators is significantly extended to encompass higher degrees. The cost of the inviscid fluxes is further reduced by constructing sparser SBP derivative operators, leveraging the presence of free variables due to the larger number of nodes than polynomial basis functions required to construct the operators. Finally, the inviscid flux discretization with the newly derived operators is combined with SBP-Ω type operators in a staggered grid formulation to reduce the cost of the viscous fluxes. We demonstrate the numerical properties of the proposed operators through test cases involving the Euler and Navier-Stokes equations.

ON A SPACE-TIME FORMULATION USING VIRTUAL ELEMENTS

Peter Wriggers[*1] and Philipp Junker*[1]

[1]*Leibniz University Hannover*

ABSTRACT

The virtual element method (VEM) for elasticity in solid mechanics was first considered in Beirao da Veiga et al. (2013). The possibility of VEM to construct of elements with arbitrary shape and arbitrary number of nodes has many ad-vantages in engineering. Thus, applications of the virtual element method were investigated in areas like finite strains, inelastic materials, contact and phase field approaches, see e.g. Wriggers et al. (2023). Another advantage is that virtual elements can be easily incorporated in classical finite element codes since they have the same number of unknowns.
So far, VEM has not been applied to space time formulations for structural el-ements like strings, trusses and beams. Here we develop a virtual element dis-cretization scheme that is suitable for dynamic applications. It is based on a space time formulation that is build upon the Hamilton principle and avoids the used of mass matrices. It will be shown that the developed elements outperfom finite elements in certain applications.

ABSTRACT

Properties of fragmentation from an explosively driven 316L stainless steel spherical shell section fabricated by a laser powder bed additive manufacturing process with minimal surface finishing are investigated. This shell is driven by an insensitive high explosive, resulting in high strain rate deformation (>8000/s) and failure of the stainless steel. Photonic Doppler velocimetry measures the expansion rate; dynamic radiography and high-speed imaging capture the fracture behavior of the stainless steel. The fracture response of the additively manufactured stainless steel shell is compared to published experimental results on additively manufactured 316L stainless steel and conventionally manufactured wrought 316L and 304 stainless steel shell fragmentation. Despite preferred crack orientation, suggesting the influence of surface grooves on fracture time, fragment size is identical to that measured in a similar experiment on wrought 304 stainless steel. Further analysis indicates that the 316L additively manufactured stainless steel shell exhibits comparable spall strength and fragmentation toughness to conventionally manufactured stainless steel yet lower failure strain due to surface stress concentrations.

LARGE-EDDY SIMULATION OF INTRUSIVE GRAVITY CURRENTS AT RIVER CONFLUENCES

Ching-Sen Wu[*1]

[1]*National Ilan University*

ABSTRACT

River confluences, a ubiquitous feature in catchment areas, play a crucial role in all fluvial networks. The complexity of flow characteristics at these junctions arises from the three-dimensional nature of the flow, attributed to tributary convergence and potential sediment transport, leading to variations in depositional areas and bed topography. Generally, gravity currents emerge as the primary driving mechanism, given their substantial interactions with the underlying bed material and ambient fluid. To grasp the intricacies of transport processes, it is essential to understand the evolution of flow morphologies and the dynamics of gravity current propagation. While numerous studies extensively explore the morphodynamics of individual channels, sinuous submarine channels, and river confluences, documented through field observations, laboratory experiments, and depth-averaged numerical models, relatively less attention has been devoted to investigating three-dimensional gravity currents intruding into the main channel under constant inflows. In this study, our aim is to gain insights into the flow dynamics of gravity currents at river confluences through large-eddy simulations. The primary controls influencing the magnitude of river morphology are identified as the ratio of driven velocity between the mainstream and the tributary and their junction angle. This study addresses several key discussions, including (1) flow morphologies, (2) flow structures, and (3) the relationship between baroclinic pressure gradients and shear layers.

MODELING CELL ADHESION AND SPREADING MEDIATED BY LIGAND DIFFUSIVITY

Di Wu[*1] and Yuan Lin*[1]

[1]*The University of Hong Kong*

ABSTRACT

Cells live in a dynamic environment where their physical connections and communication with the extracellular matrix (ECM) are mediated by receptor-ligand binding. Therefore, a precise knowledge of receptor-ligand interactions is crucial for comprehending cellular behaviors. Interestingly, recent evidence has suggested that the mobility of ligand molecules at the cell-ECM interface significantly affects cell adhesion and spreading, although the underlying mechanism remains elusive. In this study, we employed a modeling approach to address this critical issue. Specifically, we adopted Langevin dynamics to simulate the random movement of ligands by assigning a stochastic force along with viscous drag. We then analyzed the evolution of cell adhesion and subsequent spreading by considering the force-regulated binding and breakage of molecular bonds connecting polymerizing actin bundles inside the cell to the ECM. Notably, our results predicted a biphasic relationship between cell adhesion and ligand diffusivity, with maximal cell spreading occurring at intermediate ligand mobility. Furthermore, we found that the peak position was influenced by ligand aggregation, which effectively reduced their diffusivity and the kinetics of bond association/dissociation. These predictions were in excellent agreement with our experimental observations, where ligand mobility was manipulated by tuning the interactions between the self-assembly polymer coating and the surface.

ABSTRACT

Complex boundaries and material interfaces are common in scientific and engineering problems. When solving such problems with the standard finite element method (FEM) where the elements conform to boundaries and interfaces, analysts have to pay great efforts and patience for the meshing to avoid low-quality elements in the vicinity of boundaries and interfaces. Therefore, meshing or preprocessing is normally time-consuming and arduous for practical problems. The unfitted FEMs provide another path for the solution of problems with complex geometric domains, where a simple mesh not necessarily aligning to the physical model is employed. However, the boundaries and interfaces can cut the mesh and produce tiny cut elements, which causes ill-conditioning of the stiffness and mass matrix. The recently developed aggregated unfitted resolved the cut-induced ill-conditioning by linking the unknowns of nodes outside the physical domains to the adjacent nodes within the physical domain. It did not introduce any additional stability terms and, therefore, maintained the consistency. Hence, it is more favorable than stabilized unfitted FEM when consistency is desired.

The majority of geotechnical problems often involve complicated external boundaries and material interfaces. Therefore, the aggregated unfitted FEM is an excellent tool for analyzing geomechanics and geotechnical problems. In this paper, we develop an aggregated unfitted FEM for hydro-mechanical coupling problem, which is one of the most important problems in geomechanics. In the development of this methodology, we link both the displacement and pore pressure of nodes located outside the physical domain to the nodes inside the physical domain via extrapolation. The ill-conditioning is avoided as the small cut supports of the nodes outside the domain are precluded. Several benchmark hydro-mechanical coupling problems are solved with the proposed aggregated unfitted FEM. The numerical experiments demonstrate the optimal spatial and temporal convergence regardless of how the meshes are cut. Furthermore, the condition numbers of the stiffness matrix are dependent of the smallest cut ratio.

OPTIMIZATION DESIGN METHOD FOR HIGH-ASPECT-RATIO COMPOSITE WING BASED ON NEURAL NETWORK AND GENETIC ALGORITHM

Hanlin Wu[1] and Hongyu Qi*[1]

[1]*Beihang University*

ABSTRACT

Firstly, according to the given configuration and dimension of composite wing model, eight kinds of typical wing internal structure layout were designed. Through the stress analysis and comparison of the failure load and weight ratio index, the double C-beam structure has the highest structural efficiency and was selected as the wing internal structure layout scheme.

Then, the sample points were selected by Latin hypercube sampling method, and the prediction effects of seven machine learning models on the failure load and weight of composite wing were compared. The BP neural network is optimized to establish the response surface model, and the prediction accuracy can reach 93.75%

Finally, a two-level optimization method is proposed, and genetic algorithm is used to optimize the position of the composite wing beam, the thickness and the lay-up sequence of the upper and lower edge panels, leading edge and skin. The rationality of the optimization results was analyzed. The optimized results show that the failure load to weight ratio index is increased by over 146% and this method can significantly reduce the cycles of FEM analysis and achieve highly accurate response approximation results.

To construct neural-network response surfaces for composite structural optimal design, Latin hypercube sampling method is used to select the most appropriate structural analysis sample points. The constructed response surfaces are used as the objective function. Together with other conventional constraints, they form an optimization design model which can be solved by genetic algorithm. This approach is highly applicable for complex composite structural design, which can effectively guide the composite wing structure optimization problem.

ISOGEOMETRIC REISSNER-MINDLIN SHELL THEORY APPLICATION TO BUCKLING BEHAVIOR IN STIFFENED THIN-WALLED STRUCTURES

Haoyu Wu[*1], Xiaoxiao Du[1] and Wei Wang[1]*

[1]*Beihang University*

ABSTRACT

Stiffened shell structures, such as rocket casings and aircraft fuselages, play a pivotal role in the development of aerospace engineering [1]. These thin-walled structures are susceptible to buckling when enduring axial compression, which means investigation on the buckling and post-buckling behavior of these structure is of great importance [2]. As a kind of basic structural form for aerospace vehicle bodies, the stiffened shell structures are widely used and in certain degree the hub for the whole vehicle's miscellaneous systems. This result in the situation that to improve the modeling and analysis efficiency of stiffened shell structures will greatly increase the infield capacity of design department. So this research presents a framework regarding quick modeling and buckling analysis of reinforced structures with cutouts. Utilizing Non-Uniform Rational B-Splines (NURBS), we realize a parameterized modeling approach for efficiently generating analysis-suitable models. In the analysis section, an isogeometric Reissner-Mindlin shell theory is utilized, capable of handling finite rotations and large deformations [3]. The Arc-length method is additionally used to capture the complex equilibrium paths during the buckling process. Several numerical examples emphasize the notable improvement in structural load-carrying performance achieved by reinforcing these shells. The integrated design-analysis platform demonstrated significant effectiveness and convenience, enabling engineers to make informed decisions during the design and evaluation phases of aerospace vehicle bodies.

A SINGLE-LAYER WALL-BOUNDARY PARTICLE MPS METHOD FOR SIMULATING MULTIPHASE FLOWS

Jinxin Wu[*1], Guiyong Zhang[1] and Zhe Sun[1]*

[1]*Dalian University of Technology*

ABSTRACT

A Single-layer Wall-boundary Particle Moving Particle Semi-implicit (SWP-MPS) method is proposed for multiphase flows with high density ratios and violent deformation of interface. First, a particle number density compensation (PNDC) model is developed to remove the ghost particles out of boundary thoroughly. The model is verified via static pressure simulations. Then, based on previous works, the SWP-MPS method is extended to a multiphase flow solver. Finally, the SWP-MPS method is applied to model static pressure, Rayleigh-Taylor instability, sloshing flow, and two-phase dam-break. The comparative analysis with the available experimental datum and other published numerical results proved the applicability and accuracy of the proposed SWP-MPS method for simulating multiphase flows with high density ratios and violent deformation of interface.

REPROGRAMMABLE METAMATERIALS THROUGH IN-SITU ACTIVATION OF SNAP-THROUGH INSTABILITY

Lei Wu[*1] and Damiano Pasini*[1]

[1]*McGill University*

ABSTRACT

Snapping metamaterials are designed to deliver a function that is inherently governed by their nonlinear snapping response, which is characterized by a negative incremental stiffness. Once fabricated, though, their capacity to snap in a given mode is permanently sealed into their architecture, leaving no chances to change it in service, in cases where for example snap-through is deleterious. In this work, we present a class of reprogrammable metamaterials with snap-through capacity that can be activated and deactivated in-situ. This translates into a high versatile modus operandi where the user can - post-fabrication – choose the stress-strain response to be one among three: monotonic, monostable snapping, and bistable snapping, and then switch on the fly among them, as desired. We show how this class of reprogrammable metamaterials can broaden multifunctionality in several applications ranging from mechanical logic gates to in-situ adjustable energy absorbers.

SHAPE MORPHING OF SMART PIEZOELECTRIC COMPOSITE LAMINATES USING THERMO-ELECTRO-MECHANICAL LOADING

Tongyu Wu[*1] and Shaker Meguid*[1]

[1]*University of Toronto*

ABSTRACT

Smart composite laminates (SCLs) consist of active piezoelectric layers bonded to or embedded in a host structure to form self adaptive systems. The importance of SCLs is evident in their potential use for shape morphing, condition health monitoring, and active vibration control. In practical applications, SCLs operate over a wide temperature range and experience large deformations. However, most existing works ignored the effect of temperature and mainly focused on small deformations, which do not reflect the real working environment of this class of laminates.
In this work, a fully coupled nonlinear finite element (FE) model is developed to investigate shape morphing of an SCL plate subject to coupled thermo-electro-mechanical disturbances. Specifically, fully coupled field equations are developed for an SCL plate in which the mechanical displacement is described in terms of the third order shear deformation hypothesis and the geometric nonlinearity in terms of von Kármán's strain-displacement relationships. The governing equations are converted into a tractable FE model. Additionally, the temperature dependent behavior of the constituents of the SCL plate is also considered in our simulations.

This work introduces two control modes (open loop control and closed loop control) to study the influence of temperature upon the morphed geometry subject to varied electro-mechanical loading. The results of our comprehensive analysis reveal a decrease in the stiffness of the SCL plate with increased temperatures. This is due to the development of thermal stresses as well as the temperature dependent material properties. As a result, SCL performs better in shape morphing at higher temperatures because the SCL plate is more flexible and responds better to the electro-mechanical coupling effects. Additionally, the shape morphing controllability of SCLs with different configurations is discussed. SCL with surface bonded piezoelectric laminates is found to have the highest shape morphing capacity and the lowest control voltage, whereas the embedded and core piezoelectric laminates are less responsive and require higher control voltages.

FATIGUE GROWTH OF TRANSVERSE CRACK IN HIGH MANGANESE STEEL FROGS

Tung-Yu Wu[1], Ho Ieng Ieong[2], Wei-Lun Hsu[3], Chia-Ming Chang[1] and Yung-Cheng Lai[1]*

[1]National Taiwan University
[2]P&T Architects & Engineers Ltd Macau Branch
[3]National Taiwan Ocean University

ABSTRACT

Railway turnouts are critical components guiding trains during track transitions, facilitating smooth and safe changes between tracks. As one of the major structural failures of turnout frogs is fatigue cracks due to the repeated wheel-frog impact, it is essential to employ an inspection schedule that constantly monitors the crack propagation while maintaining operational efficiency. Therefore, this study aims to develop an inspection scheduling strategy specifically for railway frogs made of high-manganese steel by computationally investigating the fatigue growth of transverse cracks with various conditions. The dynamic wheel-frog impact was numerically modeled using detailed finite elements to obtain the contact pressure distribution under different train speeds and axle loads. The contact pressure was then considered as the loading in the crack growth simulation formulated in the fracture mechanics to predict the propagation of transverse cracks with varied initial locations and angles. The simulation results showed that the distance between the crack and the wheel-frog impact point was found to be the most influential factor and can result in a crack growth rate that is 12 times faster. On the contrary, although train speed and axle load can somewhat affect contact pressure distribution, their effect on the crack growth per cumulative passing tonnage is insignificant. As a result, an interval approach is proposed by considering the crack growth rate and the headway to ensure enough inspections before fatigue failure.

IMPORTANCE OF APPROPRIATE CONSTITUTIVE MODEL FOR HIGH-FIDELITY SIMULATION IN GEOTECHNICAL LARGE DEFORMATION ANALYSIS

Hongcheng Jiao[1], Wei Wu[1], Wenxiong Huang[2] and Ding Chen[2]*

[1]Universität für Bodenkultur Wien
[2]Hohai University

ABSTRACT

Understanding the extremely large deformation of soil, a complex challenge in geotechnical engineering, requires advanced numerical methods due to the dynamic change in soil structure. This study presents a numerical model to analyze the responses of granular soils, akin to sand, under such conditions. A series of simulations investigate the evolution of shear bands and inner soil structure during the whole process of large deformation.

Smoothed Particle Hydrodynamics (SPH) with Finite Particle Method (FPM) interpolation is used to circumvent the computational difficulties associated with mesh distortion and improve the precision[1]. Two different constitutive models are used to highlight the impact of different constitutive models on the simulation results, namely: the critical state-based hypoplastic model, adept at capturing the pressure- and density-dependent behavior of granular soils, and the Drucker–Prager model, a staple in large deformation geotechnical simulations. An adaptive explicit stress integration scheme, termed Modified Euler automatic Substepping with Error Control (M-E-SEC) is utilized to keep the calculation accuracy of localized deformation area independent from the choice of time step[2]. Additionally, a stability correction method is introduced to suppress the breakdown problem that occurs in low-stress states. The model's effectiveness is validated by simulating passive and active earth pressure tests, followed by its application to large deformation scenarios.

Comparative analysis of these models reveals that both can simulate the soil's free-surface outline shape during deformation. However, compared to the experimental snapshots, the critical state-based hypoplastic model more accurately replicates the intricate internal structure of the soil, which is unattainable by the Drucker–Prager model. The study identifies the progression of shear bands as the primary driver of internal soil structure development and movement. It emphasizes the significance of selecting an appropriate constitutive model for high-fidelity modelling in large deformation scenarios, particularly for capturing the evolution of shear bands and internal soil structures. Furthermore, the initial relative density of the soil is also found to influence the development of these shear bands significantly and, consequently, the overall internal structure.

AN ACCURATE PHYSICS-INFORMED NEURAL NETWORK ARCHITECTURE FOR DETERMINING THE HETEROGENEOUS MICROMECHANICAL ELASTIC PROPERTIES OF BIOLOGICAL MATERIALS

Wensi Wu[*1] and Lu Lu*[2]

[1]*Children's Hospital of Philadelphia*
[2]*Yale University*

ABSTRACT

The heterogeneous micromechanical properties inherent in biological materials have profound engineering and medical implications. Within the engineering community, the unique combination of material microstructure and properties has inspired innovative designs of artificial organs, soft robots, and wearable devices with desirable mechanical functionalities. Concurrently, within the medical fields, the mechanical properties of tissues play a crucial role in affecting tissue regenerative capacity, host reactions to organ implants, and cancer invasion. The significance of material mechanical properties across these diverse domains has motivated a need to better understand the underlying mechanism governing the microscopic properties of biological tissues and their associated functions, whether for improving material designs or disease diagnosis. In traditional engineering, identifying the unknown material parameters requires iterative inverse finite element analyses and optimization of the constitutive parameters until the finite element model achieves an acceptable level of mechanical response, aligning with experimental data. However, these analyses often assume material homogeneity, as uncovering the microscopic elastic properties of complex materials necessitates stress distribution, a challenging task to achieve experimentally. In the present work, we propose a novel approach to identify the distribution of elastic properties in hyperelastic materials using physics-informed neural networks (PINNs) and Fourier-feature PINNs. We explore the prediction accuracies and computational efficiency of standard PINNs and Fourier-feature PINNs across three synthetic materials, each varying in structural complexity. Further, we experiment with five distinct feedforward network types within each neural network architecture (i.e., standard PINNs and Fourier-feature PINNs). The objective of this work is to identify a top-performance, versatile network architecture capable of consistently and accurately reproducing the full-field elastic properties of complex materials, with L2 relative errors of less than 5%. The results of this work have demonstrated significant potential for advancing our understanding of micromechanical behaviors in biological materials, paving the way for future innovations in engineering and medical applications.

IMPROVED PHASE-FIELD-BASED LATTICE BOLTZMANN MODEL FOR DROPLET EVAPORATION AND ITS PARALLEL ACCELERATION STRATEGY

Xiaoyu Wu[*1] and Xian Wang*[1]

[1]*Xi'an Jiaotong University*

ABSTRACT

In this paper, we present an improved Allen-Cahn-based phase-field lattice Boltzmann model for heat transfer in two-phase flow with evaporation. And the vapor concentration at the liquid-vapor interface is used as the driving force for vaporization. In our improved model, four distribution functions are used to describe the velocity field, the temperature field, the vapor concentration field and the phase field, where the vapor concentration and temperature fields are coupled by the Clausius-Clapeyron correlation. We evaluate several numerical tests to verify the accuracy of the presented model, including the 1D Stefan problem and the 2D droplet evaporation problem. The results obtained by this method are in good agreement with the theoretical results. A non-zero strain rate tensor results in a non-negligible term in the constitutive equation when phase change effects are taken into account. And the effect of the corresponding viscous force term on the accuracy of the model is discussed. Since the specific heat capacitance at the gas-liquid interface varies considerably, we also consider the effect on the model of the gradient term of heat capacitance [$\nabla(\rho Cp)$] in the energy equation. Meanwhile, we investigate memory optimization and parallel acceleration techniques for the LB algorithm. The Esoteric Twist algorithm, which stores the LB distribution function for only one set of data, is introduced to compare the computational performance with the regular distribution function storage algorithm. In addition, the computational performance of AC-LBM is tested using a mixed precision approach, where a lower precision number format is used to store the distribution function and a higher precision number format is used for computation in the GPU. Based on the three floating-point data formats of double precision (FP64), single precision (FP32) and half precision (FP16), the performance of the corresponding four mixed precision is tested.

SIMULATING WIND TURBINE WAKES IN THE CONTEXT OF VARYING WIND DIRECTIONS

Yu-Ting Wu[1]*

[1]*National Cheng Kung University*

ABSTRACT

A large eddy simulation (LES) framework, coupled with the blade element momentum (BEM) approach for turbine parameterization, is used to simulate wind turbine wakes in turbulent boundary layer. A tuning-free Lagrange scale-dependent dynamic model is employed for the sub-grid-scale (SGS) stress parameterization. The BEM approach utilizes inputs such as blade chord and twist angle as well as airfoil lift and drag coefficients to model the blade-induced forces. The turbulent boundary layer is characterized by an imposed inflow condition, with a specified prevailing wind direction time series. During the simulation, the wind turbine turns as the wind direction changes, and its prevailing wind direction in an instant can be a certain angle with the computational grid direction (i.e., the x direction) changing from -45 to +45 degrees. Model validation is performed through comparison with measurements of a model wind turbine wake. Preliminary results are promising and show acceptable agreement with measured data.

DATA-DRIVEN METHOD BASED ON THE FIRST PRINCIPLES OF ELASTICITY FOR AUTOMATICALLY MODELING OF MECHANICAL SYSTEMS

ZheTong Wu[1], Hongfei Ye[1], Hongwu Zhang[1] and Yonggang Zheng[1]*

[1]*Dalian University of Technology*

ABSTRACT

It is of great scientific significance and application to establish simplified mechanical models for specific geometric structures to effectively capture and analyze their deformation mechanism and avoid solving complex equations of elasticity. In recent years, a data-driven paradigm has ushered in a new era of discovery in various areas, providing a promising way for extracting laws hidden in the data and system modeling. In this work, a novel data-driven mechanical modeling method based on the first principles of elasticity is proposed to construct simplified mechanical models for structures with specific geometric characteristics from the numerical solutions of elasticity. By applying this high-precision simulation data to the unsupervised data-driven equation identification method of Seq-SVF, the governing equations could be automatically identified without providing prior knowledge of their number and left-hand terms. The sparsity of equations is ensured to balance the precision and complexity of the established models to improve their interpretability and generalization ability. By applying this method to the mechanical modeling of slender structures, homogeneous and heterogeneous beam models are discovered respectively, which are founded having the same form as the Timoshenko beam model. The expression of shear correction coefficient is distinguished under three kinds of loading conditions, which modifies the classical models. Furthermore, it is worth noting that a new expression is established corresponding to a specific loading condition, and to our best knowledge, it has never been proposed by existing works. Numerical examples show that the models established by the data-driven method are closer to the high-precision solution of elasticity than the classical models. The combination of data acquisition based on the first principles of elasticity and data-driven modeling methods reduces the reliance on human intelligence and provides a revolutionary approach to model and analyze complex mechanical systems.

This work was supported by the NSFC (Nos. 12072062, 12072061 and 11972108) and the National Key Research and Development Program of China (No. 2022YFB4201200).

A STUDY OF RELATED MODELS OF RESILIENCE IN ADOLESCENCE

Zixuan Wu[1] and Chieko Kato*[1]

[1]*Toyo University*

ABSTRACT

In order to deal with stress and to pursue well-being, “Resilience” always appears as a keyword of this process. This study considers “Resilience” as “the ability to adapt successfully despite difficult and threatening situations” and examines related models of it. The components of “Resilience” include “personal factors”, “ability factors”, and “environmental factors”. For each of these, the “Internal Working Model (IWM)”, “Social Skills”, and “Social Support” can be noted. “IWM” refers to “mental representation extracted based on repeated interactional experiences with the object of attachment”, and can be divided into “Stable”, “Ambivalent”, and “Avoidant”. “Social Skills” refers to “verbal and nonverbal interpersonal behaviors used to respond appropriately and effectively in interpersonal situations”. “Social Support” refers to “tangible and intangible support from various people surrounding a given individual”. The purposes of this study were to examine the direct effects of “IWM”, “Social Skills”, and “Social Support” on “Resilience” and the indirect effect of “IWM” on “Resilience” mediated by “Social Skills” and “Social Support”. The hypothesized model was that the stability of “IWM”, higher “Social Skills”, and more “Social Support” would each promote “Resilience”, and the stability of “IWM” enhances high “Social Skills”, leading to increased “Social Support” and consequently promoting “Resilience”. A questionnaire survey was administered to 189 undergraduate and graduate students using the “Mental Resilience Scale”, the “Internal Working Model Scale”, the “Adult Social Skills Self-Rating Scale”, and the “Perceived Social Support Scale for Students”. The results of the structural equation modeling showed that the path from “Stable” to “Social Skills” and “Resilience”, and the path from “Social Skills” to “Social Support” and “Resilience” was significant, but the path from “Social Support” to “Resilience” was not significant. These findings suggested that “Stable” has a direct impact on “Social Skills” and “Resilience”, and “Social Skills” has a direct impact on “Social Support” and “Resilience”. According to the results, educational interventions may be essential to promote “Resilience”. Considering that “IWM” is closely related to the nurturing environment of childhood, the acquisition of appropriate family education can foster stable “IWM”. Family education, the key to laying the foundation for developing into a person with well-being, can enhance “Social Skills”, such as handling one’s emotions appropriately and developing positive and supportive relationships with others. It also promotes “Resilience”, which means coping well with stress, and mental flexibility and adaptability.

HIGH-ORDER EXPLICIT RE-PARAMETERIZATION OF IMPLICIT GEOMETRIES FOR ENRICHED IMMERSED FEA

Nils Wunsch[1], John A. Evans[1] and Kurt Maute[1]*

[1]*University of Colorado Boulder*

ABSTRACT

Immersed finite element methods enable the analysis of problems involving complex interface geometry, such as those originating from CT scans or topology optimized designs, bypassing the difficult task of generating body-fitted meshes. An accurate representation of the material interface geometry within the discretized finite element problem is paramount to obtaining accurate solutions, particularly if non-linear phenomena at interfaces are considered, such as in fluid and contact solid mechanics.

In this work, we adapt a quadrature algorithm pioneered by Robert Saye [1] for use in the eXtended IsoGeometric Analysis (XIGA) framework [2]. The algorithm recasts the material interfaces implicitly defined by higher-dimensional level-set functions into the graphs of lower dimension height functions, thereby recursively reducing the dimensionality of the integrals in the weak form. This robust process recovers the implicitly defined material topology inside intersected background elements without simplifications. Hence, the algorithm is of particular interest to the types of applications mentioned above.

Modifications to the algorithm enable the generation of a higher-order triangulated foreground mesh approximating the geometry which allows for easy visualization of the interfaces. Additionally, a mesh connectivity graph is built to analyze the material layout. The XIGA framework's Heaviside enrichment strategy enriches background basis functions based on the material layout within their supports. The strategy avoids artificial coupling that may otherwise occur in the vicinity of small features.

This talk will present the modified quadrature scheme and will discuss the performance of the approach. The latter includes a comparison of the presented approach with a more common templated subdivision-based approach for a non-linear contact problem weighing the benefits from a reduced number of quadrature points and improved accuracy against the computational cost of the additional pre-processing steps required.

PHYSICAL FEATURES-BASED DATA-DRIVEN MODEL FOR THERMAL AND RESIDUAL STRESS EVOLUTION PREDICTION IN COLD-SPRAY ADDITIVE MANUFACTURING

Chunyang Xia[1], Scott Julien[1], Elizabeth Chang-Davidson[1] and Sinan Muftu[1]*

[1]*Northeastern University*

ABSTRACT

Cold spray serves as a solid-state coating deposition technology, recently employed in additive manufacturing for individual components and restoring damaged ones. Accurate prediction and management of thermal and residual stress are pivotal in the production of additive manufacturing parts, significantly influencing the properties and performance of the final products. Finite Element (FE) analyses are conventionally used to simulate the thermal and stress dynamics during the additive manufacturing process, but the simulations are high-cost and time-consuming. The primary innovation of this study lies in the development of a physically informed, data-driven model for predicting both the thermal and residual stress fields, aiming to reduce prediction costs while maintaining a high level of accuracy. To train and test the physics-based machine learning models, Finite Element simulations of cold sprayed copper-on-aluminum were conducted. The data-driven model was validated using datasets from simulations with different path patterns and deposition layers. The results demonstrated that the prediction accuracy of both thermal and residual stress exceeded 90% when compared to the simulated outcomes.

DEEP MACHINE LEARNING FOR COMPUTER MODELLING OF POLYMER DEGRADATION

Mingxuan Xia[*1], Ran He[1], Peter Polak[1], Baber Saleem[1] and Jingzhe Pan[1]*

[1]University of Leicester

ABSTRACT

The purpose of this study is to model the degradation process of biodegradable and polymeric vascular stents by modifying the hydrolytic degradation model using artificial neural networks (ANN). The ultimate aim is to address the threat of coronary artery disease (CAD) to public health. Common treatment for CAD with non-degradable implants has a certain probability of inflammation and intimal hyperplasia . A new biomaterial that degrades is necessary to eliminate the side effects associated with the traditional materials.

A previous computational model developed by Pan and his coworker1 predicts the molecular weight change and mass loss by considering the interplay between hydrolysis reactions and diffusion of short polymer chains during the degradation process. However, as part of the governing equations, various empirical rules such as Fickian's second law for diffusion and the source for the diffusion species are assumed. These empirical rules cannot fully capture the full complexities of the processes that underpin the polymer degradation.

This talk presents an innovative approach that replaces the empirical rules with artificial neural networks (ANN) in the governing equations. A two-step training methodology is adopted: the ANNs are firstly trained using data generated from the empirical rules and then further trained using experimental data via backpropagation. In particular, a back propagation scheme is developed for ANNs embedded inside the governing equations. The datasets incorporate degradation information which is characterized through mass loss and molecular weight for PLA50 plates and films over a 30-week period. The modelling result fits the experimental data with reasonably good accuracy, indicating the potential of replacing empirical rules with ANNs, revealing possibilities for further improving model accuracy.

STOCHASTIC CONTINUUM MODELS FOR HIGH ENTROPY ALLOYS

Yang Xiang[*1] and Luchan Zhang*[2]

[1]*Hong Kong University of Science and Technology*
[2]*Shenzhen University*

ABSTRACT

High entropy alloys (HEAs) are a class of novel materials that exhibit superb engineering properties. It has been demonstrated by extensive experiments and first principles and atomistic simulations that short-range order in the atomic level randomness strongly influences the properties of HEAs. We derive stochastic continuum models for HEAs with short-range order from atomistic models. A proper continuum limit is obtained such that the mean and variance of the atomic level randomness together with the short-range order described by a characteristic length are kept in the process from the atomistic interaction model to the continuum equation. The obtained continuum model with short-range order is in the form of an Ornstein—Uhlenbeck process. This approach provides a fundamental explanation to the origin of the high strength of HEAs based on the stochastic effects on the intrinsic strength.

SPH SIMULATIONS OF METAL DIAPHRAGM FSI VIBRATION PROBLEM USING AN IMPROVED HIGH ACCURACY CONTACT ALGORITHM

Liu Xiangdong[*1] and Yang Yang[1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

The fluid-structure interaction (FSI) problem of metal diaphragms under external vibration excitation is a common issue in aerospace engineering, including complex FSI phenomena at the interface between the metal diaphragm and propellant. As a Lagrangian meshless particle method, the Smoothed Particle Hydrodynamics (SPH) method has advantages in handling FSI problems. However, the treatment of fluid-structure interfaces has always been one of the main issues affecting the accuracy of the SPH method. Therefore, an improved fluid-structure contact algorithm combining the normal flux method and repulsion force boundary method is proposed in this paper. After thorough validation using a series of benchmark cases, this algorithm is applied to simulate the metal diaphragm FSI vibration. The results demonstrate that the proposed contact algorithm achieves high-precision numerical simulation of metal diaphragm FSI vibration.

DAMAGE INSPECTION USING HIGHER ORDER MODES CLUSTER (HOMC) GUIDED WAVES AND MACHINE LEARNING MODELS

Jing Xiao[*1] and Fangsen Cui*[1]

[1]*A*Star*

ABSTRACT

Ultrasonic guided waves (UGWs) have become a prevalent choice for long-range inspection. Recently, UGWs-based techniques have garnered increasing attention, particularly within the oil and gas industry. Conventionally, UGWs-based methods operate within the low-frequency range, generating selectively non-dispersive lower-order modes in structures. Yet, the longer wavelengths inherently limit the spatial resolution of inspection. This limitation can be addressed by employing higher operating frequencies, albeit at the expense of increased dispersion. Higher order modes cluster (HOMC) encompasses multiple higher order guided waves [1,2]. Owing to their closely matched velocities, HOMC exhibits negligible dispersion over distances spanning meters. In this study, we demonstrate the interaction between HOMC waves and surface-breaking defects of various depths in a steel plate. Firstly, dispersion curves of Lamb waves in steel plates are computed and discussed to provide insights on the generation of HOMC waves. Finite element (FE) simulations are subsequently carried out to investigate the HOMC-defect interaction. Transmission and reflection coefficients are computed from simulation results, considering different defect depths. The inherent limitations associated with utilizing these coefficients are explored and discussed. Acknowledging the constraints of conventional methods reliant on HOMC, the integration of machine learning (ML) models has been employed to augment and enrich characterization capabilities. Various ML algorithms are assessed for performance, leading to the selection of the optimal one for comparison with conventional methods. It is demonstrated that the resolution of inspection can be improved.

APPLICATION OF FMQA FOR HYPER-PARAMETER OPTIMIZATION AND METAMODEL-BASED OPTIMIZATION IN DEM GRANULAR FLOW SIMULATIONS

Junsen Xiao[1], Reika Nomura[1], Mayu Muramatsu[2], Shuji Moriguchi[1] and Kenjiro Terada[1]*

[1]*Tohoku University*
[2]*Keio University*

ABSTRACT

Metamodel-based optimization is extensively applied in conjunction with numerical simulation to extract the suitable parameter combination for optimal target output in a cost-effective manner. In this approach, hyper-parameter optimization (HPO) in metamodeling and metamodel-based simulation optimization (MBSO) [1] can be considered as black-box optimization problems. In recent years, quantum annealers [2] are theoretically proven to exhibit higher computational efficiency compared to classical computers. Factorization Machines with Quantum Annealing (FMQA) [3], as a black-box optimization algorithm, has gained significant attention. Its application to these two optimization problems in the field of landslide simulation and assessment have not been fully discussed. Therefore, this study explores a FMQA framework to conduct HPO for a Gaussian Process Regression (GPR) metamodel, which is used as a low-cost approximate solver of granular flow simulations for MBSO issue sequentially. The performance of FMQA is detailed estimated in the two issues.

Discrete element method (DEM) is a conventional numerical method, taking into account the behavior of individual particles. Hence, we first conduct a series of DEM granular flow simulations to generate training data for the metamodel. GPR is then adopted to create a metamodel with the hyper-parameters optimized by FMQA. Sequentially, the metamodel is utilized as an approximate solver of the DEM simulations, coupled with the FMQA for efficient exploration of high-risk parameter settings in granular flow. The performance of FMQA on these two optimization issues is numerically evaluated in comparison with random search (RS) and Bayesian optimization (BO). In both HPO and MBSO problems, FMQA shows superiority over RS, and this superiority is more pronounced in the four-dimensional MBSO problem. The result also demonstrates that FMQA is competitive compared to the state-of-the-art BO algorithm. The value of this study is that we estimated the performance and applicability of FMQA on HPO and MBSO problems, which offers experience for the future application of quantum annealing in landslide assessment.

MULTI-TARGET/MULTI-CONDITION AERODYNAMIC CONFIGURATION OPTIMIZATION OF THE HIGH-PRESSURE CAPTURING WING BI-WING CONFIGURATION

Yao Xiao[1], Siyuan Chang[1], Kai Cui[1], Guangli Li[1] and Zhongwei Tian[1]*

[1]*Chinese Academy of Sciences*

ABSTRACT

The High-pressure Capturing Wing (HCW) configuration is a promising wide-speed-range aerodynamic configuration because of its high lift-to-drag ratio at hypersonic speed[1] and high lift force at subsonic speed[2]. Based on the typical High-pressure Capturing Wing configuration, four key design parameters of the capturing wing (half-span, leading edge sweep angle, trailing edge sweep angle and assembly angle of attack) are selected as optimization variables, and the surrogate model is constructed by using uniform experimental design and Latin hypercube experimental design methods, and reasonable targets are selected to carry out multiple rounds of single-target optimization for Mach number 6, 3 and 0.3 working conditions. On this basis, a series of high-performance aerodynamic configurations were obtained by carrying out multi-point/multi-objective optimization. The results show that the lift-to-drag ratio under Mach 6 and Mach 3 and the lift force at Mach 0.3 of the wide-speed-range multi-objective optimized configuration are significantly higher than the benchmark configuration. Furthermore, the parameter sensitivity analysis and the comparative analysis of the flow field of the above series configurations were carried out, and the effect of the four key design parameters of the capturing wing on the aerodynamic performance in different speed range was discovered, among which the assembly angle of attack had the most significant effect on the aerodynamic performance in the wide-speed-range.

PARTICLE RESPONSE TO SHEAR-INDUCED LIFT IN TWO-WAY COUPLED TURBULENT CHANNEL FLOW

Yucang Ruan[1] and Zuoli Xiao[*1]*

[1]Peking University

ABSTRACT

Particle-laden wall-bounded turbulent flows exist widely in both environmental research, e.g. sandstorm, and engineering applications, e.g. particle-based solar-power receivers. Two-way coupled point-particle (PP) direct numerical simulation (DNS) is employed to investigate heavy particle motions in turbulent channel flow. Focus is placed on the influence of shear-induced Saffman lift on particle motion and turbulence modulation.

The carrier phase is assumed to be air and is governed by three-dimensional compressible Navier-Stokes equations. The solid particles are assumed to be identical spheres which are 1600 times as dense as air, corresponding to a real density ratio of sand to air. The particle diameter is much smaller than the Kolmogorov scale. Therefore, the Eulerian-Lagrangian PP method is employed to track particles. The inter-particle collisions, particle rotation, and heat transfer between particles and fluid are neglected in the present study. The two-way coupling feedback source terms in momentum equation and energy equation are obtained by using the Particle-in-Cell (PIC) method. The feedback terms are simply distributed onto the nearest grid to the particle.

The effects of Saffman lift on mean stream-wise particle velocity and the fluctuating particle velocity are examined due to the importance in understanding and predicting the wall erosion caused by particles. It is shown that the mean stream-wise fluid velocity agrees well with the results of single-phase flow, which obeys the law-of-the-wall, whether the Saffman lift is present or not. However, the Saffman lift alters significantly particle velocity in the near-wall region. It turns out that the particles move faster than the fluid phase along the stream-wise direction under buffer layer. This is consistent with the experimental measurement and particle-resolved (PR)-DNS for large Stokes numbers. It proves that the particle velocities given by PP-DNS with Saffman lift is closer to the reality than those obtained by PP-DNS without Saffman lift.

A Eulerian model for particle velocity is established for wall-bounded particle-laden flow by modifying Maxey's model. Particularly, the material derivatives along fluid particles in Maxey’s model is replaced by the material derivatives along solid particles. The ensemble-averaged model is closed by gradient diffusion hypothesis and concept of Prandtl mixing length. The new model demonstrates that the Saffman lift alters the stream-wise particle velocity by changing the component in the wall-normal direction, which explains why the Saffman lift alters the profile of stream-wise particle velocity. The numerical results manifest that the new model successfully reproduces the stream-wise particle velocity with different Stokes numbers.

PROVABLY STABLE DISCRETIZATIONS OF THE KZK EQUATIONS USING SUMMATION BY PARTS OPERATORS AND SIMULTANEOUS APPROXIMATION TERMS

Zhongyu Xie[*1], David Del Rey Fernández[1] and Sivabal Sivaloganathan[1]*

[1]*University of Waterloo*

ABSTRACT

Over the last two decades, High Intensity Focussed Ultrasound (HIFU) has emerged as a promising non-invasive medical approach for precisely ablating local tissues, offering versatile applications in tumor treatment, drug delivery, and addressing brain disorders such as essential tremor. Its advantages include targeted energy delivery with no affect on skin integrity, low system maintenance costs, minimal impact on normal tissues, and swift recovery.

Despite its' merits, HIFU remains underutilized, primarily employed in specific breast cancer and prostate cancer treatments. To expand its range of applicability, a comprehensive understanding of the interaction between the ultrasound beam and local tissues at the focal point is essential. This study focuses on modeling critical nonlinear effects in the thermal modulation of local tissues by numerically solving the Khokhlov-Zabolotskaya-Kuznetsov (KZK) equation—which is an excellent model for the nonlinear acoustic field arising in HIFU.

Constructing stable discretizations poses challenges due to polynomial nonlinear terms and a second derivative of an integral term within the KZK equations. Employing a continuous Galerkin approach, an operator is formulated to approximate the integral term, facilitating the construction of a modified second derivative operator. This establishes a clear correspondence between continuous and discrete stability proofs. Additionally, a skew-symmetric splitting technique is used to discretize the nonlinear advective term. The proposed scheme's stability under periodic boundary conditions is proven, followed by temporal advancement using a fourth-order Runge-Kutta method. The accuracy of the resulting numerical methodology is rigorously evaluated using the method of manufactured solutions.

STUDY ON DYNAMIC MECHANISM OF HIGH-SPEED IMPACT BETWEEN A LIQUID WEDGE AND A LIQUID SURFACE

Hangfan Xiong[*1], Wangxia Wu[1] and Honghui Teng[1]*

[1]*Beijing Institute of Technology*

ABSTRACT

The impact between deformable (liquid) objects is a very fundamental problem widely existed in many highly transient multiphase flow phenomena, such as droplets impact water, bubble collapse and impact welding. Especially for the high-speed impact problem at a wedge angle, a series of complex and violent phenomena would be accompanied, including local extremely high pressure, shock wave and high-speed jet. In this work, a computational multi-component compressible flows program is employed to investigate the dynamic process of high-speed impact between a liquid wedge and a liquid surface at different wedge angles. In order to more accurately understand the properties and the generation mechanism of the high-speed jet during the impingement, the effect of surface tension is further considered. The relationships of the impact conditions with the water hammer pressure, shock waves, and the slip lines are theoretically discussed in detail. By considering the water hammer shock wave on both sides of the impact fluid, a dynamical model for the liquid wedge impact problem is established. The strength of water hammer pressure, the values of shock wave angle and slip line angle are all precisely predicted by this model compared with the numerical results. Meanwhile, the detached region of the water-hammer shock wave which is closely related to formation of the high-speed jet is also discussed.

DAMAGE CHARACTERIZATION OF THERMAL BARRIER COATINGS UNDER CMAS CORROSION

Kun Xiong[*1], Ziyang Zhou[1], Jingjing Yang[1] and Xueling Fan[1]*

[1]*Xi'an Jiaotong University*

ABSTRACT

The silicate particles, such as volcanic ash, dust and sand, impact the turbine blade with high temperature and high-speed gas and deposit on the surface of the thermal barrier coating. The molten CMAS penetrates into the coating and causes cracks in the coating, resulting in peeling failure of the coating, which has become one of the main reasons for the failure of thermal barrier coatings (TBCs) system. In this paper, the failure behavior of EB-PVD thermal barrier coatings under CMAS corrosion was studied. The critical failure strain of the surface of TBCs under different corrosion time was obtained, and the failure criterion of TBCs under CMAS corrosion was established. The results show that the infiltrated CMAS not only changes the mechanical properties of the penetration zone, but also reacts with the coating. The reaction between CMAS and thermal growth oxide (TGO) layer destroys the TGO, causing the delamination of the TBCs at the interface. Based on the buckling theory, the damage model of TBCs was established, and the relationship between the interface damage and the surface strain of TBCs was obtained. With the increase of corrosion time, the damage of TBCs accumulated continuously and showed a similar parabolic trend. When the damage accumulated to the critical value, the coating spalling failure occurred. The results provide a theoretical basis for the damage quantification and evaluation method of TBCs under CMAS corrosion conditions.

DATA DRIVEN MODELING OF UNKNOWN STOCHASTIC DYNAMICAL SYSTEM

Yuan Chen[1] *and Dongbin Xiu**[1]

[1]*Ohio State University*

ABSTRACT

We discuss a general framework for data driven modeling of unknown stochastic differential equations (SDEs). Given short bursts of trajectory data, our method is able to construct an accurate numerical model for the underlying (and unknown) SDEs. The method utilizes flow map learning (FML) technique that was developed for modeling deterministic systems. For modeling SDEs, our method employs generative models to accurately approximate the one-time-step conditional probability distribution of the system. Under the framework, generative models such as GANs, normalizing flow, diffusion model can be employed. Using an extensive set of examples, we demonstrate that the method is highly versatile, robust, and can provide accurate system predictions for very long time domain far exceeding that of the training data. The learned numerical models can also capture small probability system transitions that are not observed in the training data.

THREE-DIMENSIONAL STABILIZATION-FREE VIRTUAL ELEMENT METHOD FOR NONLINEAR PROBLEMS

Bingbing Xu[*1] and Peter Wriggers*[1]

[1]*Leibniz University Hannover*

ABSTRACT

The Virtual Element Method (VEM) can be regarded as a generalization of the classical finite element method (FEM) to general polygonal meshes. In the prior studies of the VEM, a stabilization term is required in order to ensure that the global stiffness matrix has the correct rank. In this work, we present a stabilization-free Virtual Element Method for hyperelastic materials in 3D. The main idea of the stabilization-free approach is to use an enhanced approximation space to compute a higher-order polynomial L2 projection of the gradient. This work describes the calculation process of the origibal H1 projection operator and the highrt-order L2 projection operator for three-dimensional problems. The formulation of the stabilization-free VEM for 3D hyper-elastic materials is given in the next. Some numerical examples are given to compare the accuracy of the stabilization-free VEM with the conventional VEM.

A MULTI-FIDELITY DEEP OPERATOR NETWORK (DEEPONET) FOR FUSING SIMULATION AND MONITORING DATA: APPLICATION TO REAL-TIME SETTLEMENT PREDICTION DURING TUNNEL CONSTRUCTION

Chen Xu[*1], Ba Trung Cao[1], Yong Yuan[2] and Günther Meschke[1]*

[1]*Ruhr University Bochum*
[2]*Tongji University*

ABSTRACT

The assessment of surface settlements during mechanized tunneling is of importance and remains a challenging research topic. Generally, the surface settlement can be predicted using different paradigms: either a physics-driven approach utilizing computational models, or a data-driven approach employing machine learning techniques to establish mappings between influencing factors and ground settlement. In this work, we introduce a multi-fidelity deep operator network (DeepONet) framework to combine the advantages of both approaches and assimilate the data from different sources. The presented framework, which leverages the recently developed operator learning methods, comprises two components: a low-fidelity subnet that captures the fundamental ground settlement patterns obtained from finite element simulations, and a high-fidelity subnet that learns the nonlinear correlation between numerical models and real engineering monitoring data. The results show that the proposed method can capture not only the physical laws governed by numerical simulations, but also accurately fit measured data as well. Remarkably, even with limited noisy measurement data, our model can still provide rapid, precise, and robust reconstruction of the full-field surface settlement in real-time during mechanized tunneling.

ABSTRACT

The Shifted Boundary Method (SBM) belongs to the class of unfitted (or immersed or embedded) finite element methods and was recently introduced for the Poisson, linear advection/diffusion, Stokes, Navier-Stokes equations, and many additional problems. By reformulating the original boundary value problem over a surrogate (approximate) computational domain, the SBM avoids integration over cut cells and the associated problematic issues regarding numerical stability and matrix conditioning. Accuracy is maintained by modifying the original boundary conditions using Taylor expansions. Hence the name of the method, that shifts the location and values of the boundary conditions. In the context of applying the SBM to incompressible flows involving moving boundaries or free surfaces, spurious pressure oscillations in time may result from a discrete change of the total volume of active fluid over a time step. To avoid this issue, a weighted SBM is proposed, in which the variational form of the equations is weighted by the elemental volume fraction of active fluid. The proposed weighted SBM (or W-SBM) exactly preserves states of hydrostatic equilibrium, and induces small mass (i.e., volume) and momentum conservation errors, which converge as the grid is refined. This is in analogy to cutFEMs and related unfitted approaches, which rely on an affine representation of cut boundaries. We demonstrate the robustness and accuracy of the proposed method with an extensive suite of two-dimensional and three-dimensional tests for incompressible Stokes and Navier-Stokes Flows.

QUANTITATIVE ANALYSIS OF ELECTROCHEMICAL-MECHANICAL COUPLING BEHAVIORS IN LITHIUM-ION BATTERIES

Chunhao Yuan[1] *and Jun Xu**[2]

[1]*Southeast University*
[2]*University of Delaware*

ABSTRACT

The safety and durability of Lithium-ion batteries (LIBs) are intrinsically interconnected phenomena, intricately woven with electro-chemo-mechanical dynamics. A comprehensive comprehension of these multifaceted interactions necessitates interdisciplinary endeavors. In this study, we meticulously formulate and execute mechanically constrained charging/discharging characterizations, employing a collaborative approach that integrates multiphysics modeling. This holistic methodology aims to elucidate the intricate coupling mechanisms inherent in the solid-liquid electrode-electrolyte interface and the interaction between solid-solid active materials within LIBs.

Our investigations reveal that a LIB cell subjected to mechanical constraints manifests an elevated voltage profile during charging and a reduced charging duration. This phenomenon can be attributed to augmented electrolyte resistance and diminished diffusivity resulting from a concurrent decrease in electrode porosity. The observed reaction force response of the cell is a confluence of the mechanical response of the cell structure and the electrochemical volume variations induced by Li-ion intercalation/de-intercalation processes. Notably, under mechanical constraints, the cell's capacity experiences a significant reduction in scenarios involving fast-charging; however, employing a constant-voltage charging protocol facilitates a noteworthy capacity recovery.

This study underscores the potential of multiphysics approaches in unraveling the electrochemical-mechanical coupling mechanisms, thereby providing valuable insights for directing battery system design and management strategies. The results presented herein offer a promising trajectory for advancing our understanding of LIBs and optimizing their performance through informed and targeted design interventions.

MULTI-SCALE MODELING FOR TENSILE BEHAVIOR OF PLAIN WOVEN SIC/SIC COMPOSITES CONSIDERING TEMPERATURE AND OXIDATION

Qipeng Xu[*1] and Xueling Fan*[1]

[1]*Xi'an Jiaotong University*

ABSTRACT

Ceramic matrix composites (CMCs) have a broad application prospect in high-performance aero-engine because of its excellent high-temperature comprehensive mechanical properties. The mechanical behavior and performance prediction of CMCs can provide theoretical basis and engineering methods for material design, structural analysis, and machining forming. In this paper, the tensile damage and fracture process of fiber-reinforced SiC/SiC CMCs under high temperatures and oxidizing atmosphere were investigated, then the damage mechanisms of the interface oxidation and the fiber thermal failure were considered in the stress distribution, matrix multi-cracking, interface debonding and material failure analysis. A first matrix cracking stress model and a constitutive model of unidirectional SiC/SiC CMCs were developed. The key damage variables were transferred to the fiber bundle material parameters in plain woven SiC/SiC CMCs finite element model based on real structure. Finally, a multi-scale constitutive model considering temperature and oxidation was established. Using this constitutive model, a numerical modeling for tensile behavior of plain woven SiC/SiC CMCs at different oxidation times (0-2 hours) and temperatures (25-1200℃) was conducted. The stress-strain response of plain woven SiC/SiC CMCs exhibits significant temperature and oxidation time correlations. The initial elastic modulus of CMCs remains unchanged with increasing oxidation time at the same temperature, while the tensile strength decreases with increasing oxidation time. The established multi-scale model can reasonably predict the tensile behavior and performance degradation, and the simulation curve is consistent with the experimental values.

BUCKLING TOPOLOGY OPTIMIZATION USING A LINEAR MATERIAL MODEL

Tao Xu[*1], Xiaodong Huang[2], Xiaoshan Lin[1] and Yi Min Xie[1]*

[1]RMIT University
[2]Swinburne University of Technology

ABSTRACT

In recent decades, topology optimization has been increasingly used in structural design due to its capacity to generate efficient structures with minimal materials. Given the prevalence of compressed slender members in such optimized structures, buckling emerges as a critical factor in topology optimization. A major challenge in the buckling topology optimization of continuum structures is addressing pseudo buckling modes in intermediate and low-density elements. These modes arise from penalized material interpolation schemes and the presence of stress singularities. This study tackles the issue by employing a linear material model for both stiffness and stress stiffness matrices, combined with ε-relaxation functions to effectively mitigate pseudo buckling modes. The presented algorithm is established based on the floating projection topology optimization (FPTO) method. Owing to the effective elimination of pseudo buckling modes, the optimization process achieves great stability and can be conducted from the full design domain. Numerical results demonstrate a uniform strain energy density distribution across the optimized structures, highlighting the effectiveness and efficiency of the proposed algorithm. Furthermore, the smooth and practical designs obtained through the FPTO method are readily applicable to fabrication processes, marking a significant advancement in the field of structural topology optimization.

RATE-DEPENDENT PHASE-FIELD COHESIVE THEORY: A UNIFIED MODEL FOR DYNAMIC CRACK BRANCHING VIA ESHELBY ENERGY-FLUX INTEGRAL

WenLong Xu[*1], *Hao Yu*[1] *and HengAn Wu*[1]

[1]*University of Science and Technology of China*

ABSTRACT

As the crack propagation achieves a critical velocity, the stability of dynamic front sharply decreases and even begins branching. Such critical velocity is controlled by the velocity/rate dependent fracture energy. To address the toughening process, the phase-field fracture model considering variational consistency converges to a rate-dependent cohesive zone model, where the viscous resistance is proposed without ad hoc assumption. In the crack front dynamics, the fundamental understanding of the toughening zone shape and size is still lacking, and the specific contribution of cohesiveness and viscosity to the total dissipation is still unclear. In this work, the 1-D tensile bar model has been obtained for detecting the material constitutive response (i.e., traction-separation law), where the phase-field model (PFM) is controlled by a parabolic PDE with nonlinear boundary conditions and source terms. The intrinsic separation law of the phase-field constitutive property is discovered (similar to the elasto-viscoplasticity). Meanwhile, based on the equilibrium of the Eshelby energy-flux integral around the phase-field crack tip, the compatibility conditions of the three intrinsic parameters (degradation, geometric, and viscosity coefficients) are verified during the dynamic crack branching. The proposed PFM matches well with the dynamic fracture energy and critical velocity of branching among the various materials (Soda-lime glass, PMMA, Homalite-100, and Steel) in a unified framework, where the toughening behavior is governed by a normalized toughening coefficient (F_V=c_R⁄(G_C*M)). The scaling analysis of the dissipative mechanism around the crack tip demonstrates that the remarkable viscous dissipation occurs among preexisting cohesive zone, driven by the ultra-high strain rate, and the dissipative mode transition follows a universal master curve among the dimensionless inertance, cohesiveness, and viscosity parameters.

INVERSE DESIGN OF SEISMIC METAMATERIALS BASED ON MACHINE LEARNING

Zhuojia Fu[1] and Wenzhi Xu[1]*

[1]Hohai University

ABSTRACT

The ability to efficiently design seismic metamaterials with desired functional characteristics on-demand represents the next frontier in metamaterials discovery. However, traditional gradient and non-gradient-based optimization algorithms still face difficulties in convergence and high computational cost when dealing with increasing optimization parameters. To address the inherent challenges of traditional inverse design methods, this study employs deep learning to design seismic metamaterials with specific band gaps. Firstly, a machine learning-based surrogate model is constructed to rapidly generate a dataset of three-dimensional seismic metamaterial features and their associated band structures. Subsequently, this dataset is utilized to train the inverse design deep network. Numerical experiments demonstrate that the proposed optimization strategy can efficiently design seismic metamaterials with the demanded band gap.

EFFECTS OF MATERIAL PROPERTY UNCERTAINTY ON FRACTURE MODELING OF UNIDIRECTIONAL DOUBLE CANTILEVER BEAM SPECIMENS

Md Hassan[1], Xiaodong Xu[2] and Juhyeong Lee[1]*

[1]Utah State University
[2]Cranfield University

ABSTRACT

Some composite materials exhibit spatially varying material properties stemming from the inherent randomness in their microstructures. The variation in material properties potentially results in uncontrollable random fracture initiation, which should be considered in preliminary design studies. Among all the fracture modes, composite materials primarily experience fracture through the opening mode (Mode-I), and the Mode-I cracks could alter the local stress states to initiate other fracture modes. This study focuses on the implementation of stochastic material inputs into the double cantilever beam (DCB) analysis for unidirectional (UD) composite laminates. A parametric study of Abaqus finite element (FE) models are conducted to observe how Mode-I fracture is influenced with and without stochastic material properties in the DCB models. A Box-Mueller algorithm [1] is implemented by a user-defined subroutine to generate random composite ply and cohesive properties with random variations ranging from 5% to 30% of mean values. These stochastic material inputs are also randomly assigned to individual finite elements. The results reveal that increasing variations in input properties for both cohesive elements and composite lamina elements leads to a large failure envelope, with the stochasticity of the cohesive elements having a greater impact on failure than that of the lamina elements. These findings demonstrate the need to account for spatially varying properties in composite fracture models to avoid overpredicting actual strength in composites with inherent randomness. It is important to note that conventional composite fracture models are predominantly within a deterministic framework and these models often overpredict fracture performance [1,2]. The stochastic failure model in this study can be easily applied in composite analysis with inherent material variations or uncertainties such as short fibre composites. This makes the technique broadly relevant for prognostic health monitoring (PHM) and a progressive damage model incorporating material property uncertainties.

THE INFLUENCE OF DENSITY INTERPOLATION FUNCTION IN DYNAMIC TOPOLOGY OPTIMIZATION

Xinlin Xu[1], Hiroya Hoshiba[1], Koji Nishiguchi[1] and Junji Kato[1]*

[1]*Nagoya University*

ABSTRACT

In the realm of topology optimization, the interpolation function that transforms binary integer problems into continuous problems has always been a critical component. This encompasses interpolation functions for Young's modulus and density. Conventional methods such as the SIMP method and RAMP method typically introduce penalty factors only in the Young's modulus interpolation function to facilitate the convergence of optimization algorithms, while employing linear interpolation for density. This approach is effective in static topology optimization, where the motion equation Ku=F is independent of mass. However, in dynamic topology optimization, the form of the motion equation becomes Ma+Ku=F, the dynamic influence of density on the system must be considered. Therefore, continuing to use linear interpolation functions on density may lead to a range of issues, including grayscale problems and structurally unreasonable outcomes.

To address this challenge, the present study thoroughly examines the influence of various density interpolation functions on optimization results. Considering multiple influencing factors, including the ratio of Young's modulus to density, the magnitude of applied loads, and the frequency of loads, we conduct a detailed analysis of how these factors affect the optimal density interpolation in the context of dynamic topology optimization. The objective of this research is to enhance the accuracy of the optimization model, ensuring structural robustness and excellent performance in dynamic problems.

Through systematic investigation, the present study unveils the significance of selecting appropriate density interpolation functions in dynamic topology optimization. The collaboration between different density interpolation functions and Young's modulus interpolation functions significantly influences the results of dynamic topology optimization for structures. This not only contributes to a better understanding of structural behavior under diverse conditions but also offers novel perspectives and approaches for the design and optimization of future engineering structures.

In summary, this research provides valuable insights for the further improvement of dynamic topology optimization methods. These insights are poised to drive the broader adoption of topology optimization methods in practical engineering applications, thereby offering more effective tools and guidance for structural design and performance optimization.

ABSTRACT

Additive manufacturing (AM) is attracting widespread interest as an effective tool to fabricate sophisticated structural components for a range of industrial applications such as aerospace, automotive, biomedical, construction, etc. Compared with conventional manufacturing technologies, AM allows accommodating various complex topological designs and minimizing material waste and lowering the costs of molds or tools. Concerning composite materials, AM provides more potential and flexibility to improve structural performances by creating sophisticated product designs with better use of material constituents [1]. More specifically, combining topology optimization and additive manufacturing (AM) enables the full exploitation of the capacity for heightening the performance of carbon fibre reinforced plastic (CFRP) structures. This study simultaneously performs topology optimization and fibre path design by employing the radial basis function (RBF) based level set function (LSF) [2]. Fiber paths are determined instinctively for the inherent advantages of the LSF, and fibre orientations are parameterized accordingly. Manufacturing drawbacks such as gaps and overlaps can be avoided by introducing a fast-marching method [1]. To verify the effectiveness of the optimization method, three groups of optimized and empirical designs are fabricated by the AM technique, respectively, and the experimental tests are further carried out. Finite element (FE) models are also reconstructed for the 3D printed structures, and then the FE simulation is validated by the experimental tests. With the proposed optimization method, stiffnesses for all three groups of the optimal samples are significantly improved compared with the empirical counterparts. The FE modeling technique is capable of replicating the experimental results [1]. This study paves a new way to develop an integrated framework of optimization, additive manufacturing, experimentation, and validation to deliver high-performance CFRP structures.

A MESOSCOPIC DOMAIN DECOMPOSITION APPROACH COMPOSED WITH PRECONDITIONED CONJUGATE GRADIENT FOR MODELING CONCRETE

Yang Xu[*1] and Zhang Lin*[1]

[1]*Harbin Institute of Technology*

ABSTRACT

The mesoscopic numerical method is a powerful tool for simulating concrete's mechanical behavior. However, most mesoscopic finite element methods (FEM) would consume a lot of computing resources according to the considerable elements, which is especially marked when analyzing models with a larger size. To provide a comprehensive and efficient simulator to predict the concrete's mechanical behavior, a mesoscopic domain decomposition (MDD) approach technique composed of the Preconditioned Conjugate Gradient (PCG) method is employed in this study. A group of meso-models of concrete, which were considered as a three-phase composite, consisting of aggregates, cement paste, and the interface transition zone between them. Then, these models were analyzed by the FEM and the MDD approach technique composed with PCG, respectively. By comparing with the experimental benchmark, the simulation results were validated. The computation demonstrated that the MDD approach technique composed with PCG would cost less computing time, which could provide a reasonable tool for understanding and predicting the observed macroscopic behavior of concrete.

QUANTUM COMPUTING ENHANCED DISTANCE-MINIMIZING DATA-DRIVEN COMPUTATIONAL MECHANICS

Yongchun Xu[*1], Zengtao Kuang[1], Jie Yang[1], Qun Huang[1], Wei Huang[1] and Heng Hu[1]*

[1]*Wuhan University*

ABSTRACT

Data-driven computational mechanics [1] has great potential in engineering applications by eliminating material modeling errors and uncertainty. In this computational framework, the solution-seeking procedure relies on minimizing the distance between the constitutive database and the conservation law. However, it currently suffers from computational efficiency issues in data search, especially when dealing with large-scale databases. Specifically, assume that a data search is conducted in a database with N data, and the dimension of data is D. In one nearest neighbor search, the computational complexity on a classical computer requires executing N distance calculations, each with a cost of O(D), resulting in the total computational complexity O(ND).

Addressing this challenge, we have introduced a novel framework named quantum computing enhanced data-driven computational mechanics (qDD) [2]. Our method employs an efficient quantum algorithm to estimate the distance between two data, which exponentially reduces the computational complexity from O(D) to O(log D), thus reducing the overall complexity to O(N log D). The proposed method is not only validated on the quantum computer simulator Qiskit, but also on a superconducting quantum computer from Origin Quantum.

Furthermore, quantum hardware noise remains a critical barrier to achieving accurate simulation results due to the limitation of the current Noisy Intermediate-Scale Quantum (NISQ) hardware level. We have used an error mitigation technique, zero-noise extrapolation (ZNE), to improve the accuracy of qDD when operating on a noisy quantum computer [3]. A data-driven multiscale simulation of a composite L-shaped beam confirms the effectiveness of the proposed approach. We believe the introduction of qDD represents a promising step towards using the power of quantum computing in computational mechanics and explores a new computational paradigm for further advancements in the field.

A THEORY OF HYDROGEL MECHANICS THAT COUPLES SWELLING AND EXTERNAL FLOW

Zelai Xu[*1], James Feng[1] and Pengtao Yue[2]*

[1]*University of British Columbia*
[2]*Virginia Tech*

ABSTRACT

Two aspects of hydrogel mechanics have been studied separately in the past. The first is the swelling and deswelling of gels in a quiescent bath of solvent, and the second is the solvent flow around and into a gel domain. The former neglects convection driven by external flow, whereas the latter neglects solvent diffusion driven by a gradient in chemical potential. Motivated by engineering and biomedical applications where both aspects coexist and potentially interact with each other, this work presents a poroelasticity model that integrates these two aspects into a single framework and demonstrates how the coupling between the two gives rise to novel physics in relatively simple one-dimensional and two-dimensional flows.

ENERGETIC VARIATIONAL NEURAL NETWORK DISCRETIZATIONS OF GRADIENT FLOWS

Zhiliang Xu[1], Yiwei Wang*[2] and Chun Liu[3]

[1]*University of Notre Dame*
[2]*University of California, Riverside*
[3]*Illinois Institute of Technology*

ABSTRACT

In this talk, I will describe structure-preserving neural-network-based numerical schemes to solve both L2-gradient flows and generalized diffusions. By using neural networks as tools for spatial discretization, we introduce a structure-preserving Eulerian algorithm to solve L2-gradient flows and a structure-preserving Lagrangian algorithm to solve generalized diffusions. The Lagrangian algorithm for a generalized diffusion evolves the “flow map" which determines the dynamics of the system. This avoids the non-trivial task of computing the Wasserstein distance between two probability functions. Unlike most existing methods that construct numerical discretizations based on the strong or weak form of the underlying PDE, our schemes are constructed using variational formulations of these PDEs for preserving their variational structures. Instead of directly solving the obtained nonlinear systems after temporal and spatial discretization, the minimizing movement scheme is utilized to evolve the solutions. This guarantees the monotonic decay of the energy of the system, and is crucial for the long-term stability of numerical computation. I will describe a few numerical experiments to demonstrate the accuracy and energy stability of the numerical schemes. This is a joint work with Profs. Yiwei Wang and Chun Liu.

DNN MODELING OF UNKNOWN PDE SYSTEMS

Zhongshu Xu[*1] and Dongbin Xiu*[1]

[1]*Ohio State University*

ABSTRACT

We discuss a data driven modeling framework called Flow Map Learning (FML) for modeling unknown PDE systems. Unlike other system discovery methods that seek to discover the governing equations, our method construct an accurate numerical approximation to the flow map operator of the unknown system. For PDE systems, a specialized DNN structure is required to enforce the learning of the various differential operators in the system. The method can also model PDE systems when only partial data are available. Using an extensive set of examples, we demonstrate the efficacy and robustness of the method to a variety of PDEs, as well as nonlocal problems involving fractional PDE.

AN ACTIVE LEARNING KRIGING METHOD BASED ON SPHERICAL DECOMPOSITION-MCS (AK-SDMCS) FOR STRUCTURAL RELIABILITY ANALYSIS WITH SMALL FAILURE PROBABILITIES

Guofeng Xue[1] and Maijia Su*[2]

[1]*Foshan University*
[2]*University of Trento*

ABSTRACT

The main challenge in structural reliability analysis is accurately estimating the failure probability while minimizing number of calls to the performance function. However, evaluating the performance function has significant computational costs. To enhance computational efficiency, easily computed metamodels are often utilized to substitute the performance function. Specifically, active learning reliability methods combining adaptive Kriging and simulation methods like AK-MCS (an active learning method combining adaptive Kriging and Monte Carlo Simulations) [1], which integrate the benefits of high computational efficiency of metamodels and high accuracy of simulation methods, have gained substantial attention in recent years.

Nevertheless, AK-MCS can be computationally demanding for small failure probabilities due to repeated runs of Kriging on a candidate pool with a large number of samples. To address this challenge, this paper proposes a novel active learning reliability method, termed AK-SDMCS, combining adaptive Kriging and spherical decomposition-MCS. The fundamental concept involves dividing the sample population of AK-MCS into non-overlapping subsets using a strategic spherical decomposition of the parameter space. Subsequently, Kriging is updated layer by layer through active learning while following the process of space decomposition. This approach allows for efficient active learning of Kriging, as the number of samples in the decomposed spherical rings is significantly smaller than in AK-MCS. Additionally, the number of samples in the spherical rings can be flexibly allocated based on the associated estimator variance, and hence reducing the total number of candidate samples. Furthermore, certain modifications have been implemented to enhance the computational efficiency of active learning.

Given the efficiency of active learning and the fast evaluation capability of the Kriging metamodel, the proposed AK-SDMCS method offers an implementable, accurate, and efficient option for analyzing reliability in scenarios with small failure probabilities. Moreover, AK-SDMCS maintains the generality of MCS. Three academic examples are presented to validate the effectiveness and efficiency of the proposed method.

ADVANCEMENTS IN GS4-I-ROM: A UNIFIED TIME INTEGRATION FOR COUPLED FIRST-SECOND ORDER TIME-DEPENDENT PROBLEMS

Tao Xue[1], Yazhou Wang[2], Xiaobing Zhang[1] and Kumar Tamma[3]*

[1]*Nanjing University of Science and Technology*
[2]*Technische Universität München*
[3]*University of Minnesota*

ABSTRACT

Over the years, there has been significant progress in the development of time integration algorithms for solving time-dependent problems in computational mechanics. These algorithms play a crucial role in solving first-order transient systems (e.g., fluid dynamics, heat transfer) or second-order transient systems (e.g., structural dynamics, wave propagation). Notable examples of these algorithms include LMS, composite method, and time finite element method. In previous research, Tamma's group introduced the Generalized Single-Step Single-Solve Isochronous time integration (GSSSS i-integration) approach. This innovative method allows for the direct solution of both first-order and second-order transient systems, as well as their coupled systems, without relying on separate frameworks [1]. The GSSSS i-integration is based on a three-root system that utilizes the u-v-a set of variables to adapt the two-root system (u-v system), resulting in the inclusion of a dummy variable in the scheme.
This study presents an alternative perspective on the GSSSS i-integration that starts from the u-v system and naturally extends to cover the u-v-a systems. By adopting this approach, all physics fields in both first- and second-order systems are naturally incorporated without the need for dummy variables. We demonstrate that desirable numerical features such as energy conservation, controllable numerical dissipation, second-order accuracy, and zero-order overshoot can be achieved by tuning only two algorithmic parameters. Furthermore, we integrate the proposed isochronous schemes with the proper orthogonal decomposition (POD) technique to create a unified model order reduction framework called GS4-i-ROM. This framework enables the solution of coupled problems under a single analysis, incorporating the most comprehensive set of optimal and compatible algorithms. To illustrate the effectiveness of our approach, we apply it to classical one-way and two-way coupled thermoelastic problems[2]. Through these examples, we demonstrate the adaptive procedure and numerical performance of the GS4-i-ROM approach, highlighting its improved efficiency in solving coupled problems. Ultimately, we aim to implement the GS4-i-ROM approach in studying structure/thermal/fluid interactions within computational mechanics, thereby enhancing the accuracy, efficiency, and robustness of numerical simulations involving coupled physics.

PREDICTING LINEAR AND NONLINEAR STRESS DISTRIBUTION IN COMPOSITES USING INTEGRATED CONVOLUTIONAL AND GRAPH NEURAL NETWORKS

Marwa Yacouti[*1] and Maryam Shakiba*[1]

[1]*University of Colorado Boulder*

ABSTRACT

This work introduces CompINet, a novel deep learning (DL) method to predict the linear and nonlinear stress fields in composites with high accuracy. Predicting the stress distribution in structures subjected to external loads is a crucial step in evaluating damage initiation and propagation, which are key components for structural design and optimization. While Finite Element Method (FEM) is commonly used for stress analysis, it becomes computationally expensive for complex geometries and nonlinear problems like composite materials. Thus, this study aims to propose a fast and accurate surrogate for FEM using deep learning.

Our proposed framework, CompINet, integrates graph neural network (GNN) and convolutional neural network (CNN) to predict both linear and nonlinear von-Mises stress distributions within the microstructural representation of fiber-reinforced composites. CompINet is inspired from the similarity between fiber-reinforced composite microstructures, especially the spatial arrangement of fibers and the distances between them, alongside the concept of graph neural networks. GNN is adept at capturing interactions and relationships between individual fibers, while CNN excels at extracting pixel-wise features. This combination offers a comprehensive analysis of the stress field. Moreover, particular emphasis is placed on predicting the stress distribution at the fiber/matrix interface, where a high error concentration is observed. This challenge has been addressed by incorporating a targeted physically-based method to further improve the stress field prediction. To generate the required data set, a nonlinear cohesive interface-enriched generalized finite element method (IGFEM) framework is used to simulate the microstructural representations of a fiber-reinforced composite. We assume that the fibers are linearly elastic, whereas the matrix has an elastic-plastic behavior, and we use a continuum damage relationship to predict the initiation and evolution of matrix damage. A cohesive zone model is used to simulate the interfaces. CompINet demonstrates exceptional performance and accuracy, achieving better results compared to existing DL frameworks despite using a training and validation dataset 20 times smaller. Trained with only 250 samples, CompINet achieves a mean R2 value of 0.96, emphasizing its exceptional predictive capabilities.

Quantifying epistemic uncertainties for computational predictions

ABSTRACT

This paper proposes a probabilistic model of orthonormal matrices based on the probabilistic principal component analysis (PCA). Given a sample of vectors in the embedding space, commonly known as a snapshot matrix, this method uses quantities derived from the PCA to construct distributions of the sample matrix as well as orthonormal matrices of all ranks. It is applicable to projection-based reduced-order modeling methods, such as proper orthogonal decomposition and related model reduction methods. Whereas existing methods use tangent space of a matrix manifold to carry out probabilistic modeling of reduced-order basis, the proposed method carries out the probabilistic modeling of the subspace itself. This approach helps us find the probability distribution's analytical form in certain cases. The stochastic reduced order basis (SROB) thus constructed can be used, for example, to characterize epistemic uncertainity and model-form uncertainty in particular in computational mechanics. The proposed method has multiple desirable properties: (1) it is naturally justified by a probabilistic interpretation of PCA and has analytic forms for the induced probabilistic models on related matrix manifolds; (2) it satisfies linear constraints, such as boundary conditions of all kinds, by default; (3) it has only one hyper-parameter, which greatly simplifies hyper-parameter training; (4) its algorithm is very easy to implement. We compare the proposed method with existing approaches visually in a low-dimensional example and demonstrate its performance in characterizing the uncertainty in a dynamics model of a space structure.

ABSTRACT

Stent implantation has rapidly become one of the most widely adopted endovascular treatment procedures for numerous peripheral and cerebrovascular diseases. A stent refers to a small cylindrical metallic or polymer tube, that is inserted into the blood vessel via a catheter and is subsequently expanded to prop the diseased vessel open and restore blood flow. As the vessel is distended, the contact of stent with vascular wall can create non-physiological stresses. Further, given the large displacements and geometrical nonlinearities associated with stent expansion process, the final configuration of the stent within the vessel is typically not known a priori, and can lead to lengthy interventional times and complications. Therefore, there is an immediate need to develop computational algorithms that can enable virtual planning of stent deployment.

This work proposes an efficient beam-to-shell contact framework by leveraging our previous formulations for vascular wall modelling and beam-to-surface contact mechanics [1,2]. Specifically, we recently reported a nonlinear rotation-free shell formulation that utilizes only displacement degrees of freedom to calculate both the membrane and bending mode deformations of vessel wall, while also allowing us to incorporate biologically representative nonlinear constitutive models. Additionally, we have recently reported a 3D corotational formulation to simulate a beam-to-rigid surface contact. In contrast to Total Lagrangian beam formulations, this approach separates the total motion into a rigid body component and a small local deformation, resulting in a computationally efficient formulation. In the current work, we propose to simulate stent deployment in deformable vessels by developing a fully implicit algorithm to couple the contact between the rotation-free shell element and the corotational beam element. This approach represents an efficient formulation to model stent deployment in vascular vessel as, firstly, the vessel wall is represented only via mid-plane displacement degrees of freedom and, secondly, the stent is modelled using an efficient corotational formulation. The implementation of the proposed formulation is carried out within Julia as part of our ongoing open-source developments for structural biomechanics. Following the presentation of details of the formulation and implementation, we will present several examples to illustrate the efficacy and robustness of the proposed algorithm.

SPDE-NET: NEURAL NETWORK BASED PREDICTION OF STABILIZATION PARAMETER FOR SUPG TECHNIQUE

*Sangeeta Yadav**[1]

[1]*University of Wisconsin*

ABSTRACT

We propose SPDE-Net, an artificial neural network (ANN) to predict the stabilization parameter for the streamline upwind/Petrov-Galerkin (SUPG) stabilization technique for solving singularly perturbed differential equations (SPDEs). The prediction task is modeled as a regression problem and is solved using ANN. Three training strategies for the ANN have been proposed ie supervised, L2 error minimization (global) and L2 error minimization (local). It has been observed that the proposed method yields accurate results, and even outperforms some of the existing state-of-the-art ANN-based partial differential equation (PDE) solvers such as Physics Informed Neural Network (PINN).

ABSTRACT

In recent years, substantial efforts have been dedicated towards designing acoustic metamaterials for noise attenuation across a broad frequency range. In that context, Multiresonant Layered Acoustic Metamaterial (MLAM) panels [1] offer noise attenuation at low frequencies (below 1000Hz) by leveraging the coupling effect between two resonant frequencies, resulting in notably increased noise attenuation compared to homogeneous material of equivalent mass.

This work proposes a two-phase strategy for the design of MLAM panels based on (1) a neural network-based surrogate model to efficiently assess the effective properties of individual layers computed from a homogenization approach, expediting the computation of the noise attenuation (measured as the Sound Transmission Loss), and (2) a topology optimization strategy to maximize the noise attenuation both in intensity and frequency range, while preserving a coupled STL response. The optimization strategy involves parameterizing the geometry of MLAM layers, and leveraging a genetic algorithm guided by the DNN-based models. The resultant optimized solutions exhibit noise attenuation exceeding 20 dB over 330 Hz in comparison to homogeneous materials with the same surface density.

The use of the proposed surrogate model results in enhanced accuracy in the prediction of effective properties and evaluation of the STL with respect to classical polynomial interpolation techniques, and a significant reduction in the computational cost of the optimizations when compared to direct numerical simulations, enabling cost-effective optimizations of multiple objective functions and constraints. ABSTRACT

In this study, we present a three-dimensional topology optimization method aimed at enhancing the efficiency of a two-fluid heat exchanger of a rocket engine. Given the inherent complexity and nonlinearity of the original design problem, our methodology adopts a two-step approach inspired by the previous works [1–3]: first, a low-fidelity topology optimization utilizing a Darcy flow model for rapid and stable optimization, followed by a high-fidelity evaluation in the second step. The latter involves a forward analysis incorporating a turbulence model. The results reveal that the optimized design showcases distinctive characteristics, featuring intricate flow channels that set it apart from traditional heat exchangers.

A NEW APPROACH TO CONSTRUCTING SOLVABLE PROBLEMS IN FREE VIBRATION EIGENVALUE PROBLEMS OF ELASTICITY

Takahiro Yamada[*1]*

[1]*Yokohama National University*

ABSTRACT

In various fields, dynamics problems of elastic bodies appear as structural vibrations or propagation of elastic waves. In this study, we propose a new approach to construct exact solutions of free vibration of elastic bodies and discuss the verification of numerical procedures using obtained exact solutions. Conventional exact solutions of eigenvalue problems are obtained by setting the domain and boundary conditions and searching for a solution that satisfies a partial differential equation. However, there are few problems for which the exact solution obtained by such an approach can be expressed explicitly.

In this work, two techniques are used to construct new problems with the exact solution expressed explicitly. One of them is to use the Helmholtz decomposition in elastic wave theory to decompose the problem into one expressed in terms of scalar eigenfunctions for P-wave and vector-valued eigenfunctions for S-wave. Another technique is to search for candidate eigenfunctions that satisfy the partial differential equation and derive the boundary conditions from the boundary values satisfied by these functions, instead of solving a problem with boundary conditions. From these candidate solutions, we select the ones with the numerically applicable boundary conditions and derive new problems for which exact solutions can be expressed explicitly. The obtained problems for rectangular and cylindrical domains are used to verify finite element schemes and to evaluate their numerical properties.

A CONTINUUM MATHEMATICAL MODEL FOR GENERATIVE DESIGN OF PLANAR MECHANISM

Yurika Sayo[1] and Takayuki Yamada[*1]*

[1]The University of Tokyo

ABSTRACT

Topology optimization is a useful methodology for designing the shape of structures. However, when designing a mechanism such as a link mechanism, it is necessary to specify the positions of candidate links and joints in advance. In order to achieve a generative design of mechanisms with a higher degree of freedom, it is necessary to approximate the motion of the mechanism based on the framework of a continuous system, such as continuum mechanics. To achieve this objective, a new mathematical model will be formulated.

DEVELOPMENT OF A SOCIAL SKILLS SCALE FOR CHINESE STUDENTS IN JAPAN AND JAPANESE STUDENTS IN CHINA

Airi Yamaguchi[*1] and Chieko Kato*[1]

[1]*Toyo University*

ABSTRACT

The Japanese Ministry of Education, Culture, Sports, Science and Technology (MEXT) is currently focusing on the globalization of higher education. This involves emphasizing the acceptance and retention of international students, promoting Japanese students to study abroad, and fostering the development of global human resources. In light of these circumstances, research on the social skills of international students has garnered significant attention. Social skills encompass both verbal and non-verbal interpersonal behaviors employed to respond in social situations, as well as the cognitive processes that facilitate the expression of these interpersonal behaviors. Some studies suggest that cultural understanding is better promoted when international students and host country students engage in this social skills training together. The composition of international students in Japan is predominantly Chinese, while Japanese students often opt for study programs in Europe and the U.S. This pattern implies a limited interactive exchange between Japan and China. It has been pointed out that there are differences in social skills required depending on the country of origin, culture, and country of residence. The purpose of this study was to develop a social skills scale for Chinese students in Japan and Japanese students in China. This involved employing the Social Skills Self-Rating Scale for Adults employed in Japan and a condensed version of the Chinese University-Students Social Skill Inventory (ChUSSI), commonly used among university students in China. The survey was conducted by means of an online questionnaire. The survey involved a total of 139 participants from Japanese and Chinese universities. Among them, 82 were Chinese students, and 57 were Japanese students. As a result of factor analysis using the principal factor method and promax rotation, six factors were extracted and named "inferring others," "expressing opinions," "initiating conversation," "relationship maintenance," "partner’s face," and "emotional control,". Cronbach's alpha coefficients were α=.85, .76, .78, .75, .72, and .75, respectively, indicating high internal consistency. The above results suggest the reliability of the created scale. There were factors that were compatible with the factor items of the Japanese version of social skills, suggesting construct validity. In the future, we envision the application of the social skills identified in this study to the development of social skills programs and international student education initiatives. This will involve a thorough examination of the specific contexts in which these social skills are most needed.

HYPERELASTIC CONSTITUTIVE MODELS FOR GEOMATERIALS IN SMALL STRAIN AND FINITE STRAIN: A REVIEW FROM THE ASPECT OF STABILITY

Yuki Yamakawa[*1] and Akiyoshi Ueda*[1]

[1]*Tohoku University*

ABSTRACT

This study is concerned with the stability/instability property of hyperelastic models for geomaterials. We first present the reformulation of several existing representative hyperelastic models for geomaterials with pressure-dependent bulk and shear moduli within the frameworks of small strain and finite strain. In finite strain formulation, the stress versus elastic strain relation, together with the fourth-order elastic tangent moduli tensor, in the description relative to the intermediate configuration is derived for each of the hyperelastic models. Their spatial and material descriptions are also derived. These descriptions are compatible with the multiplicative finite strain elastoplasticity. A systematic parametric study with a particular focus on the pressure-dependent property of the elastic moduli was performed to examine the constitutive response of the hyperelastic models and compare the small strain models and the finite strain models under typical cases of simple shear, pure shear, and triaxial (axisymmetric) compression. The analysis revealed significant differences in the model responses depending on the types of model, as well as on the value of material constants related to the pressure-dependency of elastic moduli. Notably, some models exhibited unexpected unreasonable decreases in stress during triaxial (axisymmetric) compression. We then examined the property of the hyperelastic models from the viewpoint of stability/instability to elucidate the mechanical cause of the above-mentioned decrease in stress. The stability criterion is defined by the positive-definiteness of the fourth-order elastic tangent moduli tensor. We therefore performed eigenvalue analysis of the elastic tangent moduli tensor, and thereby confirmed consistent correspondence between the increase/decrease in stress and the stability/instability of the material. We also discuss the significance of elasticity in the numerical computation of elastoplasticity when a hyperelastic model is combined with plasticity. Numerical examples are presented to demonstrate the important role of elasticity in providing an elastic predictor within the return-mapping scheme.

STRUCTURAL MODEL UPDATING OF STEEL FRAME FOR DISPLACEMENT PREDICTION DURING CONSTRUCTION USING DATA-DRIVEN APPROACH

Shinya Yamamoto[*1], Hideyuki Sakurai[1], Tomomi Kanemitsu[1] and Manabu Uchiyama[1]*

[1]*Shimizu Corporation*

ABSTRACT

In the construction of steel frame structures such as dome structures, numerical simulation of the structural steel erection work is conducted, and its appropriate order is determined to ensure structural stability during the construction process. However, discrepancies arise between the simulation results and observation results due to the errors related to construction accuracy. We are working on the development of a digital twin for building construction to accurately predict the behavior of structure in the process of steel erection work. Our framework employs a data-driven modeling approach to obtain the as-built model of the structure, which includes uncertainties concerning construction accuracy.
The feasibility of the proposed framework was tested using the measurement data set acquired during the construction of an actual dome structure. Based on the results of preliminary welding experiments and sensitivity analyses of the parameters in the structural model, the error sources of the as-built model were considered to be mainly derived from weld shrinkage at the joint of steel beams and the stiffness of the temporary roof support system. These properties were treated as identifying parameters with uncertainties. We sequentially updated the probability distribution of the parameters by assimilating displacement data provided from position measurements with ensemble transform Kalman filter. The displacement caused by the subsequent steel erection works was predicted by the updated model with uncertainties. The result shows that the proposed framework can reduce the prediction error compared to the conventional model without data-driven modeling.

Buckling analysis and design of thin-walled structures based on novel and intelligent computational methods

BUCKLING OF SHELL STRUCTURES BY USING THE NOVEL APPROACH

Takeki Yamamoto[1] and Takahiro Yamada*[2]

[1]*Hiroshima University*
[2]*Yokohama National University*

ABSTRACT

Shell structures are used in a wide range of fields for pressure vessels, storage tanks, submarines, and aircraft fuselages. In these structures, buckling may occur due to various loading, such as compression, bending, twisting, shearing, and internal and external pressures. For the purpose of evaluating the buckling behavior accurately, it is important to pursue the equilibrium paths. When the internal and external pressures are applied to both the top and bottom surfaces of shell structures, the behavior is different from the case where the pressure acts on either one surface.
Buckling phenomena of structures under pressure load are investigated using the finite element analysis. Toscano et al. proposed the finite element model discretized with shell elements for analyzing the buckling and buckling propagation of stiffened pipes, and verified the model by comparing the numerical results with the experimental one [1]. In this approach, the pressure load is evaluated at the midsurface of the structure. On the other hand, Zhu et al. presented the numerical calculation considering the three-dimensional finite deformation for the thick-walled cylindrical shell to evaluate the pressure load appropriately in the buckling analysis [2]. However, it needs huge computational costs in evaluating the complicated behaviors using continuum elements.
In this work, we propose a novel approach to evaluate the buckling behavior in the framework of structural elements. This approach is based on the conventional shell element, and applied to the special shell element, in which the external force is directly given to the additional nodes representing the thickness-stretch [3]. In this approach, the number of unknowns in the resulting linear system of equations coincides with that of the conventional shell elements. In the situation that a perturbative load is applied under a certain stress state, bifurcation points are searched by solving a standard eigenvalue problem.

ABSTRACT

Prediction of crack propagation and failure of the material are essential for designing engineering components. However, experimental direct observation of crack propagation inside a material is difficult. Therefore, numerical simulation of crack propagation behavior using a phase-field fracture (PFF) method has attracted much attention. On the other hand, the PFF models often require multiple parameters (e.g., interface mobility and interface energy) which are challenging to be identifed from experimental data. In this study, we develop a new data-driven method to estimate the parameters included in the PFF model by integrating experimental data and the model based on data assimilation based on Bayes' theorem (i.e., Bayesian data assimilation) [1]. In this study, the developed method was used to simulate the time evolution of crack propagation behavior and strain evolution of an asymmetrically notched aluminum alloy sheet specimen. The full-field strain evolution on the surface of the specimen obtained by the digital image correlation method was assimilated to the PFF model [2] using the DMC-TPE method [3, 4]. The results demonstrate that the parameters related to the fracture toughness and three parameters of the strain hardening law were successfully estimated.

3D MULTI-PHASE-FIELD LATTICE BOLTZMANN SIMULATIONS FOR SEMI-SOLID DEFORMATION IN THIN FILM

Namito Yamanaka[*1], Shinji Sakane[1] and Tomohiro Takaki[1]*

[1]*Kyoto Institute of Technology*

ABSTRACT

In the casting process, semi-solid deformation induces the formation of solidification defects such as band segregation. Thus, it is essential to thoroughly evaluate the semi-solid deformation behavior. Currently, X-ray in-situ observations have enabled the evaluation of the interaction between moving grains during semi-solid deformation, and it has been reported that the deformation behavior is dominated by grain rearrangement. However, the fluid flow that strongly affects grain rearrangement cannot be observed. Thus, numerical simulation is indispensable, whereas the simulation studies are insufficient, and no definitive method has been developed yet.
In our previous study [Comp. Mater. Sci. 197 (2021) 110658], a multi-phase-field lattice Boltzmann (MPF-LB) model was developed to evaluate polycrystalline solidification with fluid flow and grain motion, and was applied to semi-solid deformation. In the MPF-LB model, the contact between grains was modeled by considering the overlap between the phase-field variables, and the solid walls were modeled using phase-field variables as a solid. Through this model, semi-solid deformation with various deformation conditions was simulated. However, all simulations were limited to two dimensions. In this study, the MPF-LB model is extended to three-dimensional problems, and simple shear deformation in thin film is evaluated. Through systematic 3D MPF-LB simulations of semi-solid simple shear deformation, the relationship between solid grain rearrangement and fluid flow is investigated in detail.

SURROGATE COMPUTATIONAL HOMOGENIZATION FOR COMPOSITES CONSISTING OF MULTIPLE VISCOELASTIC MATERIALS WITH TIME-TEMPERATURE SUPERPOSITION PROPERTIES

Yosuke Yamanaka[*1], Shuji Moriguchi[1] and Kenjiro Terada[1]*

[1]*Tohoku University*

ABSTRACT

We propose a surrogate computational homogenization for viscoelastic composites by means of RBF interpolation. Nowadays, mechanistic machine learning techniques (MMLT) is incorporated into the field of computational mechanics to realize or accelerate numerical simulations for complex phenomena. The multiscale problem is one of the targets of the application of MMLT, by which several studies have achieved micro-macro two-scale analysis of composite nonlinear materials with less computational cost than that of conventional methods; see, e.g., reference [1]. To the best of our knowledge, those studies mostly owe a class of neural network, one of the deep learning methods. However, from a mathematical point of view, deep learning does not have significant advantages over shallow learning such as kernel methods in representing continuous function [2]. Therefore, NNs are not necessarily the best method for predicting mechanical behavior because the nonlinear multiscale problem is completely continuous. In this regard, we employed radial basis function (RBF) interpolation, a shallow learning method to globally interpolate a lot of discrete data as was done in our previous study[3], to create a surrogate model that can replace the entire microscopic analysis in the two-scale problem of viscoelastic composites. In other words, the macroscopic stress of a viscoelastic composite is represented by the created surrogate model in consideration of the dependencies on strain rate and temperature.

The proposed method is validated through numerical examples. First, by conducting numerical material tests (NMTs) on a representative volume element consisting of multiple viscoelastic materials, we obtain a data set representing the macroscopic constitutive relationships for various deformation patterns. Second, using the data set, we create a surrogate model by performing RBF interpolation. Third, for validation purposes, the responses of the surrogate model are compared with the results of NMT that has been performed with unseen loading and temperature histories. Finally, a FE analysis is performed as macroscopic simulation by utilizing the surrogate model, and the result is compared with that obtained by direct numerical simulations to demonstrate the validity of the present methodology.

NOVEL METHOD FOR DESIGNING STIFFENERS BY SIMULTANEOUS OPTIMIZATION METHOD OF SHAPE AND TOPOLOGY

Daiki Yamane[*1] and Masatoshi Shimoda*[1]

[1]*Toyota Technological Institute*

ABSTRACT

Stiffeners are structural elements with superior mass-to-stiffness ratio and are widely utilized in the engineering structures. Determining the optimal layout and size of stiffeners without relying solely on the designer's intuition has attracted much attention in recent years. Previous researches have focused on finding the optimal layout under the pre-prepared height and thickness or optimizing the height and thickness under the pre-prepared layout.

In this study, we propose an optimal stiffener design method that automatically finds the optimal layout and shape of stiffeners at the appropriate locations without any prior preparation from a bulk solid structure using simultaneous optimization method of shape and topology. A SIMP (Solid Isotropic Material with Penalization) based topology optimization method is used for strategically placing stiffeners within the specified design domain, while the non-parametric shape optimization method is used for determining the optimal shape of stiffeners. The objective function, compliance, is minimized under several constraints; the equilibrium equation for designing the stiffener, the total volume, the maximum height and the width. A fictitious equilibrium equation is also introduced to control the width of the stiffeners efficiently.

After formulating this simultaneous design optimization problem, the shape and density sensitivity functions are derived using the Lagrange multiplier method and the adjoint method. The shape and density sensitivity functions are applied to the vector-type(1) and the scalar-type H1 gradient method(2),(3), respectively, which provides the detail determination of optimal shape and topology. The introduction of the both types of H1 gradient method serves a dual purpose, enabling the achievement of a smooth optimal external shape of the stiffeners while concurrently addressing inherent issues related to grayscale and checkerboard patterns, as well as reducing the objective function. Several numerical examples prove the effectiveness of the proposed method.

THE INFLUENCE OF FAMILY ENVIRONMENT ON PERSONALITY

Kazuma Yamane[*1], Eiichi Yubune[1] and Chieko Kato[1]*

[1]Toyo University

ABSTRACT

Introduction
Research on human character and personality has been ongoing for many years. A frequently debated question is how these personalities are formed. It is now common to believe that heredity and environment mutually influence personality through experiments with twins. The family environment is often cited as an environment that influences personality. One well-known example is Bowlby's attachment theory. This theory suggests that attachment relationships in infancy also influence future relationship formation and psychological health. The purpose of this study is to investigate the family environment on personality and to consider the causes of the influence to help discover and develop methods to reduce the unfavorable influence of the family environment on personality.

Method
Approximately 130 male and female undergraduate and graduate students, both physically and mentally healthy, attending Toyo University participated in the study. A psychological test using the Tokyo University Egogram TEG and a questionnaire survey using a domestic atmosphere diagnostic test will be conducted together to examine the correlation between the two.

Result
Overall correlation and multiple regression analyses did not show these relationships. However, in the Nurturing Parent (NP) dominant group, Free Child (FC) and warmth in the home and Adapted Child (AC) and brightness in the home were moderately correlated. Approximately 30 other combinations showed moderate correlations (0.4 or higher).

Conclusion Discussion
Persons with low FC are generally considered to be depressive. Although limited to the NP-dominant group, a warm and democratic home environment can be expected to foster a high FC personality. It was suggested that FC could be enhanced by increasing warmth and democracy in the home. Also, by examining the impact of these influences, it may be possible to find factors that increase or decrease FC.

Further challenges
The number of samples was too small to examine the correlations in many cases, but discoveries may be made in the future when a larger number of samples are secured and correlations are examined. It is also necessary to investigate the causes of the influence of the family environment on personality in the future.

SURROGATE MODELING FOR EFFICIENT SEISMIC DISASTER SIMULATION USING DETAILED FINITE ELEMENT ANALYSIS

Takuzo Yamashita[*1] and Jun Fujiwara*[1]

[1]*National Research Institute for Earth Science and Disaster Resilience*

ABSTRACT

We have developed an E-Simulator, a numerical simulation designed to replicate the damage and collapse behavior of structures during major earthquakes. Given the high computational cost, using the E-Simulator for regional seismic disaster prediction is impractical. To address this, we are developing a surrogate model for detailed finite element (FE) analysis of building structures.

Surrogate modeling using machine learning is a growing field, but generating large training datasets for large-scale simulations is challenging. Our approach trains individual components of the target structure, allowing us to generate a feasible dataset and assemble these components into a complete structural model.

This study introduces a surrogate model for a structural member unit consisting of beams, columns, and a connection. We employ a recurrent neural network with proper orthogonal decomposition to reduce the dimensionality of the neural network's input and output nodes. The model effectively replicates physical fields such as displacement, stress, and strain from nonlinear FE simulations, maintaining high accuracy with minimal loss.

Our work demonstrates the potential of surrogate models in computational mechanics, offering a practical solution for large-scale structural simulations in seismic response analysis.

A PHYSICS-INFORMED OPERATOR LEARNING FRAMEWORK INSPIRED BY THE FINITE ELEMENT METHOD FOR PREDICTION OF DYNAMICS PHYSICAL PHENOMENA: CASE STUDY ON TRANSIENT HEAT CONDUCTION

Yusuke Yamazaki[*1], Ali Harandi[2], Stefanie Reese[2], Mayu Muramatsu[1] and Shahed Rezaei[3]*

[1]*Keio University*
[2]*RWTH Aachen*
[3]*Access e.V.*

ABSTRACT

In this study, we present a novel physics-informed operator learning framework that allows for predictions of evolutionary physical phenomena described by a time-dependent partial differential equation using a loss function inspired by the finite element method (FEM). Transient thermal conduction is considered to demonstrate the performance of the present framework. For the thermal problem, the networks take a temperature field at the current timestep as input and predict a temperature field at the next timestep. The Galerkin-discretized weak formulation of the heat equation is employed to incorporate physics into the loss function, which is coined finite operator learning (FOL) [1]. Furthermore, we introduce an additional term to the loss function with the aim of restricting the evolution speed of temperature fields over time. After sufficient training, the networks successfully predict temperature evolution over time for unseen cases even after multiple timesteps at high accuracy compared to the solution by FEM. We also confirm the applicability of the framework to cases with heterogeneous heat conductivity and various timestep sizes.
The advantages of the proposed FOL framework are summarized in the following two points: first, the training of the networks is performed completely in an unsupervised manner, in which, in contrast to data-driven deep learning models, one does not need to prepare a huge data set from costly simulations or experiments. Instead, a data set of random temperature patterns generated by the Gaussian random process and the Fourier series in combination with constant temperature fields is used as training data to cover a wide range of possible temperature cases. The other important feature is that shape functions and backward difference approximation are exploited for spatial and temporal discretization, respectively, resulting in a pure algebraic equation analogous to data-driven loss functions. This allows for enhancing training efficiency, as one avoids time-consuming automatic differentiation when optimizing weights and biases.

The present FOL framework for dynamic systems could be extended to other types of dynamic partial differential equations, such as the Allen-Cahn and Cahn-Hilliard equations that describe dynamic phase separation.

DATA-DRIVEN DIGITAL TWIN FOR DYNAMIC STRUCTURES BASED ON REDUCED-ORDER MODELS AND MACHINE LEARNING

Bo Yan[*1], Qingshan Wang[1], Mao Deng[1] and Yingbo Gao[1]*

[1]*Chongqing University*

ABSTRACT

A data-driven method for digital twin of dynamic structures based on reduced-order models and machine learning algorithm is proposed. High-fidelity finite element (FE) models reflecting the undamaged and damaged states of a physical structure during service are established, and model order reduction method is then used to project all the high-fidelity FE models into reduced-order models. A dataset is created from the numerically simulated dynamic responses of the reduced-order models under calibration loads. Using the numerically determined strains at the locations where sensors will be placed on the physical structure as input data, a machine learning algorithm is used to train the model selector, which will infer the real-time state of the physical structure during service utilizing the sensor data. Digital twin based on the Krylov subspace model order reduction method and the random forest algorithm is presented. Physical structure of a spatial frame was built to experimentally and numerically illustrate the efficiency of the digital twin. Effects of the difference among various states of the structure, sensor arrangement and calibration load on the classification accuracy of the trained model selector are investigated. It is discovered that: (1) The presented method is suitable for structures subjected to dynamic load, and the Krylov subspace model order reduction method is efficient for reducing the order of structural dynamic equations. (2) The digital twin can be updated online if its response time is shorter than the sensor sampling time, and can be updated offline if its response time is longer than the sampling time. The digital twin can operate during any period of time and in any damaged and undamaged state during structure service. It is not necessary to operate the digital twin uninterruptedly. (3) The amplitudes and frequencies of calibration loads should cover all the possible values of the excitation loads the structure subjected to during service. (4) Sensor arrangement scheme play a key role for the classification accuracy of model selector. The closer the sensors to the damage zone the better the accuracy. Sensors far away from the damage zone are not beneficial and even jeopardize the accuracy. (5) The effects of uncertainties regarding material properties and geometrical features of the structure, operation parameters, loading and environment as well as noise in sensor data need to be studied in the future.

LEVEL-SET ASSISTED ENRICHED IMMERSED BOUNDARY METHOD FOR STEFAN PROBLEM WITH APPLICATIONS TO ADDITIVE MANUFACTURING

Jinhui Yan[*1]*

[1]*University of Illinois Urbana Champaign*

ABSTRACT

Stefan problem is ubiquitous in many engineering problems such as welding, heat exchangers, and additive manufacturing. However, it is challenging to solve Stefan problem involving the moving material interface with conventional numerical methods while preserving boundary accuracy and mesh flexibility. In this talk, we introduce the level-set assisted enriched immersed boundary method to track the fluid-solid interface and enforce the critical Neumann boundary conditions accurately on the material interface. The main feature is to generate the interfacial surface which is independent of the volumetric computational domain with a level-set field based on the Neumann boundary condition for the fluid-solid interface and duplicates the DoFs at the interfacial domain to enforce Dirichlet and Neumann boundary conditions. We will present a set of examples to show the proposed approach in phase transition problems and additive manufacturing and the comparison it with existing methods will be also presented.

A REPARAMERIZATION OF TOPOLOGY OPTIMIZATION USING PINN AND CNN FOR STRESS AND FREQUENCY OPTIMIZATION

Shengyu Yan[*1] and Jasmin Jelovica*[1]

[1]*The University of British Columbia*

ABSTRACT

Topology optimization (TO) represents a forefront methodology in structural optimization, facilitating the discovery of innovative and optimally tailored structural solutions. These solutions cater to diverse objectives and constraints, while not being bound by preconceived shapes. However, TO's application is predominantly confined to high-integrity or small-scale structures, constrained by its substantial computational demands and limited capabilities in managing complex objective/constraint functions. Additionally, as a non-convex optimization problem, TO's solution optimality can be further enhanced through achieving superior local optima.

This work address these TO challenges by integrating machine learning (ML) techniques, specifically focusing on accommodating complex objective functions such as p-norm von Mises stress and eigenvalues. The integration of various ML approaches into TO has been explored, ranging from models that predict structural responses to comprehensive ML strategies that directly optimize designs. Informed by the pioneering work of Hoyer et al. [1] and Zhang et al. [2], this study introduces a novel reparameterization of topology optimization utilizing physics-informed neural networks (PINNs) and convolutional neural networks (CNNs). This approach is devised to simultaneously minimize the maximum von Mises stress and maximize the first natural frequency of structures.

Significant reductions in computational cost have been achieved through the implementation of advanced sparse solvers and modified constraint handling techniques. The newly implemented reparameterization has led to the discovery of enhanced designs for both stress-based and vibration-based TO applications, showcasing the potential of ML in pushing the boundaries of traditional topology optimization.

SIMULATION OF ROLLING CONTACT FATIGUE UTILIZING A PHASE FIELD MODEL

Sikang Yan[1], Jochen Hebel*[2], Matthias Krug*[2] and Ralf Müller*[3]

[1]*University of Kaiserslautern Landau*
[2]*Thomas Magnete GmbH*
[3]*TU Darmstadt*

ABSTRACT

Fatigue failure is one of the most crucial issues in manufacturing and engineering processes. Repeated cycles can cause cracks to form and grow over time, eventually leading to structural failure. To avoid these failures, it is important to predict fatigue crack growth by simulation methods. In the past decade, the phase field method for fatigue fracture has drawn a lot of attention for its uniform description of complicated crack evolution behaviors. However, there is still a lack of studies on the applicability to industrial problems. In this work, we use the phase field fatigue model to analyze the rolling contact fatigue tests.

A DISTRIBUTED COMPUTING FRAMEWORK FOR MODEL-FREE DATA-DRIVEN METHODS

Wei Yan[*1], Maoyuan Jiang[2] and Jie Yang[1]*

[1]*Wuhan University*

[2]*Hubei Key Laboratory of Theory and Application of Advanced Materials Mechanics, Wuhan University of Technology*

ABSTRACT

Model-free data-driven methods provide a new computing diagram for solving boundary value problems (BVP) in computational mechanics[1]. This paradigm can bypass the explicit material modeling by directly incorporating material data into BVP solution. The computational complexity of this paradigm mainly arises from data search, especially in high-dimensional phase space. However, the amount of material data required for the data-driven computing grows exponentially with the number of dimensions. The dramatic increase in data volume and computational complexity exceeds storage and computing capabilities of most single PC. To overcome such a problem, we have developed a distributed computing framework for model-free data-driven methods.

The distributed computing framework can coordinate multiple computers to process high-dimensional data. The Hadoop Distributed File System (HDFS)[2] is introduced to split a large-scale material dataset into small data blocks and store them on different computers. The MapReduce computing engine[3] is used to process material data search in parallel on multiple computers. First, a global data search task is mapped to each data block with excuting the local distance calculations in parallel. Then, all local distance data are aggregated and sort. Finally, the results are merged into the output of the global nearest data and the minimized distance.

A 3D elasticity test case was used to examine the performance of the distributed computing framework built on a cluster of three computers. As the size of datasets increases, the advantages become apparent due to parallel computation on multiple computers. We used this distributed framework to perform the data-driven computing on a material datasets up to 400 million points of twelve-dimensional data. This work shows that the distributed computing framework is essential for developing the model-free data-driven algorithms for large-scale high-dimensional problems.

HIGH-FIDELITY MODELING OF MULTI-MATERIAL ADDITIVE MANUFACTURING

Wentao Yan[*1]*

[1]*National University of Singapore*

ABSTRACT

Additive manufacturing possesses promising capabilities of fabricating new materials by mixing multi-material powders and manipulating chemical compositions. In this talk, we will present our latest work on high-fidelity modeling of the complex additive manufacturing process: from powder spreading to melting. To evaluate the mixture uniformity of the powder layer/stream, we employ the computational fluid dynamics (CFD) and discrete element method (DEM) coupling method to simulate the powder spreading/blowing processes of mixed multi-material powders. To thoroughly understand the material composition distribution in the melting procedure, we develop a multi-physics thermal-fluid flow model to simulate the different melting/flow/solidification behaviors of different powders as well as the interactions between solid powders and molten pool. Various scenarios are simulated from micro-/nano-particle reinforced composites to in-situ alloying for new materials. All these models are validated against experiments, and show appealing potentials to provide guidance for additive manufacturing of mixed powders.

MULTI-PHYSICS FIELD-DRIVEN INVERSE DESIGN AND MANUFACTURING FRAMEWORK FOR MECHANICAL METAMATERIALS ACCELERATED BY NEURAL OPERATORS

Ziming Yan[*1], Xiang Li[2], Zhanli Liu[1] and Zhuo Zhuang[1]*

[1]*Tsinghua University*
[2]*Hainan Normal University*

ABSTRACT

Mechanical metamaterials derived from phase separation patterns of spinodal decomposition have garnered attention due to their lightweight, high-strength and tunable mechanical properties. Generally, the spatiotemporal evolution of spinodal decomposition can be characterized using the Cahn-Hilliard equation. However, the computational challenges in numerically solving the 3D Cahn-Hilliard equation, such as high computational complexity and the need to maintain numerical stability, significantly impede the design of the metamaterials with desired mechanical properties. To overcome these challenges, this study proposes a multi-physics field-driven inverse design and manufacturing framework significantly enhanced by advanced neural operators. A Cahn-Hilliard with anisotropic diffusion parameters is utilized to analyze the solution patterns in the frequency domain through Fourier transformation. Then, a novel Fourier neural operator model is developed to simulate diverse anisotropic phase separation patterns, accounting for varying diffusion parameters, initial conditions, and boundary conditions. Specifically, the architecture of the model uniquely combines three-dimensional spatial field transformation in the frequency domain with temporal encoding using the self-attention mechanism, ensuring rapid and accurate prediction of concentration fields. This approach directly integrates anisotropic diffusion parameters, initial conditions, and boundary conditions as model inputs, enabling it to predict concentration fields across various time points with remarkable computational efficiency and accuracy, representing a significant leap over traditional numerical methods of PDEs. Moreover, the relationship between phase separation patterns and desired mechanical properties is discussed. Utilizing anisotropic diffusion parameters and evolutionary time as inputs, a multilayer perceptron (MLP) based on physical parameters is built to predict the corresponding mechanical properties, facilitating inverse identification of optimal diffusion and evolutionary time parameters through a proposed global optimization algorithm. The practical application of the proposed method in metal additive manufacturing is demonstrated, particularly in fabricating personalized medical implants from Ti6Al4V tailored to match the orthotropic mechanical properties of natural bones. The proposed method achieves a rapid, physics-driven inverse design, eliminating inexplicable design variables of traditional generative machine methods and substantially improving generalization performance. This study establishes a new paradigm in designing and manufacturing mechanical metamaterials derived from parametric PDEs, offering a robust and efficient pathway for broad application across engineering fields.

COMPUTATIONAL EMOTION MECHANICS AND INQUIRY PROCESS

Hideyoshi Yanagisawa[*1]

[1]*University of Tokyo*

ABSTRACT

Inquiry stands as an essential human activity embedded in scientific research, creation and education, steered by emotions such as curiosity and interest. We propose a mathematical model encapsulating these emotions, using information gains derived from the principle of free energy minimization. Free energy, representing prediction errors with the uncertainty inherent in the Bayesian brain, diminishes through recognition and learning, generating information gain and inducing positive emotions. The psychological concept of arousal potential indicates that an optimal level of arousal induces positive emotions. Two kinds of curiosities are identified, namely diversive and specific, which are instrumental in achieving the optimal arousal level that maximizes positive emotion. Free energy or surprise signifies emotional arousal. We model the curiosities using information gains resulting from reductions in free energy during recognition and learning. We propose that the alternate maximization of these information gains defines an ideal inquiry cycle, guiding toward the optimal arousal level, with curiosity serving as the driving force propelling this cyclic process. By employing the Gaussian generative model supplemented by a uniform likelihood, we found that information gains manifest as an upward-convex function of arousal (surprise) with an optimal arousal level. We comprehensively analyzed the effects of prediction uncertainty (prior variance) and observation uncertainty (likelihood variance) on the peaks of the information gain function, considered as optimal surprises. The results show that greater prediction uncertainty, indicative of an open-minded attitude, and reduced observational uncertainty, signifying precise observation with focused attention, are expected to provide greater information gains across a broader spectrum of exploration. The proposed mathematical framework unifies the free energy principle of the brain and the arousal potential theory. It explicates emotional valence as an information gain function, proposing an idealized inquiry process driven by epistemic emotions.

NUMERICAL MODEL OF A STEEL END-PLATE MOMENT CONNECTION USING A NOVEL CYCLIC LOADING PROTOCOL

Jorge Pi Luco[1], Sergio Yanez[1], Miguel Medalla Riquelme[2], Juan Carlos Pina[1] and Carlos Felipe Guzmán[1]*

[1]*University of Santiago of Chile*
[2]*Universidad de los Andes*

ABSTRACT

Bolted connections are an efficient solution for erecting steel elements in buildings and industrial structures in regions with high seismic activity. The performance of these connections depends on factors such as the number of bolts, the thickness of the plate, the presence of stiffeners, and others, which can cause the connection to fail in a brittle or ductile manner. This performance is even more crucial when earthquakes occur in subduction zones. Given their profound impact on structural performance, there is a pressing need for research into novel moment connection configurations. This study addresses this gap by proposing a new loading protocol tailored to assess the performance of bolted end plate moment connections under the damage induced by mega-earthquakes in subduction zones. Through numerical modeling, bolted moment connections subjected to both monotonic and cyclic loads are analyzed using the finite element method. The loading protocol introduces an alternating vertical displacement at the free end of the beam, progressively increasing in amplitude between load steps. Contact interactions between connected parts allow for separation between the end plate and the column flange. An increase in the Plastic Deformation Index (PEEQ) was observed when the plate thickness is reduced by 25%. Furthermore, the Rupture Index (RI) exceeds unity for all bolts, indicating crack formation. A novel loading protocol that integrates the damage caused by mega-earthquakes in subduction zones offers a comprehensive understanding of the structural response of various steel beam-column bolted end-plate connections with diverse bolt configurations. Finally, the stress-strain response of the connections was obtained to propose new design considerations for seismic-resistant structures.

FAILURE DAMAGE ANALYSIS OF UHWMPE/PET FOAM SANDWICH STRUCTURES UNDER HIGH-VELOCITY IMPACT

Bin Yang[*1]

[1]*University of Edinburgh*

ABSTRACT

The present work deals with the high-velocity impact (HVI) behaviour of composite sandwich structures based on experimental and numerical method. The composite sandwich structure consists of two ultra-high molecular weight polyethylene (UHWMPE) laminates and a PET (polyethylene terephthalate) foam core. A series of HVI tests were conducted on the UHWMPE/PET foam sandwich structures to investigate the HVI performance and damage mechanisms. Micro-computerized tomography (μCT) characterization method was used to detect the internal damage patterns in the sandwich structures. A finite element model (FEM) was developed which Puck's failure criteria simulates intra-layer failure, cohesive law simulates inter-layer failure and the crushable foam plasticity model combined with ductile damage criterion simulates the foam failure. After validation of the proposed model by experimental results, the damage mechanism of the sandwich structures under HVI loading was examined, and the effects of impact velocity on the failure patterns and residual velocity were discussed.

Several key conclusions from this study are summarised as follows:
1. Circular hole-type damages were only observed on the upper panel, even though the impactor penetrated the composite sandwich structure. On the lower panel, only linear crack-type damage along the fibre direction were generated due to the rebound of the stretched fibres after the impactor penetrated.
2. Generally, the peak impact force and energy absorption values increase with higher impact velocity. However, when the impact velocity is less than the critical value (Critical velocity =200 m/s for the composite sandwich structure in the study), both the impact force load and energy absorption values remain relatively stable and are not significantly influenced by variations in impact velocity.
3.Foam cores in composite sandwich structures generate an upward rebound force during HVI when they are compressed to a certain extent, resulting in the appearance of a third peak in the impact load curve and absorbing more energy.
4.The presence of UHMWPE fibre interspersed in the panel tended to inhibit the spread of damage in the impacted region. Only matrix tension damage showed noticeable propagation during HVI, and matrix tension damage increased with the impact velocity, reaching a plateau when the velocity exceeded 250 m/s.

DTN BOUNDARY CONDITION BEM AND FEM

Chen Yang[*1], Yongmao Pei[1], Jiaqiong Liu[1], Sohichi Hirose[2], Zhenghua Qian[3] and Bin Wang[3]*

[1]Peking University
[2]Tokyo Institute of Technology
[3]Nanjing University of Aeronautics and Astronautics

ABSTRACT

Wave scattering emerges in many applications such as sonar, radar, antennas, seismic exploration, crack detection, satellite imaging, and microscopy. Dirichlet-to-Neumann boundary conditions (DtN bc) are often encountered in wave scattering calculations. By effectively handling DtN nonreflecting bc, the amount of computation is reduced to a certain extent, and the stability and accuracy of calculation will be significantly improved. These advantages are further amplified especially in high-frequency computations. In this paper, DtN boundary condition BEM and FEM are proposed in typical infinte structures, such as infinitely long pipe, infinite plate, half-space and infinite domain. In our proposed method, DtN boundary condition at artificial interfaces will be used to construct the linear mapping matrix of displacement and force, which will be incorporated into BEM and FEM as a modified term.

A STABILIZED MIXED-FORM MATERIAL POINT METHOD FOR FREE SURFACE FLOW MODELING

Cheng-Chun Yang[1], Cameron Rodriguez[1] and Tsung-Hui Huang[1]*

[1]*National Tsing Hua University*

ABSTRACT

The material point method (MPM) can effectively model engineering problems under large structural deformation with potential material separation. The Lagrangian particle description, adopted with a background Eulerian-style approximation in MPM, bypasses the mesh entangling issue commonly seen in mesh-based approaches. However, when MPM is applied to free surface flow problems with Navier-Stokes equations, it may suffer from volumetric locking and pressure oscillation due to the imposition of the incompressible condition, similar to other conventional numerical methods. In addition, the well-known MPM cell-crossing effect will affect the solution accuracy. To address these issues, a stabilized Galerkin mixed-form MPM is proposed to circumvent the numerical artifacts arising from incompressibility. Furthermore, the locking issue can be relaxed by revisiting the semi-Lagrangian kinematics [1] of MPM, deriving a corrected velocity update scheme. Last but not least, the reproducing kernel (RK) approximation [2] is employed to mitigate cell-crossing instability. The proposed algorithms are proven to be effective in solving a series of benchmark problems.

SHIFTED BOUNDARY METHOD FOR FLOW SIMULATIONS OVER COMPLEX OBJECTS

Cheng-Hau Yang[1], Guglielmo Scovazzi[2], Adarsh Krishnamurthy[1] and Baskar Ganapathysubramanian[1]*

[1]*Iowa State University*
[2]*Duke University*

ABSTRACT

The Shifted Boundary Method (SBM) [1, 2] is a novel variant of the immersed method to perform simulations in complex domains without using boundary-fitted meshes. Traditional computational fluid dynamics (CFD) methods face challenges in mesh generation and imposing boundary conditions accurately due to complex geometries. SBM addresses these issues by applying boundary conditions on a surrogate boundary with the boundary conditions changed appropriately using Taylor expansions. Conventional immersed boundary methods, such as the Finite Cell Method (FCM) and Immersogeometric Analysis (IMGA), require integration at the true boundary. On the other hand, in SBM, the boundary conditions are imposed by integrating at the Gauss points along a surrogate boundary, which aligns with the existing mesh structure. Additionally, SBM avoids the requirement of adaptive quadrature in intercepted elements, a common requirement in FCM and IMGA for accurate volume integration, thus simplifying the parallel implementation process. One of the standout benefits of SBM is its capability to resolve the issue of sliver cut cells, which often leads to poor conditioning of the stiffness matrix and challenges in numerical stability in other methods.

Recent advancements in SBM have extended its application to octree mesh frameworks [3], revealing the crucial role of selecting an optimal surrogate boundary in minimizing the error. This optimization has demonstrated significant benefits in solving Poisson and linear elasticity equations. In this study, we extend the application of SBM to tackle the Navier-Stokes equation using octree-meshes and an optimal surrogate boundary. We validate the method's efficacy through fluid dynamics benchmark cases, including flow around circular geometries and spheres, lid-driven cavity flow with a circular obstacle, and various aerodynamic problems at different Reynolds numbers. Our findings underscore SBM's robust capacity to address complex geometries in solving Navier-Stokes equations, showcasing its potential as a powerful tool in the realm of CFD for tackling complex geometries.

PROBABILITY DENSITY INTEGRAL EQUATION FOR UNCERTAINTY PROPAGATION AND TIME-VARIANT MOMENT FUNCTIONS OF STRUCTURAL RESPONSES

Dixiong Yang[*1], Junwen Wang[1] and Guohai Chen[1]*

[1]*Dalian University of Technology*

ABSTRACT

Stochastic dynamic system follows the principle of probability conservation, which means when the randomness of system propagates and evolves from the input to output response, the probability measure determined by initial random source remains invariant. The principle of probability conservation presents two kinds of form, namely stochastic differential form and integral form. Based on the principle, this paper derives the probability density integral equation (PDIE) which is a stochastic integral form by using two ways. Then, several typical probability density evolution equations are derived through PDIE, namely, the Liouville equation, Fokker-Planck-Kolmogorov equation, Dostupov-Pugachev equation, and generalized probability density evolution equation, which are stochastic differential equations. This derivation reflects that the PDIE is fundamental equation characterizing the randomness propagation of system. Further, new time-variant moment functions of the system response are deduced from PDIE. Moreover, the calculation formulas of correlation functions of several random responses with multiple instants in input space are given for the first time. Finally, typical examples verify the correctness of the derived formulas and demonstrate the time-varying moment functions of responses of interest.

ABSTRACT

Coronary microvascular dysfunction (CMD) is caused by impaired microvascular vasodilatation, leading to insufficient supplement of blood, oxygen, and nutrients to the myocardium [1]. The index of microcirculatory resistance (IMR) serves as a quantitative measurement of coronary microcirculatory function, and is currently considered as the gold standard [2]. Despite its benefits, the invasive nature of IMR assessment using an intravascular guide wire has led to its underutilization in current clinical practice. Consequently, a non-invasive, computationally efficient approach for accurate IMR assessment is highly desired.

In this study, a data-driven framework is proposed to (1) leverage the information encapsulated within angiography data, the primary modality for assessing coronary artery disease, and (2) computationally assess IMR based on angiography data. A multi-physics computational fluid dynamics (CFD) model of contrast injection is developed and calibrated to generate computational angiography data, providing a tool to interpret the dynamics of the contrast injection and washout within the coronary arteries. An encoder-based convolutional neural network is constructed to learn the correlation between the dynamics of the contrast and IMR, which is also derived from the CFD models. Results demonstrate that the computational CFD model effectively simulates the process of iodine contrast injection and yields meaningful computational angiography data. Furthermore, the data-driven framework presents a non-invasive, rapid, and accurate approach for IMR assessment.

PRECONDITIONED B-SPLINE-BASED FINITE ELEMENT METHOD WITH UNFITTED MESHES FOR KIRCHHOFF PLATE

Han Yang[1], Wenquan Yuan[1], Chenguang Li[1], Fanke Wu[1] and Zhijun Liu[1]*

[1]*Lanzhou University*

ABSTRACT

B-splines are gaining popularity in finite-element approximations for solving fourth-order systems, such as Kirchhoff plate bending problems. This is due to their ability to not only provide exact geometric representations of curved domains (similar to the isogeometric concept) but also achieve higher global continuity with relative ease. However, the standard B-splines can only be constructed on Cartesian grids, which causes mesh cutting for complex domains and difficulties in imposing the Dirichlet boundary condition. Furthermore, difficulty in constructing high-quality mesh for complex domains facilitates the use of unfitted meshes. Unfitted finite element methods (FEMs) have been widely applied to second-order partial differential equations (PDEs), but their applications for fourth-order PDEs are rare. In this paper, we propose an unfitted FEM based on B-splines for the Kirchhoff plate problem, which is a typical fourth-order problem. A preconditioner based on global normalization and local Gram–Schmidt orthogonalization of bases is used to eliminate the ill-conditioning induced by mesh cutting. Besides, trimmed surface analysis is employed for the curved boundaries accurately.

The overall performance of the proposed methodology was evaluated through detailed numerical experiments of biharmonic equations and Kirchhoff plate bending problems. The methodology demonstrated excellent accuracy and optimal convergence. The proposed preconditioner effectively suppresses the ill-conditioning caused by the extreme cut and keeps the conditioning number at a very low level stably. The result demonstrates that the conditioning numbers and accuracies are approximately independent of how the mesh is cut by the model.

AN INTEGRATED TOPOLOGY AND TOPOGRAPHY OPTIMIZATION FRAMEWORK FOR BUCKLING PERFORMANCE ENHANCEMENT OF THIN-WALLED STIFFENED STRUCTURES

Haotian Yang[*1], Renjing Gao[1] and Shutian Liu[1]*

[1]*Dalian University of Technology*

ABSTRACT

For thin-walled structures widely used in industry, external pressure and axial compression are common load cases and buckling is a key design consideration. The traditional method improves structural stability by designing stiffeners, but neglects their stiffness. Therefore, an integrated optimization design approach for base surface and stiffeners of thin-walled structures under uniform external pressure and axial compression is presented to improve stiffness and stability in this paper. In the first step, the Non-Uniform Rational B-Spline (NURBS) technique is used to parameterize the base surface, and then the control parameters are used as variables to change the shape of the base surface. In the second step, the Heaviside-function based Directional Growth Topology Parameterization (H-DGTP) is utilized to simultaneously optimize the layout and height of the stiffeners. In addition, the buckling load factors are computed by linearized buckling analysis, the lower bound of which is constrained to ensure the structural stability. By solving the optimization problem, the shape of base surface and the design of the stiffeners can reach a desirable match such that the structural stability is ensured and the stiffness is also optimized. The effectiveness of the proposed approach is demonstrated with numerical examples.

ELECTRO-CHEMO-MECHANICAL DEGRADATION OF NCM CATHODE MATERIALS: FROM POLYCRYSTAL TO SINGLE CRYSTAL

Hui Yang[*1]*

[1]*Huazhong University of Science and Technology*

ABSTRACT

Ni-rich transition metal layered oxides (NCMs) have been identified as the promising lithium-ion batteries (LIBs) cathode materials for their high reversible capacity. However, during electrochemical cycling, NCMs always suffer from fast structural degradation, leading to the inevitable performance fading of LIBs, which severely restricts their large-scale practical applications. Understanding the underlying mechanism of structural degradation is critical for the successful design of NCM structures with significantly enhanced cycling stability. Herein, an electro-chemo-mechanical model is developed to investigate the lithiation/delithiation cycling behaviors of both polycrystalline and single crystalline NCM cathode materials, including phase transformation, morphological change, stress generation, and damage evolution, based on which the underlying failure mechanism is uncovered. The new insight gained by this study is further adopted to guide the construction of NCMs from the aspect of surface modification to structural design, effectively promoting their cycling performance.

A TIME-DEPENDENT COLLOCATION FRAMEWORK FOR MULTI-PHASE COUPLING PROBLEMS WITH GEOMETRY EFFECTS

Judy Yang[*1] and I-Ting Liao*[1]

[1]*National Yang Ming Chiao Tung University*

ABSTRACT

In this work, a collocation framework is proposed for incremental-iterative analysis of double-diffusive natural convection problems in a porous enclosure on the basis of reproducing kernel collocation method. To untangle the nonlinear coupling problems, the forward difference method and Newton-Raphson method are adopted for temporal discretization and iteration, respectively. For verification purpose, the average Nusselt and Sherwood numbers are computed and compared with the reference solutions in the literature. The robustness of the proposed framework is demonstrated through solving various double-diffusive natural convection problems with satisfactory accuracy and efficiency.

HYBRID BI-LEVEL FILTERING METHODS FOR INVERSE PROBLEM AND DATA ASSIMILATION IN GEOPHYSICAL APPLICATIONS

Juntao Yang[*1], Jeff Adie[1], Simon See[1] and Gianmarco Mengaldo[2]*

[1]NVIDIA

[2]National University of Singapore

ABSTRACT

Bayesian inverse problems and data assimilation are prevalent in various applications, including subsurface modeling and weather data assimilation. Traditional statistical approaches, such as the Markov Chain Monte Carlo (MCMC), Ensemble Kalman Filter (EnKF), and Particle Filter, have been very successful in solving such problems but are often computationally expensive due to the repeated sampling of high-fidelity forward solvers. Alternatively, deterministic approaches also incur high computational costs as they require repeated solutions of the forward model and additional costs for solving adjoint models for gradient in the optimization loop. Recent advancements in deep learning-based surrogate models, such as DeepONet and Fourier Neural Operator, have demonstrated potential in significantly accelerating the solving of inverse and data assimilation problems. However, these pure data-driven approaches often fail to conserve physical quantities due to the absence of physical information. Although models like Physics-Informed Neural Networks attempt to address this issue, they are challenging to train and do not guarantee physical conservation, especially for complex problems with multiple data and physical constraints.

To better incorporate physical information in a different approach while using AI models, we proposed a hybrid bi-level MCMC approach to accelerate the solving of Bayesian inverse problem with accuracy comparable to pure numerical results. In this talk, we will first review some recent AI surrogate models for geophysical applications such as subsurface model and weather forecast. Then with the consideration of utilizing these advanced yet imperfect AI surrogate models, we will present the theoretical and computational framework of hybrid bi-level MCMC method and also extend the hybrid approach to the filtering methods such as EnKF and particle filter. In essence, we run two parallel MCMC chain or two level of filter algorithm with both AI surrogate model and numerical model. The GPU-accelerated AI surrogate model will run a long primary MCMC chain with a large number of samples, thereby reducing sampling error. And another shorter chain with much less numerical samples will correct the bias error from the primary MCMC chain with non-physical conserved AI surrogate model. We will demonstrate our approach through numerical experiments on some canonical mathematical examples as well as applications of bi-level filtering methods (EnKF and Particle filter) to simplified subsurface models, weather prediction models. In conclusion our hybrid methods allows the usage of current state of art AI models for practical application prior more robust physics informed machine learning methods become available.

IMPROVEMENT OF PREDICTIVE ACCURACY FOR REDUCED ORDER MODEL IN APPLICATION OF EULERIAN-LAGRANGIAN SIMULATIONS USING POSTERIOR ERROR ESTIMATION

Kai-en Yang[*1], Shuo Li[1], Guangtao Duan[1] and Mikio Sakai[1]*

[1]*The University of Tokyo*

ABSTRACT

Multi-phase flows involving solid particles are widely studied by Eulerian-Lagrangian (E-L) simulations. Conventionally, such simulations are usually performed by discrete element methods coupled computational fluid dynamics (DEM-CFD). However, its applications easily suffer from high computational cost due to the huge amount of particles and complex physical equations.
Recently, with the advancements in data-science, development of surrogate model (SM) is extensively studied in numerical simulations for its advantage of high computational speed. It holds significant potential to tackle the computational cost challenge. One standing-out SM is the reduced order model (ROM). It is a typical SM that simplifies the original model mathematically through dynamics identification techniques such as proper orthogonal decomposition (POD). Previously, the preliminary adequacy and applicability of ROM on reconstructing granular systems with fluid-solid flows have been reported [1-2].

However, how to improve the predictive accuracy of SM on granular systems with violent fluid-solid flows remains unknown and challenging [3]. This is due to the lack of consistency between the high-fidelity model and SM caused by insufficient training data. As a result, the predictive accuracy can be easily deteriorated. This necessitates trial-and-error processes to find sufficient training data, which hinders the industrial applications.

To address this issue, this study newly reveals a finding that the data density is a key to improve the predictive accuracy through a posteriori error estimation. Sequentially, a novel technique for deciding the data density of SM is proposed. Specifically, a feasibility index is proposed to anticipate the predictive accuracy. Consequently, it is demonstrated that when the training data density is determined under proposed feasibility index > 2, the consistency of granular dynamics between SM and high-fidelity model can be guaranteed. Employed in the standing-out SM, reduced order model (ROM) for a bead mill simulation, this technique enables the successful decision of sufficient training data, resulting in the remarkable predictability (relative error < 5%) with an acceleration more than 1500 times compared to DEM-CFD. This technique offers a new approach to improve the predictive accuracy for SMs in applications of E-L simulations without trial-and-error.

MULTISCALE MODELING OF SEISMIC WAVE PROPAGATION UNDER MULTIDIRECTIONAL SHAKING

Ming Yang[1], Giuseppe Buscarnera[1] and Mahdi Taiebat[2]*

[1]*Northwestern University*
[2]*University of British Columbia, Vancouver*

ABSTRACT

Nonlinear deformation analysis of seismic site response under multidirectional shaking requires representative constitutive models that accurately capture the intricate material behavior characteristics of such complex shearing conditions. This poses a significant challenge for existing advanced sand constitutive models, which are often formulated, developed, and refined based on laboratory experiments involving unidirectional cyclic shearing. While continuous refinement of these constitutive models to address the complexities of multidirectional shaking is possible, the discrete element method (DEM) provides an alternative approach to bypass such extensive efforts. Particle assemblies prepared by DEM effectively encapsulate the crucial aspects of the response of granular materials under multidirectional loading.

This study develops a multiscale modeling framework that hierarchically couples a global-scale finite element method (FEM) for resolving hydromechanical feedback with a local-scale DEM solver, which can adequately replicate the sand deformation response under dynamic loading. This approach addresses the modeling challenges of sand deposits subjected to multidirectional shaking. The effectiveness of this framework is first evaluated by simulating benchmark examples, including 1D consolidation and cyclic simple shear tests. This framework is then validated by modeling centrifuge experiments that involve the dynamic response of a soil column under both uni- and multidirectional shaking. The simulations reveal the more detrimental effects of multidirectional shaking, including the accumulation of higher excess pore pressure and induction of larger settlement, compared to unidirectional shaking. The simulation results are also compared with experimental measurements, including acceleration history, spectral response, excess pore water pressure development, and subsequent vertical settlement. These comparisons demonstrate the capability and reliability of the multiscale modeling framework in accurately capturing the complex behavior of sand deposits under multidirectional shaking.

A THERMODYNAMICALLY CONSISTENT PHASE-FIELD-MICROMECHANICS MODEL OF MICROSTRUCTURE EVOLUTION IN SINTERING-BASED ADDITIVE MANUFACTURING

Qingcheng Yang[*1] and Arkadz Kirshtein*[2]

[1]*Shanghai University*
[2]*Tufts University*

ABSTRACT

Sintering is a pivotal technology for processing ceramic and metallic powders into solid objects in additive manufacturing. A profound understanding of microstructure evolution during sintering is essential for manufacturing products with tailored properties. While various phase-field models have been proposed to simulate microstructure evolution in solid-state sintering, correctly incorporating the densification assumption—where particles move toward each other by rigid body motion—remains a challenge.

The fundamental obstacle lies in the ad hoc treatment of particle motion, where the thermodynamical driving force cannot be derived from the system's free energy. In this work, we present a novel phase-field-micromechanics model for sintering. We relax the rigid body assumption, allowing powder particles to mechanically deform through surface and grain-boundary tensions. Subsequently, a unified energy law is defined, and the governing equations for microstructure evolution in sintering are derived using variational principles.

Our approach ensures thermodynamic consistency, with the driving force for particle motion derived from the system's free energy. Consequently, the proposed phase-field-micromechanics model guarantees the evolution of microstructure in a direction that reduces the system's energy. We rigorously validate this model against recent benchmarks of theoretical analysis.

MODE-SWITCHING METAMATERIALS ACHIEVING ASYMMETRIC, NON-RECIPROCAL, AND ADJUSTABLE POISSON'S RATIOS THAT BREAKS THERMODYNAMIC LIMITS

Qingsheng Yang[*1] and Aijie Tang*[1]

[1]*Beijing University of Technology*

ABSTRACT

While metamaterials with unconventional Poisson's ratios have been extensively explored for their counterintuitive and desirable properties, most exhibit only a single behavior. Here, we design novel metamaterials capable of both positive and negative Poisson's ratios, which simultaneously demonstrate outstanding performances: asymmetric, non-reciprocal, and even exceeding thermodynamic limits. These abnormal properties are achieved by combining honeycomb and re-entrant structures with self-contacting stops set at different positions. The unique topology allows for mode switching, where the unit cell can transition between "honeycomb" and "re-entrant" configurations under different load conditions. This mode convertibility endows the metamaterials not only different signs of Poisson's ratios under various load conditions in a single direction but also anisotropy in orthogonal directions. Through theoretical analysis, the deformation modes and the corresponding Poisson's ratios are predicted. Experiments and simulations then validate the intriguing Poisson's ratios and the model predictions. Notably, these Poisson's ratios can be further tailored by adjusting the initial states of the self-contacting stops, offering a powerful tool for manipulating Poisson's ratios and unlocking new functionalities of metamaterials.

MESOSCALE STUDY OF POLYMER PYROLYSIS USING COARSE-GRAINED MOLECULAR DYNAMICS SIMULATIONS

Vinh Phu Nguyen[1], Inseok Jeon[1], Seunghwa Yang[1] and Seung Tae Choi[1]*

[1]Chung-Ang University

ABSTRACT

A deep understanding of how polymeric materials break down under heat is crucial for designing effective thermal protection systems. However, gaining this understanding involves grappling with complex phenomena that occur at various spatial and temporal scales. To bridge the gap between the many detailed simulations and broader modeling approaches in existing literature, we undertake an innovative mesoscale investigation of the pyrolysis process using coarse-grained molecular dynamics (CG MD) simulations. In this study, we use atomically bonded polyethylene (PE) with implicit hydrogen as a representative model for polymers. The changes in PE composition during thermal decomposition are modeled by incorporating bond-breaking phenomena based on either bond energy or bond length criteria. To refine the protocol for bond dissociation, cook-off simulations are implemented to compare reaction products with ReaxFF simulations. This approach extends to simulating aerobic high-thermal pyrolysis under extensive oxygen bombardment on a nanoscale. This allows us to observe intricate phenomena occurring from the material's surface to its depths. Mesoscale simulations effectively predict the intrinsic thermal durability of model polymers under extreme conditions, regardless of the presence or absence of an oxygen environment. These predictions provide crucial thermal degradation characteristics necessary for broader-scale degradation and removal simulations. This work represents an initial exploration into understanding polymer pyrolysis at the mesoscale, contributing to a deeper comprehension of the concept on a larger scale.

AN IMMERSED BOUNDARY APPROACH FOR FLUID-STRUCTURE INTERACTION SIMULATION USING THE MATERIAL POINT METHOD

Wen-Chia Yang[1] and Yu-Ting Lin*[1]

[1]*National Chung Hsing University*

ABSTRACT

The Material Point Method (MPM) has proven effective in modeling large deformation scenarios and in tackling complex fluid-structure interaction challenges. This method is potentially a valuable tool for understanding structural behavior during extreme events such as tsunamis, flash floods, and debris flows. In these scenarios, the dimensions of structural components, like beams and columns, are often significantly smaller than the computational domain, leading to inaccuracies in stress distribution within particle-represented structural elements when grids are sized according to the domain scale. To address this, Yang's (2016) immersed boundary approach for MPM is extended into a contact algorithm between beam-column elements and MPM computational grids. It treats beam-column elements as velocity boundary conditions during grid evolution phases and updates these elements during the particle updating phases. This algorithm integrates smoothly into the MPM framework with minimal changes to existing MPM codes. The presentation will explore the procedures of this contact algorithm in MPM with beam-column elements, its validation through two-dimensional simulations involving frictional sliding and impact loads on beams, and conclude with a demonstration of a complex two-dimensional water-structure interaction problem, showcasing the algorithm's capabilities.

NUMERICAL SIMULATION FOR THE REACTIVE MULTIPHASE FLOW IN POROUS MEDIA DURING THE CARBON CAPTURE AND STORAGE PROCESS

Wenxin Yang[*1], Hai Sun[1], Lei Zhang[1], Dongyan Fan[1], Shuaishi Fu[1], Junjie Zhong[1] and Jun Yao[1]*

[1]*China University of Petroleum*

ABSTRACT

In recent years, the extensive using of fossil fuels has led to a substantial release of greenhouse gases, resulting in a pronounced warming trend in the Earth's climate. To mitigate the process of global climate warming, Carbon Capture, Utilization, and Storage (CCUS) projects have gained prominence, with the efficient sequestration of CO2 into geological formations becoming a focal concern. In the process of CO2 sequestration, the permeation behavior of CO2 in water crucially determines its storage capacity and rate. On the one hand, the dissolution of CO2 in water increases the storage capacity. On the other hand, some rocks in the formation, such as glauberite, will dissolve under the combined action of carbon dioxide and water, thereby increasing the storage space of carbon dioxide. To comprehensively investigate the various influencing mechanisms in the CO2 sequestration process, pore-scale simulations offer an effective approach, allowing for a microscopic examination of mechanisms and a systematic analysis of influencing factors to further guide the sequestration of CO2. The lattice Boltzmann method, as a mesoscale approach, efficiently facilitates multiphase and multiscale coupling, enabling the treatment of complex solid-liquid/gas-solid boundary conditions. Thus, in this study, the lattice Boltzmann method was adopted for research purposes.

In this study, a new LB model was built to consider the effect of both CO2 dissolution in water and salt dissolution mechanisms on the CO2 storage process. What’s more, the CST-LB model was adopted to describe the interfacial mass transfer, and the VOP method was used to update the structure of porous media. The impacts of factors such as wettability, salt concentration, and porosity on the CO2 sequestration process were comprehensively explored. The results indicate that, during the displacement and dissolution processes of CO2 in the aqueous phase, an increase in CO2 concentration in water leads to the gradual dissolution of some soluble salts in the solid phase. But there are some risks. While this expands the storage space for CO2, the dissolution of soluble salts results in the phenomenon of breakthrough points between CO2 and water, forming preferential channels that cause a substantial outflow of CO2. Additionally, when the wettability angle of the rock phase is greater, after CO2 displacement, some water remains in the porous medium, reducing the CO2 storage space and consequently diminishing sequestration capacity. This study provides crucial guidance for the sequestration of CO2.

A NEW PARADIGM FOR UNCERTAINTY QUANTIFICATION USING THE KOOPMAN OPERATOR

Bian Li[1], Yi-An Ma[2], Nathan Kutz[3] and Xiu Yang[*1]*

[1]Lehigh University
[2]University of California, San Diego
[3]University of Washington

ABSTRACT

We propose a new uncertainty quantification (UQ) framework for dynamical systems with random parameters. Unlike conventional UQ approaches in which a set of basis functions associated with random variables are used to construct a surrogate model of the quantity of interest (QoI), our new method uses the eigenfunction and eigenvalues of the Koopman operator of the system to construct the surrogate. The advantage of this new approach is that the eigenpairs of the Koopman operator incorporate key features of the dynamics, hence it can be more efficient in capturing behavior of the system. Empirically, our approach exhibits exponential convergence if the solution is smooth. The approach does not use time integration algorithms like the Runge-Kutta scheme as the statistics of the QoI relies on the moment-generating function of the random variable in the system. In addition to this intrusive approach, we will present a non-intrusive method that is compatible with most sampling strategies from Monte Carlo simulation to probability collocation method. This non-intrusive method reuses the computed eigenfunctions and eigenvalues of the underlying system's Koopman operator to reduce the computational cost dramatically. Moreover, for stochastic dynamical systems with additive noise like stochastic differential equations, our approach can directly evolve moments, which helps to evaluate the system's statistics, e.g., mean, variance, skewness, efficiently. Finally, our algorithms enable parallelization for solving dynamical systems with or without uncertainties from a new perspective. We will demonstrate the accuracy and efficiency of our new methods using ordinary and partial differential equations.

RESIDUAL STRESS PREDICTION IN LPBF USING A FINITE VOLUME METHOD BASED COUPLING FRAMEWORK

Xuan Yang[*1], Biao Li[1] and Yazhi Li[1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

Residual stress generated in laser powder bed fusion (LPBF) process is a key factor impairing the integrity and reliability of additively manufactured engineering structures. This work proposed a novel finite volume method-based coupling framework to predict the integrated thermal-fluid-metallurgical-mechanical behaviors during LPBF process. The framework directly unifies the high-resolution fluid flow and solid deformation/stress simulations in LPBF, which enables the fast residual stress simulation at track scale, and facilitates a thorough investigation into the effects of microstructures and solidified geometry profiles on residual stress fields. Various operating conditions including single-track, multi-track and multi-layer were simulated to explore the spatiotemporal variations of thermal stress and final residual stress fields. And the influences of solid-state phase transformation and pores defects were clarified. The metallographic and the nanoindentation experiments were separately carried out on the well-crafted samples to evaluate the microstructure and RS fields. Comparisons between the simulations and experiments demonstrated a dependable similarity, which validates the effectiveness of established framework for full-process and multi-physics modeling of LPBF. The findings of this work will enhance the comprehension of RS origination and offer practical instructions for RS prevention in the LPBF manufacturing.

INVERSE PROBLEM PREDICTION BY USING THE BEM AND DNN

Yang Yang[*1] and Yijun Liu[2]*

[1]Shenzhen MSU-BIT University
[2]Southern University of Science and Technology

ABSTRACT

An approach for solving the inverse problem of computational mechanics is developed by the data driven algorithm in conjunction with model driven method based on BEM. The inverse problem is formulated as a regression problem, which extracts the solution of highest probability through machine learning (ML) from a large amount of data. The efficiency and accuracy of data generation is guaranteed by using the BEM, which also actualizes the data compression by means of dimensionality reduction. The efficiency of this approach is illustrated by two examples. First, five-step damage identification including damage detection, location, classification, extent and prediction is carried out. The boundary strains of the forced structures are collected by the elastostatic BEM, which is also easy to collected though the strain gauge sensors settled on the boundaries of the monitored structures. A series connection neural network algorithm composed of classification and regression NN models is established to accomplish complete 5-stage damage identification. Next, acoustic localization is presented. Acoustic pressure on microphone array and source plane is analyzed by the acoustic radiation BEM. The mapping relationship is constructed by a CNN model. A high precision about 99% can be achieved for both of two examples by the present algorithm and which is also feasibility to apply in the actual structural health monitoring and acoustic localization.

A NEW COMPUTATIONAL FRAMEWORK OF FPM BASED ON MATRIX DECOUPLING

Yang Yang[*1], Xu Fei[1] and Li Yaoyu[1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

Finite Particle Method (FPM) is a significant improvement to the traditional SPH method, which could effectively improve the accuracy in the interface or the boundary region. In traditional FPM format, the numerical iteration scheme for solving higher order derivatives was creatively transformed into the calculation of the derivatives simultaneously through linear equations, while the resulting long computational time has become a major obstacle to its development. In this paper, a new computational framework of FPM was proposed based on matrix ecoupling, in which the kernel function information, the particle distribution information and the function information could be clearly decoupled. Based on this framework, some new FPM improvement formats and their derived combination formats were proposed under different assumptions, and then were successfully applied to some typical numerical examples.

CURING INSTABILITY ON INTERFACE TRACKING UTILIZING WEAKLY IMPOSED DIRICHLET CONDITIONS

Yundong Yang[*1] and Jaewook Nam*[1]

[1]*Seoul National University*

ABSTRACT

Understanding the behavior of interfaces in engineering processes involving fluids is crucial. One such industry is secondary battery manufacturing, which utilizes the coating process. Numerical computation is used to reproduce the interface in this process, which includes a liquid-gas interface with a high aspect ratio, presenting several challenges.

One of the main challenges is the instability of the liquid-gas interface caused by oscillatory behavior along the computational domain. Fluctuations in the pressure field generate wiggles in the interface, which amplify over time. This instability resembles the "checkerboard mode" observed in various flow simulations [1].

The instability occurs when the Dirichlet condition excessively restricts the degree of freedom of interfacial nodal displacement. The interface tracking technique requires a no-penetration condition for the liquid-gas interface, restricting only the displacement in the surface's normal direction. However, additional conditions that limit the tangential direction are commonly used for computational convenience.

A method that weakly imposes the Dirichlet condition, such as Nitsche's method, is commonly used to address this issue in remeshing including the elastic mesh update method [2]. Nitsche's method retains the advantages of Lagrange multiplier and penalty methods, providing variational consistency and a symmetric linear system.

This study modifies Nitsche's method by restricting only the normal direction with a penalty term. It aims to investigate the impact of this relaxation of restrictions on the transient behavior and instability of the interface using a 2D model problem that incorporates the aspect ratio and characteristics of the coating process. The study also aims to empirically determine the influence of the penalty parameter and select the optimal value. The findings of this study could provide insights into the behavior of liquid-gas interfaces and contribute to stable interface simulations in various processes.

PREDICTION OF STRUCTURE-PROPERTY LINKAGES IN HIGHLY PARTICLE-FILLED POLYMER COMPOSITES UNDER VARIOUS STRAIN RATES AND TEMPERATURES USING THE MACHINE LEARNING

Zheng Yang[*1], Rui Liu[2] and Pengwan Chen[2]*

[1]North University of China
[2]Beijing Institute of Technology

ABSTRACT

In the study of highly particle-filled polymer composites (HPFPCs), the complexity of their microstructure makes it difficult to predict their mechanical properties using standard numerical calculation methods. This study employs machine learning techniques to effectively predict the effective mechanical properties of HPFPCs under various microstructures, such as effective elastic modulus and peak strength. The initial step in the study was the design and establishment of a relevant dataset for HPFPCs, which is crucial for assessing the role of machine learning. To create a comprehensive and effective dataset, the research involved analyzing Scanning Electron Microscope (SEM) images, from which we can extract the dispersion of particles within HPFPCs, including details about particle size, distribution, and volume fractions. Additionally, mechanical parameters were obtained using our in-house nonlinear finite element numerical framework. Subsequently, several neural network models were designed and implemented specifically for this problem. Utilizing our established training set, these neural network models were trained and tested. The study conducted a comparative analysis to evaluate the effectiveness of different neural network models in predicting the material structure-property relationships of HPFPCs under varying strain rates and temperatures. Furthermore, the research explored how hyperparameters in the neural network models, such as activation functions, loss functions, and structural hyperparameters, affect the prediction accuracy. The findings indicate that neural network models, particularly those based on image recognition technology, are highly effective in revealing the mechanical properties of HPFPCs. Our work explored the combining advanced machine learning with traditional analysis to predict the mechanical properties of HPFPCs. As to the future work, by designing and building a new comprehensive dataset, we can extend the HPFPCs problem to more advanced machine learning models like Vision Transformers. Meanwhile, we aim to automate our hyperparameter tuning process, which could be applicable to other similar machine learning problems in material science.

A ROM-ACCELERATED ENSEMBLE TRANSFORM FILTER FOR DATA ASSIMILATION OF NONLINEAR DYNAMICAL SYSTEMS

Geoff Donoghue[1] *and Masayuki Yano**[1]

[1]*University of Toronto*

ABSTRACT

We present an ensemble transform filter (EnTF) accelerated by hyperreduced-order models (HROMs) to enable rapid and reliable data assimilation of large-scale dynamical systems that exhibit strong nonlinearities. The filter estimates the state of the system using a mathematical model based on nonlinear unsteady partial differential equations (PDEs) and noisy, sparse observations. Our formulation builds on two key ingredients. The first is the EnTF [1], which generalizes the standard ensemble Kalman filter (EnKF) to stronger nonlinearities by constructing a nonlinear transport map between the filtering and analysis distributions. However, the EnTF scales poorly with the state dimension and requires a large state ensemble, which renders it cost prohibitive for large-scale PDE-governed dynamical systems. To overcome this computational challenge, we introduce the second key ingredient: HROMs constructed using proper orthogonal decomposition and the empirical quadrature procedure [2]. The HROMs (i) significantly reduce the state dimension, which mitigates the scaling issue of the transport map, and (ii) reduce the cost of ensemble simulation in the forecast step, which enables the use of a larger ensemble. Moreover, we analyze the stability issue that arises when EnTF is applied to HROMs that use a modal state representation, and devise a strategy to stabilize the filter. We apply the filter to unsteady, compressible, separated flow over an airfoil in the presence of synthetic velocimetry data. We demonstrate that the combination of the EnTF and HROM enables nonlinear filtering of the PDE-governed dynamical system, and assess the efficacy of the nonlinear EnTF relative to the standard EnKF.

WEAR ANALYSIS AND OPTIMIZATION DESIGN OF THE ROPE SHEAVE WHEEL MECHANISM

Dongyan Shi[1], Shijie Yao[1], Renjie Huang[1], Shuo Xing[1] and Bingnan Sun[1]*

[1]Harbin Engineering University

ABSTRACT

With the continuous improvement of modern transmission equipment, lifting mechanism has been widely used, among which the rope sheave lifting mechanism because of its small size, strong closing, high transmission efficiency, high timeliness, convenient and other characteristics, is widely used in high-altitude operation combat, building inspection and maintenance and life transportation and other important fields.However, the rope sheave structure is still designed based on experience and experimental test results. There is little research on the mechanical properties between the flexible rope and the rope sheave and the composite wear of the rope. Therefore, this paper builds a mathematical model of static rope composite wear based on the basic wear law,and optimize the flexible rope sheave wheel lifting mechanism.Firstly, the nonlinear equations with single objective and multiple parameters are established by mathematical model, and the structural parameters of rope sheave wheel are designed by ASA algorithm to minimize the compound wear of static rope.Secondly, based on the optimization design of rope sheave wheel system performance, the multi-objective equations of lifting force, composite wear and rope sheave wheel structure parameters are established. NSGA-Ⅱ algorithm is used to optimize the design of rope sheave wheel structure parameters, so that the static rope compound wear is minimized and the rope wheel system performance is optimized.It provides theoretical guidance and design basis for more precise application of flexible rope sheave wheel lifting mechanism.

MULTI-OBJECTIVE OPTIMIZATION OF PIEZOELECTRIC ENERGY HARVESTERS FOR POWER GENERATION AND SENSING IN STRUCTURAL HEALTH MONITORING

Shuai Yao[1], Elena Atroshchenko[1], Mehrisadat Makki Alamdari[1] and Andres Felipe Calderon Hurtado[1]*

[1]*University of New South Wales*

ABSTRACT

As infrastructure such as bridges plays an increasingly important role in social operations, structural health monitoring (SHM) implemented by wireless sensing devices has become the main way to protect human safety and property. However, long-term and real-time data transmission poses challenges for the energy supply of sensors. Piezoelectric energy harvesters (PEHs), as green devices capable of harvesting universal and stable mechanical vibrations, have the potential to address the constraints of unsustainable energy supply in SHMs. On the other hand, piezoelectric materials are commonly used as actuators and sensors to provide sensing functions, but the energy-harvesting effect of piezoelectric materials has been ignored. Therefore, this study explores the multifunctional integration of PEHs, combining energy supply and sensing. PEHs are modelled as cantilever structures based on Kirchhoff-Love plate theory and Isogeometric Analysis (IGA) to obtain accurate and efficient simulation results. In addition, the sensing process aimed at detecting bridge damage is based on the voltage signal generated by PEHs during energy harvesting. Then the Wavelet Synchro-squeezed transform (WSST) is applied to obtain damage features after the pre-processing of the voltage signal. Moreover, WSST images are used as the input of an unsupervised learning algorithm, namely convolutional variational autoencoders (CVAE), for label-free training and identification of bridge damage severity and location. It is worth mentioning that both the simulated signals from the vehicle-bridge interaction (VBI) model and collected signals from a real bridge in Australia are employed to demonstrate the practicability of this study in actual engineering. In order to further improve the sensing and energy harvesting capabilities of PEHs, the shape optimization based on the Particle Swarm Optimization (PSO) algorithm retrieves the optimal geometric configuration under multi-objectives, achieving the optimal self-powered sensing system based on PEHs.

A CHEMO-MECHANICAL COUPLED PHASE FIELD MODEL FOR STRESS CORROSION CRACKING

Weian Yao[1], Xiaofei Hu[1], Lang Min[1] and Zhi Sun[1]*

[1]*Dalian University of Technology*

ABSTRACT

A thermodynamically consistent framework for chemo-mechanical-fracture coupled model is presented in this contribution to simulate the stress corrosion cracking (SCC) process. The film rupture mechanism is used to simulate SCC process, the dissolution process of the metallic material is governed by a diffusion-convection equation. To overcome the numerical oscillation problem stemmed from the standard Galerkin finite element procedure when convection term is in dominate, a streamline upwind Petrov-Galerkin (SUPG) finite element method is adopted in this work. The fracture process is simulated by using the facture phase field method, the degradation effects of corrosion on mechanical properties is considered and investigated. The proposed model is validated through several numerical simulation examples.

PROBABILISTIC MODELING AND SAMPLING OF CONSTITUTIVE LAWS FOR HYBRID COMPOSITE MATERIALS USING PROBABILISTIC LEARNING ON MANIFOLDS

Roger Ghanem[1], Venkat Aitharaju[2], Zhengtao Yao[1] and Philippe Hawi[1]*

[1]University of Southern California
[2]General Motors Research Center

ABSTRACT

In this paper we describe the application of Probabilistic Learning on Manifolds for constructing constitutive laws for complex material systems. These laws can be synthesized either from a training dataset obtained either from experimental data or from a high-fidelity simulation that resolves sub scale details. This experimental dataset is used to synthesize a joint density function for tuples of stress, strain, microscope characteristics, and damage. For damage, we use both strain energy density as function of strain, and the toughness of the specimens. For microscale characteristics we use mechanical properties of fibers and resin.

Once the joint density function is constructed, conditioning on strain values produces the probability density function of stress values. Probabilistic scatter of these stress values is attributed to unobserved (unspecified) properties of micro-constituents and damage. Alternatively, by conditioning on fiber properties, the probability density function of damage quantities can be calculated. In this manner, sensitivity of probabilistic quantities of interest to any observable can be assessed.

ABSTRACT

We propose an immersed-boundary approach, based on five-point integrated radial basis function (IRBF) stencils and smooth extension of the solution, for solving the two-dimensional elliptic partial differential equation (PDE) in a geometrically complex domain. The discretisation is simply based on a rectangular Cartesian grid, which does not conform to the geometry of the domain. High-order accuracy is achieved by including nodal derivative values in local IRBF approximations, and forcing the solution to be globally smooth in the entire encompassing domain. In solving for the smooth extension of the solution, the constants arising from the process of integrating the RBFs are utilised to include the boundary values of the derivatives in the IRBF approximations, which enables high-order PDEs in the extension domain to be enforced at every interior node. Numerical experiments will demonstrate that the approach provides a simple, efficient and high-order immersed boundary scheme which can solve problems with smooth and non-smooth boundaries.

ABSTRACT

We are developing a simulator technology for chemical reactors that leverages both data and domain knowledge. Conventionally, reactor simulation uses pure physics-based models which can be challenging to build when the reactions involved have complex or unknown kinetics. Meanwhile, recent works based on data-driven approaches can only generate black box models which do not give insight on actual reaction pathways.

Against this background, we adopted a data-driven model that uses differential equations for chemical reactors called “Chemical reaction neural network” (CRNN) [1]. The CRNN was designed to follow basic physical laws, such as the law of mass action and Arrhenius law, generating an explainable data-driven model. It discovers kinetic models and predicts concentrations; however, its scope is limited to constant-temperature reactors.

In this study, we propose a dynamic temperature CRNN (DT-CRNN) which extends the application of the original CRNN to reactors with dynamic temperature. In this extension, instead of forcing a constant temperature output data as in the previous approach, we add time-series temperature as input data to the neural network calculation. We specifically feed temperature data in the evaluation step of the neural network as ordinary differential equations. In this way, the DT- CRNN captures the underlying behavior of reactor temperature while maintaining the simple architecture of the original CRNN. We specifically study a hypothetical batch reactor equipped with a temperature control system for two irreversible and exothermic reactions as target reactor to evaluate the proposed DT-CRNN [2].

Results show that DT-CRNN could closely approximate the reaction equations of the target reactor. The kinetic parameters were also estimated within 2% error. Moreover, the accuracy of the simulated concentrations did not drastically change when the measured concentration data for training was reduced from every 1min to every 60min. Overall, results suggest the effectiveness of the DT-CRNN for building reactor models even with time-varying temperature data and limited concentration measurements. Combining the DT-CRNN with a temperature prediction model is left as future work.

MODELS AND METHODS FOR CONTACT MECHANICS AT THE ROUGHNESS SCALE

Vladislav Yastrebov[*1]*

[1]*MINES Paris - PSL, CNRS*

ABSTRACT

In the modeling and simulation of numerous engineering systems involving contact, friction, wear, and lubrication, surfaces are often assumed to be smooth and well-described by the associated CAD models. However, in some particular cases, surface roughness must be taken into account, either through a special constitutive interface model or in a more explicit manner. In either case, both for constructing relevant constitutive tribological models and for direct numerical simulation, it is necessary to properly characterize surface roughness and incorporate it into computational models. At the same time, it is important to use material and friction models relevant to the considered scale. The complexity of the arising problems stems from the multiscale nature of roughness, the lack of scale separation, and the necessity to handle the problem in three-dimensional space.

In this talk, we will provide a brief overview of the available methods, including the FEM (finite element method) and the BEM (boundary element method) in classical, FFT, and fast-BEM formulations constructed on hierarchical or H-matrix concepts. Additionally, we will present a combined FEM/BEM approach that enables handling the contact problem in a non-intrusive way, as an auxiliary one. Some examples of multiphysical coupling strategies for thermo-electro-mechanical contact problems will be demonstrated.

Apart from the methodological aspects, we will discuss models capable of accounting for the effect of roughness on the evolution of the true contact area, static friction, electrical and thermal conductivity, and fluid transmissivity. The presentation will conclude with a discussion on the future challenges and opportunities in the field.

FROM VEHICLE BRIDGE INTERACTION TO VEHICLE-SCANNING METHOD FOR BRIDGE MONITORING

Jong-Dar Yau[*1] and Shota Urushadze*[2]

[1]*Tamkang University*
[2]*Czech Academy of Sciences*

ABSTRACT

Vehicle-Bridge Interaction (VBI) happens when a vehicle crosses a bridge, leading to vibrations in both the vehicle and the bridge [1]. The Vehicle-Scanning Method (VSM) [2] uses these vibrations to understand the bridge's condition. It's like using the vehicle as a moving sensor to pick up information about the bridge, such as its natural frequencies and mode shapes. From a theoretical analysis, VSM also simplifies VBI, making it easier to understand and interpret the interaction between the vehicle and the bridge. It separates the responses of the vehicle and the bridge, based on the idea that the vehicle's weight doesn't really affect the bridge's vibration. Compared to traditional bridge inspection methods, VSM has several benefits. It's cost-effective, doesn't disrupt traffic, can be used continuously, and can be easily scaled up. In short, VBI is a complex but interesting area of research with real-world applications for bridge engineering. It's the foundation for developing VSM, a promising way to monitor and assess the health of bridges. But we need more research to better understand and use VBI and VSM.

AXISYMMETRIC VIRTUAL ELEMENTS

Louie Yaw[*1]*

[1]*Walla Walla University*

ABSTRACT

Recent research extends the capabilities of the virtual element method (VEM) by introducing axisymmetric virtual elements. Axisymmetric virtual elements are achieved by modifying a 2D VEM formulation by augmenting the strain displacement matrix to include tangential strains. Mean value coordinates (MVC) are utilized to provide the required ingredients while still allowing for concave and convex elements. Element volume is properly accounted for by using the volume of revolution associated with each element. Axisymmetric problems of elasticity and plasticity are successfully solved and compared to benchmark problems. For certain classes of solid mechanics problems, the ability to use an axisymmetric virtual element is computationally more efficient than an otherwise required 3D discretization. Very good results are also demonstrated for problems of near incompressiblity. Results and future research directions are discussed at the conclusion of the presentation.

DUCTILE FRACTURE ASSESSMENT IN TI-6AL-4V ALLOY FABRICATED BY ELECTRON BEAM MELTING (EBM)

Mohammad Hossein Shaterzadeh Yazdi[1], Pouria Bahrami Ataabadi*[2], Larissa Driemeier[2] and Marcilio Alves[2]*

[1]*FEI University*
[2]*Universidade de São Paulo*

ABSTRACT

Additive Manufacturing (AM) has introduced in a new era of complex and optimized geometries, necessitating an in-depth exploration of the mechanical behavior of AM components. This research investigates into the Ti-6Al-4V alloy manufactured through Electron Beam Melting (EBM), as AM technique. Employing a hybrid experimental-numerical approach, the study focuses on evaluating and modeling Ductile Fracture (DF) under diverse loading conditions.

Three ductile fracture models, the Johnson-Cook (JC), Modified Mohr-Coulomb (MMC), and Hosford-Coulomb (HC) models, are employed to simulate fracture behavior. Simulations are developed using ABAQUS software. The JC model is available on software library, and the MMC and HC model were implemented through VUMAT subroutine. The JC model excels in compression cases, while the MMC and HC models demonstrate superior performance in positive triaxiality situations. Seeking a comprehensive model, an extended MMC model is proposed to predict fractures under both negative and positive triaxiality, displaying an average error of less than 7% when compared to experimental results. This modification introduces novel conditions, enhancing the model's applicability across a broader spectrum of scenarios.

This study advocates for the adoption of the proposed ductile fracture model, calibrated through experimental tests, as a robust tool for predicting fracture behavior in Ti-6Al-4V alloy components fabricated using EBM. The model's versatility is underscored by its ability to accurately capture fracture deformations across a range of loading conditions, providing valuable insights for optimizing AM processes.

NOVEL COMPUTATIONAL METHODS FOR THE MECHANICAL PROPERTY OF ULTRA-SOFT TWO-DIMENSIONAL MATERIALS

Hongfei Ye[*1], Dong Li[2], Hongwu Zhang[1] and Yonggang Zheng[1]*

[1]*Dalian University of Technology*
[2]*Anhui University of Science and Technology*

ABSTRACT

The ultra-soft and ultra-thin features bring challenges for accurately evaluating the mechanical property of two-dimensional materials. In this work, we propose some novel computational method of the elastic modulus, shear modulus, Poisson's ratio and bending stiffness. The analytical atom-based molecular mechanics model is established to predict the elastic modulus, Poisson's ratio and shear modulus of the single-layer 2D transition-metal dioxides and dichalcogenides. This method is validated through the calculation of the mechanical property of Molybdenum disulfide (MoS2). The results indicate that the elastic modulus, Poisson's ratio and shear modulus of MoS2 with infinite size are 178.9 GPa, 0.22 and 73.3 GPa, respectively. We can observe the obvious dependence of the elastic modulus, Poisson's ratio and shear modulus on the chiral direction and characteristic size. Based on the constructed analytical method, we report a library composed of the mechanical properties of 34 types of 1H-MX2. It is found that the mechanical performances of 1H-MX2 depend on the period and group numbers of elements. The obtained results are in good agreement with the existing experimental and numerical results. Furthermore, the roles of molecular structure and force field on the mechanical properties are revealed, which is beneficial in predicting the mechanical performances of the potential and unreported 1H-MX2. For the bending stiffness, a coaxial spring-driven method is established, which exhibits great ability in the computation of the bending behavior for the ultrasoft two-dimensional materials. The findings offer an important theoretical basis for the reverse design and optimization of 1H-MX2 material-based nanodevices, nanochannel, etc., through nanostructure-property relationships. CONCURRENT OPTIMIZATION METHOD OF PRINCIPAL STRESS ORIENTATION INTERPOLATED CONTINUOUS FIBER ANGLE (PSO-CFAO) AND STRUCTURAL TOPOLOGY

Hongling Ye[1], Yongjia Dong[1] and Jicheng Li[1]*

[1]*Beijing University of Technology*

ABSTRACT

Abstract: Continuous fiber-reinforced polymers (CFRPs) have been widely applied in aerospace and other fields due to their excellent mechanical properties, and have become the best substitute for traditional metal materials. The designability of CFRP structural topology and fiber distributions provides an opportunity for achieving better physical properties through optimization. However, local optima and the dependence of initial fiber angle variables during optimization process make the concurrent optimization of fiber orientation and topology a challenging problem, which cannot exploit the full potential of CFRPs. In this paper, the principal stress orientation interpolated continuous fiber angle optimization (PSO-CFAO) method combined with the independent continuous mapping (ICM) method is proposed to realize the design of CFRP structures with a clear macroscopic topology and microscopic fiber distribution. A sigmoid function is applied to interpolate the fiber angle variables by the principal stress orientation. The fiber angle variables are modified and a continuous fiber design is obtained during the iteration process, which reduces the possibility of a local optimum. Numerical examples are provided to prove the effectiveness and stability of the proposed method, and the expected results are acquired for different initial fiber angles and mesh densities. The proposed method is effective to reduce the risk of local optima and can apply to the optimization problem with a large number of elements, which can provide guidance for the design of CFRP structures and the planning of fiber paths.

ABSTRACT

A modern approach to control sound is through the development of sound-control materials/structures, which enable a wide range of applications such as noise reduction and non-contact particle manipulation. Designing these sound-controlling metamaterials requires accurate and efficient simulation methods for solving the unbounded acoustic wave equation with changing domain and frequencies. To facilitate the design optimization, surrogate models that are significantly more efficient than full-scale simulations are highly desirable. In this work, we present our recent work on the development of such surrogate models based on the concept of Fourier neural operators (FNO). FNO was originally developed to learn the mapping from a parametric space to the solution space for a family of partial differential equations within a finite domain (Li et al., 2020). However, for unbounded problems with changing domains, directly applying FNO is not feasible. Therefore, we propose to a method that combines the boundary element method (BEM) with FNO. The acoustic BEM offers advantages such as boundary discretization only and is particularly suitable for solving wave propagation problems in infinite domains. In our approach, we use FNO to construct a surrogate model that maps the boundary Euclidean space, representing the geometry of the sound-controlling structure, to the corresponding boundary solution space. Once the boundary values are known, the boundary integral equation is then applied to calculate the acoustic pressure at desired points within the infinite domain. To validate the performance of the BEM-FNO approach, we conducted simulation experiments on a set of 2D benchmark problems with various structures, including ellipses, Helmholtz resonators, and acoustic diffusers. We compared the performance of our approach with conventional BEM approaches and surrogate models based on convolutional neural networks. The results demonstrated that the proposed BEM-FNO approach can accurately and effectively solve the acoustic wave equation with varied structures and frequencies.

LEARNING A RELIABLE COMPRESSION OF IN-SITU, HIGH-SPEED CAMERA DATA FOR ADDITIVE MANUFACTURING

Tian Yu Yen[1], Anthony Garland[1], Daniel Moser[1], Cody Lough[2], Ben Brown[2] and Jon Zettwoch[2]*

[1]*Sandia National Laboratories*
[2]*Kansas City National Security Campus*

ABSTRACT

New experimental setups in additive manufacturing (AM) now allow for in-situ monitoring of the AM process via high-speed cameras centered at the point of interest. However, the volume of data generated from the high-speed camera even for a single layer of a build can be too large to store and analyze in a reasonable time frame. We propose utilizing a variant of autoencoders to learn a reliable compression algorithm from previous video data and show that the compressed representation encodes key quantities of interest relevant to the build quality, as well as the image reconstruction error. We discuss the limitations and benefits of our approach to in-situ monitoring of the AM process.

BACTERIAL MULTIPHYSICAL INTERACTIONS WITH HARD AND SOFT MATERIALS INTERFACES: TOWARDS COMPUTATIONAL DESIGN OF ENGINEERED LIVING MATERIALS

Jingjie Yeo[*1]*

[1]*Cornell University*

ABSTRACT

Diverse sets of mechanisms underpin the ubiquity of bacterial interactions with surfaces and allow different bacterial species to adhere and proliferate. These mechanisms can often be effectively harnessed as guiding principles for producing materials for engineering purposes. For instance, microbially induced carbonate precipitation can help create new building materials that are less energy-intensive to manufacture and have lower lifetime operating costs. We computationally coupled multiphysical interactions in individual-based models to determine how bacteria form biofilm and biomineralize on patterned surfaces and in porous structures. Structural designs were proposed using data-driven modeling to optimize targeted biofilm properties, such as growth or adhesion. Similarly, differences in the molecular structures of healthy and diseased mucus in the human gut can alter the adhesion of bacteria on mucus. Intestinal mucus is the first line of microbial defense, a comparatively soft interface that allows for bacteria adhesion but obstructs penetration. We developed a coarse-grained mucus model that captured the molecular structures of two glycoproteins abundant in human gut mucus. Utilizing this model, we studied the dependence of nanoparticle diffusion on the particle size. Machine-learned fingerprints were employed to provide a mechanistic understanding of nanoparticle diffusional behavior. Our model provides a promising platform to study the pharmacokinetics in mucus.

Multiscale computational homogenization for bridging scales in the mechanics and physics of complex materials

A SIMPLE AND EFFICIENT FRAMEWORK FOR ADAPTIVE MULTISCALE MODELLING WITH DIRECT FE2

Kirk Ming Yeoh[*1], Karthikayen Raju[1], Leong Hien Poh[1], Tong-Earn Tay[1] and Vincent Tan[1]*

[1]National University of Singapore

ABSTRACT

While much more efficient compared to single scale models, computational homogenisation approaches remain unfeasible for large engineering structures. This is due to the sheer size of the model, as finely meshed representative volume elements (RVE) are included at every integration point of the macroscale mesh. In engineering structures however, the presence of various features as well as practical requirements result in only small regions of nonlinearity. As such, detailed RVE analyses are only required for such limited areas, while homogenised elastic properties can be used for the remaining areas of the macroscale structure.

As such, this work presents a simple and efficient framework to perform adaptive multiscale modelling with Direct FE2, where RVEs are progressively included into the analyses as necessary. Beginning with the unit strain analyses of the heterogeneous RVE, the framework first derives the homogenised macroscale elastic properties as well as the nonlinearity transition criterion for the structure. Subsequently, the main analysis is initiated with only the macroscale mesh and the homogenised properties.

As the analysis progresses, the macroscale integration point strains are checked against the nonlinearity transition criterion. If the criterion is satisfied, the macroscale element is first adapted into a Direct FE2 element before the analysis continues. For this adaptive process, the macroscale element is first assigned null properties. The deformed configuration of the RVE is then calculated before including it into the main analysis along with the scale transition relations. This check and adapt process is then repeated until the analysis is solved completely,

Compared to a full Direct FE2 model, such an adaptive approach can reduce the number of computations required significantly, by up to 50%. The proposed adaptive framework can be implemented entirely in Abaqus without the need to develop any subroutines. This means that the framework can be implemented by any user who is keen on multiscale modelling. More importantly, the entire process can be automated using Python scripts. Once the initial inputs are provided, no further user intervention is required, further simplifying the user task significantly. Several refinements are implemented to further optimise the adaptive framework and improve its efficiency.

MULTIPHYSICS PHASE-FIELD SIMULATION OF MICROSTRUCTURE EVOLUTION IN ADDITIVE MANUFACTURING

Min Yi[1] and Min Yi*[1]

[1]*Nanjing University of Aeronautics and Astronautics*

ABSTRACT

Predicting the microstructure evolution during additive manufacturing (AM) is of great interests, which can complement the current time and cost expensive trial-and-error principle with an efficient computational design tool. However, it still remains a great challenge to simulate the microstructure evolution during AM due to the complex underlying physical phenomena. In this talk, I will present multiphysics simulations to capture the microstructure evolution during the selective laser sintering (SLS) and selective laser melting (SLM) AM process. The multiphysics simulations are based on our recently proposed thermodynamically consistent non-isothermal phase-field model including multiphysics (i.e. full or partial melting, pore structure evolution, diffusion, grain boundary migration, coupled heat transfer, grain coalescence, etc.), and interaction of powder bed and laser power absorption. The first part of the talk focus on the structural materials such as stainless steel. In the second part, we turn to the functional materials and take magnetic FeNi as an example to show our first attempt in simulating microstructure evolution and predicting magnetic properties by integrating finite element analysis, CALPHAD (CALculation of PHAse Diagrams), and micromagnetics.

PROBABILISTIC FAILURE ENVELOPES OF MONOPILES IN SCOURED SEABED BASED ON A NEW NON-STATIONARY RANDOM FIELD MODEL

Ping Yi[1], Xinshuai Guo[1] and Jun Liu[1]*

[1]*Dalian University of Technology*

ABSTRACT

Monopiles, which have been most extensively used in the offshore wind industries, are usually subject to threats from local scour. The effects of local scour on the bearing capacity of monopiles have been studied based on deterministic soil properties and local scour dimensions. However, both the properties of the seabed soil and the dimensions of the local scour have uncertainty. In this study, a new non-stationary random field model, which can better simulate the non-stationary characteristics of the seabed clayey soil and result in a safer probabilistic design of foundations, is proposed to characterize the spatial variability of the seabed clayey soil. Then, the effects of the spatial variability of the seabed clayey soil and the uncertainty of the local scour depth on the bearing capacity of monopiles are investigated under both uniaxial loading and VHM combined loading using random finite element method combined with Kriging meta-modeling technique and Monte Carlo simulation. The undrained shear strength of the seabed clayey soil was simulated with a log-normally distributed non-stationary random field and the local scour depth was treated as a uniform random variable. The negative correlation between them was also considered. The results show that the factor of safety required for the local scoured seabed decreases from 3.3 to 2.6 as the negative correlation enhances, greater than or equal to that (FS= 2.6) for the intact seabed. The procedure of analyzing the design failure envelop of monopile in spatially variable clayey soil with a local scour proposed in this study can provide a reference for geotechnical engineers.

PHYSICS-PRESERVING ENRICHED GALERKIN METHOD FOR THERMO-HYDRO-MECHANICAL PROCESSES IN GEOMECHANICS

Son-Young Yi[*1] and Sanghyun Lee*[2]

[1]*The University of Texas at El Paso*
[2]*Florida State University*

ABSTRACT

In this talk, we consider a new numerical method for thermo-hydro-mechanical (THM) processes described by Biot's thermo-poroelasticity model. Modeling THM systems has been a subject of great interest in various geomechanics applications, including thermal treatment for declogging wellbores, geothermal energy production, radioactive-waste disposal, etc. We will propose a coupled enriched Galerkin (EG) method utilizing two types of EG methods to provide a robust and physics-preserving method for the governing model. Specifically, the mechanics sub-problem is solved using a locking-free EG method, while the flow and heat sub-problems are solved using a locally-conservative EG method. The proposed method offers mass and energy conservation properties with much lower costs than other methods with the same properties, including discontinuous Galerkin methods and mixed finite element methods. Moreover, the new coupled EG method is free of common numerical instabilities that tend to appear in poroelasticity and coupled flow-transport simulations. We will discuss theoretical aspects of the new EG method, including mass and energy conservation properties and optimal convergence. We will also present some numerical examples to confirm the theoretical results and to demonstrate the robustness of the method in realistic scenarios.

FLUID COHOMOLOGY

ABSTRACT

The vorticity-streamfunction formulation for incompressible inviscid fluids is the basis for many fluid simulation methods in computer graphics, including vortex methods, streamfunction solvers, spectral methods, and Monte Carlo methods. We point out that current setups in the vorticity-streamfunction formulation are insufficient at simulating fluids on general non-simply-connected domains. This issue is critical in practice, as obstacles, periodic boundaries, and nonzero genus can all make the fluid domain multiply connected. These scenarios introduce nontrivial cohomology components to the flow in the form of harmonic fields. The dynamics of these harmonic fields have been previously overlooked. In this paper, we derive the missing equations of motion for the fluid cohomology components. We elucidate the physical laws associated with the new equations, and show their importance in reproducing physically correct behaviors of fluid flows on domains with general topology.

ABSTRACT

Simulating quantum many-body systems away from equilibrium is computationally challenging. To make it easier, a practical way is to examine the Green's function based on the many-body perturbation theory. However, the Kadanoff-Baym equations (KBEs) which describe the dynamics of the two-time non-equilibrium Green's function (NEGF) form a set of coupled nonlinear integro-differential equations difficult to solve. To deal with this problem, I applied DMD, which is a data-driven model order reduction technique, to simulate the long-time dynamics of the NEGF by using snapshots computed within a small time window. This technique was first applied to the time-diagonal of the two-time Green's function, and then to the off-diagonal elements by decomposing the Green's function into a number of one-time functions. The effectiveness of DMD is demonstrated on a two-band Hubbard model system. In the equilibrium limit, the DMD analysis yields results that are consistent with those produced from a linear response analysis. In the nonequilibrium case, the extrapolated dynamics produced by DMD is more accurate than a special Fourier extrapolation scheme. A potential pitfall of the standard DMD method comes from the insufficient spatial/momentum resolution of the discretization scheme. For the model system, this problem can be overcome by using a variant of DMD known as the higher order DMD (HODMD).

A SEQUENTIAL FLUID STRUCTURE INTERACTION ANALYSIS OF GAS SLAM CLOSURE OF FLAPPER SAFETY VALVES

Allan Zhong[1], Hadi Arabnejad[1], Terapat Apichartthabrut[1], Shengjun Yin[1], Shobeir Pirayeh Gar[1] and Junmei Zhang[1]*

[1]Halliburton

ABSTRACT

Downhole safety valves are a shut-in device that prevent the uncontrolled release of hydrocarbons in the event of a catastrophic incident from a well. These fail-safe valves typically incorporate a flapper type closure mechanism that is biased to close and is normally held open by an energized control mechanism. When the control mechanism is inactivated, the flapper gets caught into the flow and closes against the flow. This slam closure can cause damage to the hinge of the valve or to the flapper valve itself as the closing impact velocity is typically high due to the high fluid production rates. Because this valve is a safety device, it is important to ensure safe and effective operation of the valve post-closure. A safety valve system involves multiple components and a few control mechanisms. A fully coupled unsteady fluid-structure interaction (FSI) analysis is typically complex and requires intensive computational resources. A sequential Fluid Structure Interaction (FSI) methodology is developed to solve this challenge.

The first step of the sequential FSI analysis is the computational fluid dynamics (CFD) analysis. This step only considers the interaction between the flapper and the fluid where structural deformation is neglected. The CFD provides predictions of forces on the flapper valve as well as its angular velocity in addition to flow characteristics. The finite element model for structural dynamic analysis includes all components of the safety valve system and accounts for all interactions between the components. The control mechanisms in the system are modeled analytically and implemented through user subroutines to the FEA code. The effects of fluid on the structure are accounted for through CFD simulation and result in the force and pressure on the flapper valve as well as flapper's angular velocity. The force on the flapper predicted by CFD is applied in the FEA model and is monitored as a function of flapper angular position instead of time to improve the coupling between the CFD and FEA models.

The proposed sequential FSI methodology was calibrated by physical tests where the analysis predictions correlated well with experimentally observed results in terms of the location and extent of the potential damages. The sequential methodology proved to be very efficient computationally and has been successfully applied in regular design evaluations under different well conditions.

INTEGRATED DESIGN AND PERFORMANCE ANALYSIS OF PEANUT PICKING MECHANISM

Yongran Yin[1], Yuguang Zhong[1], Dongyan Shi[1], Zeping Liu[1], Zhengyu Zhang[1] and Zeyi Wang[1]*

[1]*Harbin Engineering University*

ABSTRACT

Peanuts, as a vital oilseed crop, play a crucial role in global edible oil production and safety., and peanut picking is a highly complex nonlinear dynamics process. At present, the peanut picker has some problems, such as serious pod damage, low cleaning rate and straw blocking. Therefore, this paper proposes a movable integrated peanut picker for peanut picking and peanut straw crushing problems. Utilizing the structural characteristics of the separation drum and vibrating screen, the paper designed a peanut-picking mechanism to achieve a dual screening process for peanut fruits, and designed a crushing mechanism and incorporated dust-absorbing devices to ensure the efficient cleaning of crushed peanut seedlings, thus finalizing the integrated design of the peanut-picking machine. After the motion characteristic analysis and modal analysis, the rotating parts of the mechanism, the separation drum damage occurs mainly in the middle part, the rotating blade damage occurs in the tip of the top of the knife. And when operating the drum at 720 rpm, the primary blade at 1250 rpm, and the secondary blade at 950 rpm, this mobile peanut picker accomplishes the efficient screening of peanut fruits and the crushing of peanut seedlings. This study enhances both the efficiency and quality of peanut picking while providing a theoretical analysis and a foundational design basis for agricultural picking mechanisms.

ABSTRACT

We study the aerodynamics of fractal trees by using a simulation based on the Lattice Boltzmann Method with a cumulant collision term suitable for a large-eddy simulation model. We have applied L-SYSTEM[1] rules to construct self-similar fractal tree models in aerodynamic computations. We found that the drag coefficient closely matches that of real trees at high Reynolds number ($Re \geq 60{,}000$). A normalization process capable of collapsing turbulence intensity for various tree models is made. This process reveals that, at the same Reynolds number, different tree models exhibit the same behavior in the turbulence intensity of their wake region. On the other hand, in the case of the same tree model, when the Reynolds number is larger than 60,000, the turbulence intensity in the wake region exhibits the same behavior. Our assessment of global and local isotropy in the turbulence generated by fractal trees reveals that at high Reynolds number ($Re \geq 60{,}000$), the distant wake can be considered as nearly locally isotropic. Finally, the present numerical results confirm the non-equilibrium dissipation behavior previously observed in the case of space-filling fractal square grids[2]. In the wake region, the non-dimensional dissipation rate $C\epsilon \approx$ constant is not valid. Instead, it is inversely proportional to the local Taylor-microscale-based Reynolds number, $C\epsilon \propto 1/Re\lambda$.

[2]*Shibaura Institute of Technology*

ABSTRACT

Biological bone structures are determined through spatially heterogeneous cellular dynamics, such as hypertrophy and proliferation, which are affected by the mechanical and biochemical environment during morphogenesis. Therefore, to understand the mechanism of the formation of physiological bone structures, it is essential to investigate changes in the macroscopic tissue structure depending on microscopically heterogeneous cell activities. In this study, we aimed to connect microscopic cell activity to the elastic behaviors of the macroscopic tissue by developing a novel computational model of cell proliferation by extending the material point method (MPM), in which material points are used for the calculation of elastic deformation.

The growing bone tissue composed of chondrocytes and the surrounding chondrocyte matrix was modeled as a hyperelastic material following the compressible neo-Hookean model. We assumed that a material point in MPM represents a cell and surrounding matrix, to describe the individual cell activities during tissue morphogenesis. In this framework, we developed a continuum-based particle model of cell proliferation by combining unidirectional growth and division of material points [1].

Based on the developed model, we simulated random proliferation in multicellular cubic tissue. Macroscopic tissue growth and spatially heterogeneous cell volume and strain energy density were successfully simulated as a result of microscopic cell proliferation. Here, we confirmed that any cells in the tissue can be traced during tissue growth.

In this study, we developed a multiscale method to investigate multicellular tissue morphogenesis by constructing a continuum-based particle model of cell proliferation and enabled tracing cells in the growing tissue. Future extensions of the proposed models will allow us to consider cellular activities depending on the history of cell differentiation. Therefore, the developed model will contribute to understanding multiscale phenomena, such as cancer development and multicellular tissue morphogenesis forming various bone structures, through a computational approach.

PHYSICS GUIDED TRAINING OF GAN MODEL TO IMPROVE ACCURACY IN A DESIGH SYNTHESIS

*Kazuo Yonekura**[1]

[1]*The University of Tokyo*

ABSTRACT

In a mechanical design, a design that meets requirements has to be obtained. Deep generative models have been recently utilized for design synthesis. In literature, conditional generative models, such as conditional variational autoencoder (CVAE) and conditional generative adversarial networks (cGAN), are trained to generate designs with requirements as conditional labels. However, it is reported that the obtained shapes do not exhibit the same performance as the requirements. In this study, we use physics-guided GAN (PG-GAN) to improve accuracy in the design task for airfoils and ship hull shapes. In the GAN model, a discriminator distinguishes real data from fake data, but physics is not considered to distinguish reality, which leads to low accuracy in mechanical performance. In PG-GAN, reality is defined using a physics model; more precisely, if generated data is physically reasonable, the data are considered real, otherwise fake.

A physics informed neural network (PINN) is proposed in the literature to consider physics models. PI model uses the residual of the physics equations to be minimized. In PINN, he physics equations must be implemented in the neural network models to enable back propagation. Hence, general purpose software cannot be used. However, PG-GAN can use arbitrary physics models since the model is only used to label the generated data if the data is physically reasonable or not, and the physics model is outside the backpropagation chain.

The PG-GAN is applied to generate airfoil shapes and ship hull shapes, and the accuracy was improved.

REINFORCEMENT LEARNING-BASED TOPOLOGY OPTIMIZATION FOR ADAPTIVE METAMATERIAL USING WAVELET ACTION SPACE

Gil Ho Yoon[*1], Jaemin Jeon[2] and Yoon Young Kim[2]*

[1]*Hanyang University*
[2]*Seoul National University*

ABSTRACT

Ultrasound imaging is widely employed in medical and industrial fields due to its real-time capabilities, non-invasiveness, and cost-effectiveness. Despite these advantages, the inherent limitation of ultrasonic waves impeding their transmission through obstacles has spurred investigations into the utilization of metamaterials to overcome such hindrances. Notably, the variable characteristics of real obstacles, such as the human skull, across inter- and intra-subjects pose a significant challenge. Due to this variability, the efficacy of metamaterials designed for specific obstacles diminishes considerably in practical applications. The topology optimization methodology has been frequently used to identify optimal metamaterial designs meeting predefined design requirements. However, finding new optimal metamaterial designs in response to changes in the circumstances surrounding the design domain remains a challenge.

This research introduces a novel topology optimal design methodology aimed at robustly and efficiently creating adaptive metamaterials by harnessing the real-time response capabilities of reinforcement learning. In addressing a limitation of existing reinforcement learning-based methodologies, namely the exponential increase in training time with resolution, we propose the innovative concept of a “wavelet action space.” To overcome the issue posed by resolution-dependent training time, we converted the space where the reinforcement learning agent selects actions into a multi-scale action space using binary wavelet transformation. This approach enabled multi-resolution design by constraining the range of actions that the agent could choose at each design step. The outcome of this research includes the successful training of an agent capable of altering metamaterial geometry to facilitate the penetration of ultrasonic waves through obstacles with varying thicknesses, achieving an efficiency exceeding 90 %. This pioneering methodology is expected to establish a significant milestone in the emerging reinforcement learning-based topology optimization design field, offering promising avenues for further exploration and advancement.

PORE-SCALE REACTIVE TRANSPORT AND FLOW BEHAVIOR INVOLVING DISSOLUTION AND PRECIPITATION IN HETEROGENEOUS POROUS MEDIA

Hongkyu Yoon[*1]*

[1]*Sandia National Laboratories*

ABSTRACT

Recent advances in experimental methods and multi-scale imaging capabilities have revolutionized our ability to quantitatively characterize flow and transport processes in porous media. Reactive transport and chemical reactions involving phase change take place in pores and along the mineral surfaces in confined porous media. These coupled reactive transport processes are critical to various subsurface applications such as subsurface resource recovery, carbon sequestration, and environmental fate and transport. In this work, pore-scale experiments in single fractured systems including calcite and cements are used as a basis for understanding coupled processes among hydrodynamics, transport, and reactions at the (sub) pore-scale. Optical and confocal microscopic imaging at multiple scales from ~0.1 to 5 micron resolutions will be used to trace how these chemical reactions will induce the change of morphology on single fracture surfaces via dissolution and precipitation. These experimental data will be analyzed by developing coupled pore-sale simulation using the hybrid lattice Boltzmann method for flow and finite volume method for reactive transport. Once pore scale simulations are validated against well-controlled experimental data, we utilize pore scale simulations to generate a number of datasets under a range of key parameters including the Peclet and Damkhöler numbers with different geometries. Dissolution and precipitation dynamics especially affect the flow field, resulting in transient behavior of reactions. We will show how these data can be utilized to train a machine learning model for upscaled reactive transport parameters. SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

SHAPE DESIGN OPTIMIZATION OF MAGNETIC ACTUATOR USING ISOGEOMETRIC BOUNDARY ELEMENT METHOD

Minho Yoon[*1], Bonyong Koo[2] and Jaewook Lee[3]*

[1]*University of Seoul*
[2]*Kunsan National University*
[3]*Gwangju Institute of Science and Technology*

ABSTRACT

A continuum-based shape design sensitivity analysis (DSA) method is developed for two-dimensional multi-domain magneto-static problems using the isogeometric boundary element method (IBEM) that directly utilizes NURBS basis functions in CAD systems in response analysis. Since the compatibility condition between the NURBS patches for multi-domain problems in BEM should be satisfied, discontinuous element formulation is adopted. Especially for a surrounded domain for all directions in an inhomogenous multi-domain problem such as magnetostatics, additional imposition of material property is introduced. Generally, the magnetic potential has a strong dependency on the geometry of ferromagnetic materials, and the exact boundaries of multi-domain are expressed using the NURBS basis function and control points in response analysis. Consequently, the developed isogeometric shape DSA method gives more accurate information as the gradient of the objective function for guiding one directional search in optimization. Through the numerical examples, the robustness of developed discontinuous IBEM and DSA is demonstrated.

NUMERICAL SIMULATIONS OF BREAKING WAVES

Seokpyo Yoon[*1], Ju Seong Bang[1] and Hyung Taek Ahn[1]*

[1]*University of Ulsan*

ABSTRACT

We present numerical simulations of free surface flow problems[1], specifically focusing on breaking wave phenomena that include spilling and plunging breaker. The incompressible Navier-Stokes equations are solved using the weighted essentially non-oscillatory (WENO) scheme, ensuring accuracy[2]. For capturing the moving immiscible interface, the tangent of hyperbola for interface capturing with weighted line interface calculation (THINC/WLIC) method is employed. Wave breaking processes are presented and discussed through interface diagrams and energy dissipation. The result of the present simulation compares well with other numerical results and is successfully applied to breaking wave phenomena.

CONTROLLING ENZYME ORIENTATION FOR OPTIMAL ELECTRON TRANSFER ON BIOELECTRODE SURFACES THROUGH ELECTRIC FIELD MODULATION: INSIGHTS FROM MOLECULAR DYNAMICS INVESTIGATION.

Taeyoung Yoon[*1] and Sungsoo Na[1]*

[1]*Korea University*

ABSTRACT

Developing bioelectrochemical devices requires the critical surface immobilization of biocatalysts with a favorable orientation. Enhancing the performance of electrochemical electrodes has traditionally involved complex and costly processes for biocatalyst surface modification and engineering. One proposed method for achieving proper biomolecule orientation and deposition on the surface involves applying an external electric field (EF) to small molecules. In this study, we introduced a unidirectional external EF for the first time to oxygen-reducing enzymes with high catalytic activity. Using computational methods, we constructed a Laccase-graphene interface. The applied external EF induced rotation of the active site of laccase, leading to an improved electron transfer rate compared to enzymes physically immobilized on graphene. We also evaluated the external EF fabrication process for different graphene congeners (graphene oxide (GO) and reduced GO (rGO)). The electrode surface morphology was visualized, and computational methods were employed to confirm binding conformation, dipole moment orientations, secondary structure, and binding stability. Among the graphene materials tested, graphene exhibited the most promise, surpassing GO and rGO by 10% and 5%, respectively, in terms of DET rate. These findings suggest that employing an external EF to achieve a favorable orientation in the Laccase-graphene interface could represent a straightforward, cost-effective, and efficient approach for bioelectrode fabrication.

[3]*Ryoyu Systems Co. Ltd.*

ABSTRACT

The boundary layer near the leading edge of a conventional swept-wing aircraft is dominated by instability of the crossflow perpendicular to the streamline direction. This instability arises as a disturbance originating from surface roughness and promotes the turbulence transition. There are wide variety of shapes in the aircraft wing surface roughness, and the complex interference of disturbances from various roughness leads to the turbulent transition. In particular, at high Reynolds numbers of order O(10^7) corresponding to actual flight conditions, the boundary layer is so thin that even very slight roughness influences the transition. However, both flight tests and wind tunnel experiments of the surface roughness-induced transition in the actual flight conditions are demanding and costly.

In this study, we aim to elucidate the relationship between the surface roughness and the transition position of an infinite swept wing (TAMU0706 [1]) under Reynolds number equivalent to the actual flight. We employ Reynolds-averaged Navier-Stokes (RANS) equations including laminar flow region for the external flow surrounding the entire wing. For the vicinity of the wing surface with roughness, we employ direct numerical simulation (DNS) where the boundary condition for the outer flow is given by the RANS simulation. The turbulent transition position located far downstream is determined using the nonlinear parabolized stability equations with the disturbance amplitude obtained by the DNS. With this combined method, we can investigate the roughness-induced flow accurately while maintaining low computational cost .

Our analysis unveiled the relationship between the turbulent transition position and the roughness properties, such as the arithmetic mean roughness (Ra) and spatial distribution. The transition position advances to leading edge by increasing Ra, and above the critical Ra, the turbulent transition occurs immediately from the leading edge. Even for the same Ra, the spatial distribution of roughness influences the transition position. In addition, we found a range of the roughness wavelength that does not affect the transition position. In the presentation, we will discuss some other roughness shape parameters, such as the maximum roughness height and the root-mean-squre value of the roughness.

PHASE-FIELD MODEL FOR VISCOUS DOMINATED HYDRAULIC FRACTURING

Tao You[1] *and Keita Yoshioka**[1]

[1]*Montanuniversität Leoben*

ABSTRACT

With increasing popularity in versatile fracture problems, phase-field models have been applied for hydraulic fracturing by extending the Francfort-Marigo energy functional to poroelastic media. However, when hydraulic fractures propagate in a viscous-dominated regime, in which the surface energy dissipation is negligible compared to the fluid viscous dissipation, existing phase-field models become unstable and often lead to non-localized phase-field (damage) profiles. In this presentation, we propose a micro-poroelastic based phase field fracture model to overcome the non-localized damage and pore-pressure profiles. The proposed model allows for a variationally consistent formulation and rational derivation of effective stress and phase-field--dependent poroelasticity. The fixed stress split scheme was applied to solve the hydro-mechanical coupling problem which includes two independent pressure variables. We first verified this model against typical micro-porosity problems and then extended it to viscous-dominated hydraulic fracture examples.

AUTONOMOUS FINITE ELEMENTS COMBINED WITH DEEP LEARNING IN ORTHOPEDIC AND ENDOCRINOLOGY CLINICAL PRACTICE

Zohar Yosibash[1], Nir Trabelsi*[2] and Amir Sternheim[3]

[1]*Tel Aviv University*
[2]*Shamoon College of Engineering, Beer-Sheva*
[3]*Tel Aviv Sourasky Medical Center*

ABSTRACT

Finite element analysis requires a qualified analyst to generate the necessary input data, verify the output and post process the analysis results for a meaningful conclusion. The required expertise and labor efforts precluded the use of FEA in daily medical practice for example. Recent scientific advancements such as low dose CT scans, machine learning, and high order FEA which allows an inherent verification methodology of the numerical accuracy, make it possible to provide a fully autonomous process for assessing bone strength and fracture risk.

This autonomous process, named autonomous finite element (AFE) analysis, introduces a paradigm shift in the use of FEA. This talk addresses a novel AFE for patient-specific analysis of human femurs used nowadays in clinical practice: it involves an automatic segmentation of femurs from CT-scans by U-Net, an automatic mesh generation and application of boundary conditions based on anatomical points, a high-order FE analysis with numerical error control, and finally an automatic report with a clear assessment of bone fracture risk. Two specific applications of AFE in clinical practice that were validated by clinical trials are presented:
a) Determination of the risk of fracture for patients with tumors of the femur and whether a prophylactic surgery is needed.
b) Identifying patients with high hip fracture risk as a result of fall on the side.

DEEP GENERATIVE APPROACH FOR BIOINSPRIED STRUCTURAL MATERIALS BY DESIGN

Chi-Hua Yu[1]*

[1]*National Cheng Kung University*

ABSTRACT

The fusion of Artificial Intelligence (AI) with bioinspired structural materials design represents a groundbreaking shift in material science, merging the complexity of nature's designs with the precision of modern engineering. By harnessing deep learning and reinforcement learning, AI accelerates the development of materials that mimic natural structures, offering efficiency and resilience unmatched by traditional materials. This integration significantly shortens the pathway from conceptual design to practical application, with AI's ability to analyze large datasets from simulations and empirical studies playing a key role. It enables a deeper understanding of the behaviors of natural materials, paving the way for the engineering of novel structures that aim to exceed the performance of their biological inspirations.

Moreover, AI enhances the manufacturing processes of these bioinspired materials, optimizing production to ensure quality while prioritizing sustainability. This optimization aligns with the global push towards reducing waste and energy consumption, heralding a new era of materials with unparalleled properties and environmental benefits. The collaboration between AI experts and material scientists accelerates innovation, leading to sustainable material development and the creation of cutting-edge materials. As AI technologies continue to evolve and become more integrated with bioinspired design, the potential for creating materials with superior performance characteristics expands, promising a future where the synergy between nature's ingenuity and AI's analytical prowess sets new benchmarks in material innovation and sustainability.

COMPUTATIONAL ANALYSIS OF THE FINITE IMMERSION DEPTH DIP COATING PROCESS

Dongkeun Yu[1], Jisoo Song[1] and Jaewook Nam[12]*

[1]*Seoul National University*
[2]*Institute of Chemical Processes*

ABSTRACT

Dip coating with finite immersion depth is a newly defined coating process which has both characteristics of the conventional dip coating and the liquid transfer process. In contrast to its wide range of industrial applications, studies on the dip coating with finite immersion depth are limited due to the complexity of analysis. Since most conventional dip coating studies assume a very long immersion depth of the substrate, the coating layer thickness which is a function of the dimensionless numbers becomes uniform above the dynamic meniscus region and thus the steady-state studies can be performed. However, due to the relatively short immersion depth compared to conventional dip coating, the finite depth dip coating does not guarantee an uniformity of the film thickness. Furthermore, due to the severe topological changes in the liquid, which is one of the characteristics of the liquid transfer process, studies should be performed in a transient way. Unlike the liquid transfer process, which moves the liquid from the cell or groove to the substrate, the liquid source has no contact lines in the dip coating with finite immersion depth. In addition, there is an effect of viscous drag originated from the vertical wall which is one of the characteristics of the conventional dip coating process.

In this study, we implement the computational model to understand the dynamics of the liquid and the interface in the finite immersion depth dip coating by combining the interface treatment schemes. We utilized the phase field method, which is one of the well-known interface capturing schemes, to describe the movement of the liquid-air interface. On the other hand, we moved the nodal points with the scheme of Arbitrary Eulerian Lagrangian(ALE) method for the movement of the solid substrate. To analyze the process, we divided the process with several stages based on the onset of its characteristics. Then we track the change of the quantities of the spatial regions divided by the specific horizontal planes with respect to the characteristics of each stage. Comparing the changes of the quantities between different parameters, we find out how much the process parameters affect the formation of the coating layer shape. In addition, the simple model which describes the major dynamics will be presented.

A DATA-DRIVEN METHOD FOR MECHANICAL PROPERTIES PREDICTION OF MATERIAL BUILT BY METAL ADDITIVE MANUFACTURING

Fei Yu[*1] and Yanping Lian*[1]

[1]*Beijing Institute of Technology*

ABSTRACT

Metal additive manufacturing (AM) represents a transformative and advanced technology characterized by low cost, short production cycles, and integrated design and manufacturing processes. It holds vast potential and promising prospects in aerospace, nuclear power, and medical applications. However, the as-built material by AM presents a complex microstructure and inevitably contains manufacturing defects. Therefore, developing accurate and efficient methods for mechanical property prediction is crucial for predicting the actual performance of manufactured parts. In this study, a crystal plasticity finite cell - self-consistent clustering analysis method (CPFC-SCAM) is presented. It consists of an offline data preparation stage and an online rapid calculation stage. During the offline stage, the crystal plasticity finite cell method and clustering algorithms are applied to construct a discrete database of the actual microstructure representative volume elements (RVEs) efficiently. In the online stage, the Lippmann-Schwinger equation of the RVEs is solved by the subdomain-based weighted residual method with the clusters from the offline stage. The crystal plasticity model under finite deformation is utilized in the CPFC-SCAM. The macroscopic equivalent mechanical properties of the material are obtained through the homogenization of stresses and strains within the RVE. Several numerical examples, RVEs with and without the irregular void, are presented to showcase the accuracy and efficiency of the proposed method. Moreover, the proposed method is applied to study the mechanical properties of IN625 alloy fabricated by selective laser melting AM. The results demonstrate that this work provides an efficient computational method for predicting the mechanical properties of the built material by metal AM.

SPATIAL AND TEMPORAL CONSTRAINTS OF THE COHESIVE MODELING: A UNIFIED CRITERION FOR FLUID-DRIVEN FRACTURE

Hao Yu[*1]

[1]*University of Science and Technology of China*

ABSTRACT

We present a unified criterion for cohesive modeling of fluid-driven fracture based on the dimensional analysis to simultaneously provide the constraint for cohesive element and time step sizes. Complicated by the nonlinear interaction between solid deformation and fluid flow, the underlying correlation between discretization and physical parameters of fluid-driven fracture is still unclear. This work studies this correlation through the dimensionless process of the governing equations that associate the cohesive element and time step sizes in a discrete regime. Three characteristic parameters (i.e., related to crack opening, fluid pressure, and fracture length) are introduced in the derivation, and two dimensionless parameters are proposed to construct the unified criterion. The criterion is validated by numerical tests of toughness-dominated fracture with various conditions including the modulus of solid, injection rate of fluid, fracture energy, and in-situ stress. The proposed criterion determines the spatial and temporal constraints of the cohesive zone model (CZM) for modeling fluid-driven fracture, which is often treated empirically in previous practices.

EFFECT OF THE RATIO OF DIFFUSE LENGTH SCALE AND IRWIN'S MATERIAL CHARACTERISTIC LENGTH SCALE L0/LCH ON THE PHASE FIELD MODELING TO BRITTLE OR QUASI-BRITTLE FRACTURE

Hongjun Yu[*1] and Yaode Yin*[1]

[1]*Harbin Institute of Technology*

ABSTRACT

In the phase field model (PFM), the discrete crack is diffused, which enables to deal with complex fracture patterns for brittle or quasi-brittle materials. The classical PFMs lack of the information on the material strength. To capture the material strength, the length scale l0 of the diffuse crack is tie to the characteristic length lch of the crack process zone. The ratio of l0/lch usually remains constant for the classical PFMs, resulting in the size scale of the diffuse crack is limited by the material properties. To overcome this limitation, we construct novel degradation functions to decouple the diffuse length scale l0 from the characteristic length lch, making the ratio of l0/lch adjustable whether to small or to large. Based on the analysis of the homogeneous solutions for 1D tension under various diffuse crack topologies, the effect of the ratio of l0/lch on the constitutive behaviors of the PFMs is investigated. It is found that the appearances of the elastic phase and the strain hardening phase as well as the softening law are influenced by l0/lch. For a large value of l0/lch, the snap-back instability occurs and the constitutive behavior showcases very brittle. For a small value of l0/lch, the constitutive behavior is very ductile with no elastic phase. When the ratio of l0/lch increases, the fracture type is transformed form quasi-brittle to catastrophe. As a consequence, the ratio of l0/lch, a nondimensional number, governs the competition between the strain energy and surface energy in the PFMs.

THERMO-HYDRO-MECHANICAL COUPLED MATERIAL POINT METHOD FOR SIMULATING THE FREEZE-THAW BEHAVIOR OF POROUS MEDIA

Jidu Yu[*1], Jidong Zhao[1], Shiwei Zhao[1] and Weijian Liang[2]*

[1]*Hong Kong University of Science and Technology*
[2]*Hong Kong Polytechnic University*

ABSTRACT

Climate warming is causing disruptions in the normal freeze-thaw cycles of permafrost and seasonal frost regions. This leads to an increase in climate-driven disasters such as ground collapse and retrogressive thaw slumps, which pose increased risks to the stability of infrastructure in cold regions. However, understanding and predicting the freeze-thaw behavior of ice-rich porous media is challenging due to its inherent complexities. These include multiphysics and multiphase interactions, phase transitions, ice-dependent constitutive behaviors, fluid-like failure patterns, and large deformations. To address these challenges, this study presents a thermo-hydro-mechanical coupled MPM framework for modeling time-dependent phase transition and large deformation behaviors. The framework includes four features: (a) fully coupled u-v-p-T governing equations to describe the interactions of heat transfer, pore-liquid flow, and solid deformation in freezing and thawing porous media based on single-point multiphase MPM, (b) a soil freezing characteristic curve and relative hydraulic conductivity model to describe the phase equilibrium and the influence of ice saturation on permeability, (c) an ice-saturation dependent Mohr-Coulomb model to characterize the effect of ice cementation on soil strength, and (d) a fractional-step-based semi-implicit integration algorithm to solve the coupled formulations.

The presented framework is validated by several thermo-hydro-mechanical coupled examples to demonstrate its effectiveness in simulating thermal variations due to heat conduction, convection, and latent heat of fusion, mechanical behaviors due to thermal expansion/contraction and liquid-ice phase transition, and hydraulic changes due to ice saturation and porosity variations. The semi-implicit MPM formulation is shown to maintain both satisfactory numerical stability and computational efficiency when dealing with nearly incompressible fluids and extremely low permeability conditions in frozen porous media. Finally, the framework is used to simulate a thawing-induced slope slide and the large settlement of a strip footing placed on a thawing ground. The results showcase the significant influence of strength reduction during ice melting on the stability, bearing capacity, and failure pattern of ice-rich soils. This study presents a powerful tool for predicting the impact of climate warming on engineering practices in cold regions. It can be further enriched by employing a multiscale approach (e.g., MPM-DEM) and a fracture model to model more comprehensive behaviors in ice-rich soils.

A COMPARATIVE STUDY OF THE STATE OF CHARGE ESTIMATION FOR LITHIUM-ION BATTERIES USING SINGLE PARTICLE MODEL AND KALMAN FILTER

Kintak Raymond Yu[*1], Francis Lacombe[1] and Florin Ilinca[1]*

[1]*National Research Council of Canada*

ABSTRACT

Effective and accurate state of charge estimation for lithium-ion batteries is of paramount importance for reliable and safe operations of lithium-ion batteries and it is an important function of the battery management system. At present, a popular applied scheme involves coupling an equivalent circuit model (ECM) together with a Kalman filter. ECM employs electric circuit elements, like resisters and capacitors, to mimic the cell voltage response given an input current load. The model relies on experimental data for calibration; hence inherently, it is limited for model extrapolation and predict less accurately in the loading situation where the experimental data does not cover well. Therefore, in literature, there is growing interest in using a single particle model (SPM) with a Kalman filter for state of charge estimation. SPM is a simplified physics-based model, considering each electrode as a single spherical particle whose area represents the porous electrode active surface area. SPM accounts for solid diffusion in the electrode particles and the intercalation reaction kinetics. The ohmic potential drop in the electrolyte is incorporated using a lumped solution resistance term. To couple with the Kalman filter, it is necessary to convert SPM into the state-space formulation. In literature, there is little consensus on how such conversion should proceed. Among the many proposed approaches, two more different schemes are mentioned: (1) discretizing both solid diffusion equations directly using finite difference and (2) solving the diffusion for the internal states of “only one” electrode and recovering the states of the other electrode using algebraic expression to “enhance model observability”.
Here, we present a comparative study on these two coupling schemes of SPM with two popular nonlinear Kalman filters. We evaluate their accuracy and required resolution time, as well as investigate the importance of enhancing the model observability. The results provide useful insights on how to address the implementation challenges faced in real-life applications.

COMPUTER MODELLING OF FLASH SINTERING

Michael Yu[1], Ran He[1], Jingzhe Pan[1], Cathryn Hickey[2] and Graeme ODowd[2]*

[1]*University of Leicester*
[2]*Lucideon Limited*

ABSTRACT

Flash sintering is a time-efficient and energy-saving method compared to traditional sintering. However, due to the high heating rate and the nature of ceramic sintering, deformation and distortion can occur during the process. This is where computer modelling becomes instrumental. It allows us to analyse and predict the conditions of deformation and distortion during the flash sintering process. By understanding these behaviours, we can pre-adjust the green body (pre-sintered ceramic) and sintering conditions to achieve an optimal outcome, leading to a substantial reduction in material waste and energy cost. Therefore, this study aims to predict the heating and deformation conditions of a ceramic part undergoing the flash sintering process.

In this study, we will simulate the flash sintering process of a ceramic part using COMSOL Multiphysics. We will apply a pair of cathode and anode to the green body using Electric Potential functions. Due to the Joule heating effect, these will cause localised high temperatures in the ceramic part, leading to regionally increased sintering and creeping rates. This can result in a non-uniform distribution of temperature in the ceramic part, preventing it from being evenly sintered and causing non-uniform deformation. This becomes critical when the sintered part is dimensionally sensitive. We will carry out a series of simulations to simulate the Joule heating effect during the flash sintering process, yielding the distributions of electric potential and temperature in the ceramic part. We will also simulate its sintering behaviour, yielding the temporal evolutions of grain size and relative density.

This study establishes a foundational procedure for predicting ceramic flash sintering deformation through finite element analysis methods. It demonstrates the effectiveness of this approach for deformation prediction in the ceramic flash sintering process, potentially leading to a reduction in material waste and energy costs. The simulation outcomes validate this approach for predicting flash sintering deformation, providing a basis for further research in this field.

NUMERICAL MODELLING OF THE DYNAMIC FAILURE IN FIBER-REINFORCED CONCRETE

Rena C. Yu[*1], Elisa Poveda[1] and Gonzalo Ruiz[1]*

[1]*Universidad de Castilla-La Mancha*

ABSTRACT

We present a two-level model for cement-based composites reinforced with fibers.

First, the pull-out behavior of a single fiber from the matrix is modeled and validated against experimental results. At this mesoscopic level, the fiber can be smooth or with hooked ends, based on the explicit representation of the fiber, the cementitious matrix and the interface in between. Consequently, the effect of friction, loading-rate dependency, in particular, the fiber orientation, are cast into an equivalent constitutive law for each fiber at a given orientation. Numerous simulations are performed to create a database of fiber behavior with different orientations.

Second, at the macroscopic level, the fibers are fed with constitutive relations from the previously generated database. A notched three-point bending beam with a central cohesive crack sewed with fibers is modeled and the global response validated against experimental results.

Third, the same concept is applied to a mixed-mode fracture propagation. A fiber distribution is generated based on images obtained from micro Computerized Tomography scanning. In this case, the constitutive relation for each fiber is activated according to the current principal stress directions. The global response is also compared with its experimental counterpart.

LATTICE BOLTZMANN METHOD FOR FLOWS AND TRANSPORT IN POROUS MEDIA BASED ON ADAPTIVE MESH REFINEMENT

Shilin Yu[*1], Wandong Zhao[1] and Xiaodong Cai[1]*

[1]*National University of Defense Technology*

ABSTRACT

In accordance with the weakly compressible flow model proposed by Qian [1], and the incompressible flow model introduced by Guo [2], a numerical simulation solver for the flow and transport in porous media with lattice Boltzmann method (LBM) under the AMROC(Adaptive Mesh Refinement in Obiect-oriented C++) [3] framework was established via the massively parallel adaptive mesh refinement (AMR). The flow characteristics in porous media was carried out by employing the established AMR-LBM model. The effects of different pore structures (ordered and disordered structures), porosity, Reynolds number(Re), and inlet conditions on the flow evolution were investigated in detail. The flow process associated with velocity, velocity vector, and vorticity under various physical property parameters was obtained. The numerically obtained results of varying structures and flow conditions were analyzed so as to gain a good performance of flow ability and transport capacity. The current investigation combines the advantages of LBM in dealing with pore structure easily and AMR technology, which ensure numerical accuracy and also improve computing efficiency owing to the high refinement strategy of AMR technique. The obtained results were also verified by the previous experimental results, which proves the accuracy and robustness of the current numerical simulation. It is hoped that this study could extend the numerical simulation ability in the massive parallel simulation and AMR technology in the LBM community.

DESIGN OF HIERARCHICAL MICROSTRUCTURES WITH ISOTROPIC ELASTIC STIFFNESS

Xue Yu[1] and YiQiang Wang*[1]

[1]*Dalian University of Technology*

ABSTRACT

Microstructured metamaterials are a class of artificial materials with rich geometric configurations. By designing their geometries, they can achieve extraordinary properties that cannot be found in natural materials, such as negative Poisson's ratio, bimodal properties, etc[1]. In recent years, rapid advance of 3D printing technology offers a unique way to fabricate high-resolution microstructured metamaterials with various configurations[2]. Among various properties, elastic stiffness is one of the most fundamental properties. Particularly, the microstructures with isotropic stiffness are insensitive to changes of loading directions and suitable for complex conditions, and thus they have attracted great interest from researchers[3]. To date, most isotropic microstructures are designed either based on mechanics principles or by using numerical optimization strategies. However, because of the limitation of the design space and modelling methods, the existing isotropic microstructures are composed of features in a single length level. Exploring a wider range of isotropic microstructures becomes a key and also an open problem.

This paper identifies a new family of isotropic microstructures by introducing hierarchical features, which is called the Isotropic Hierarchical Microstructures (Iso-HMs). They are made by introducing another level of features into the solid parts of the original single-level microstructures, which have orthotropic stiffness. By designing the second-level microstructures and adjusting the geometric parameters, isotropic stiffness can be realized. Numerical results show that both the Young’s modulus and shear modulus of the Iso-HMs are bigger than the minimal directional stiffness of the single-level microstructures. Furthermore, Iso-HMs can achieve over 50% improvement of the buckling strength compared to the single-level counterparts, when subjected to a uniaxial loading. Several specimens were 3D printed by using the Projection Micro-Stereolithography technology. The minimal feature size was 50 micro-meter, and the size ratio between the specimens and the minimal features reached 400:1. The testing results from the uniaxial compression also demonstrate the stiffness isotropy of the specimens. Such a hierarchical design significantly expands the already-known space of isotropic microstructures.

AN ADAPTIVE INCREMENTAL STAGGERED SCHEME FOR THE PHASE FIELD MODEL OF FRACTURE

Yuanfeng Yu[1], Chi Hou[1], Yifei Deng[1], Xiaoya Zheng[1] and Meiying Zhao[1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

For the standard staggered solution scheme widely used in phase field model, although it shows excellent convergence and robustness, the computational efficiency is slow and a large number of iterative steps are required, resulting in huge time cost. In order to improve computational efficiency, an efficient and robust solution scheme based on adaptive time field is proposed. This scheme is inspired by the space field adaptive mesh method, and an error indicator based on phase field and history field variables is established. The time field is coupled with the phase field and energy field in the space field, allowing the time step to adaptively adjust with iteration, improving convergence rate and significantly reducing time cost. The proposed scheme is validated through some representative examples. The results indicate that the presented scheme not only significantly improves computational efficiency, but also has accurate computational results. Compared to the standard staggered scheme, the time cost of the presented scheme is less than 4% of the time of the standard scheme. Furthermore, this novel scheme can effectively reduce the impact of load increment in the standard scheme on the results, improve stress distribution, and enable cracks to propagate along the correct path. What's more, the presented scheme has a faster computational efficiency than the monolithic BFGS scheme and excellent convergence characteristics.

TOWARD FOUNDATION MATERIAL MODEL WITH NONLOCAL ATTENTION OPERATOR

Yue Yu[*1], Ning Liu[2], Tian Gao[3], Siavash Jafarzadeh[1] and Stewart Silling[4]*

[1]*Lehigh University*
[2]*Global Engineering & Materials, Inc.*
[3]*IBM*
[4]*Sandia National Laboratories*

ABSTRACT

Despite the recent popularity of attention-based neural architectures in core AI fields like natural language processing and computer vision, their potential in modeling complex physical systems has been relatively underexplored. Unlike traditional machine learning tasks, physical systems in real-world applications feature scarce measurements and changing hidden states, and therefore calls for an automated self-adaptive mechanism capable of evolving continuously with the current state of system. To this end, we consider the learning of material responses as an exemplar complex physical system modeling problem, and investigate the self-adaptive capability of attention mechanisms toward developing a foundation material model. Specifically, we first show that the attention mechanism is equivalent to a nonlocal neural operator with data-dependent kernels, such that enables the automatic updating of the evolving physical properties via the attention matrix. We then propose Nonlocal Attention Operator (NAO), which provides a forward model in the form of nonlocal constitutive law, ensuring adherence to fundamental physical laws. In a wide variety of scientific applications ranging from constitutive modeling of material deformation, stress wave propagation, to digital twin modeling, we empirically demonstrate the advantages of NAO over the baseline neural operators and state-of-the-art methods in capturing the change of hidden physical states.

DEEP LEARNING ENHANCED POLYCUBE METHOD FOR HIGH-QUALITY HEXAHEDRAL MESH GENERATION AND VOLUMETRIC SPLINE CONSTRUCTION

Yuxuan Yu[*1], Yuzhuo Fang[1] and Jessica Zhang[2]*

[1]*Donghua University*
[2]*Carnegie Mellon University*

ABSTRACT

In this study, we present a novel algorithm that integrates deep learning with the polycube method to generate high-quality hexahedral meshes, which are then utilized to construct volumetric splines for isogeometric analysis. Our algorithm begins by establishing a connection between surface triangular meshes and polycube structures. We employ deep neural network to effectively classify and transform surface triangular meshes into their corresponding polycube structures, thus capturing relevant spatial structural information of the geometry models. Following this, we combine the acquired polycube structural information with unsupervised learning to execute precise segmentation of surface triangular meshes. This step overcomes the sensitivity to the initialization and the noise encountered in traditional polycube methods, but also significantly enhancing the segmentation results while reducing the requirement for manual intervention. Quality hexahedral meshes are then generated from the polycube structures, employing octree subdivision and mapping techniques. The incorporation of deep learning for creating polycube structures, combined with unsupervised learning for segmentation of surface triangular meshes, substantially elevates the efficiency and quality of mesh generation. Finally, truncated hierarchical B-splines are constructed on the generated hexahedral meshes. We extract trivariate Bézier elements from these splines and apply them directly in isogeometric analysis. This study also offers several examples to demonstrate the robustness of our algorithm.

UNIVERSAL CONTACT STIFFNESS OF AXISYMMETRIC INDENTATIONS CONSIDERING THE EFFECT OF MEMBRANE TENSION ON THE SURFACE

Weike Yuan[*1], Yue Ding[1] and Gangfeng Wang[1]*

[1]*Xi'an Jiaotong University*

ABSTRACT

Many biological systems exhibit in-plane membrane tension on their surfaces, a factor often overlooked in existing indentation analyses despite its significant impact on contact responses. This presentation introduces a boundary element method designed to address the normal contact problem of elastic solids covered with thin tensed membranes. Utilizing this method, we calculate the contact stiffnesses associated with indentations using various axisymmetric indenters. Notably, the membrane tension effect leads to contact stiffness values considerably higher than those predicted by conventional theories (e.g., Hertz theory, Sneddon's solution) when the contact size diminishes to the same order as the ratio of membrane tension to elastic modulus. Theoretically, we found that the contact stiffness of arbitrary convex indentations can be universally expressed as a function of contact radius, with an explicit expression derived by modifying conventional solutions. Building on this universal contact stiffness, a straightforward analysis method is proposed to estimate the membrane tension and elastic modulus of biological systems using experimentally recorded indentation load-depth data. This approach proves useful in analyzing indentation experiments conducted on cells and lungs.

PHASE FIELD METHOD BASED ON REDUCED-ORDER-HOMOGENIZATION FOR FIBROUS COMPOSITE MATERIAL

Zifeng Yuan[*1] and Nianqi Liu*[1]

[1]*Peking University*

ABSTRACT

This report proposes a novel multiscale phase field method (PFM) based on reduced-order-homogenization (ROH) approach to investigate the damage evolution for the fibrous composite material, namely the ROH-PFM. In the ROH-PFM, the matrix phase is described by the PFM, and the fiber phase could be modeled by some other classic constitutive model. The overall response of the fibrous composite material then is obtained by averaging and homogenization approaches through the ROH framework in order to obtain the macro-scopic stress and consistent material moduli. In the present work, we derive the governing equations in terms of the displacement field and the matrix phase field. Through the ROH and the Francfort–Marigo variational principle, we can obtain the governing elliptical partial differential equation for the matrix phase field in terms of the stress states of the matrix and fiber phases. The corresponding weak form is derived, and numerical algorithm through the finite element method is derived as well. Finally, three groups of numerical simulations are selected to verify the functionality of the ROH-PFM, while the fibers are assumed to follow an isotropic continuum damage model. The numerical examples show good performance of the ROH-PFM in stating various material degradation mechanism.

DEEP LEARNING FOR MICROSTRUCTURE DESIGN OF VISCOELASTIC COMPOSITES WITH DESIRED RELAXATION MODULI

Kyeonsoo Yun[*1]

[1]*Gangneung-Wonju National University*

ABSTRACT

Viscoelastic materials are widely used in various engineering applications including vibration damping, acoustics, tissue engineering and medical devices. Despite the versatility of viscoelastic materials, it is hard to find one that exhibits the desired relaxation moduli. Composite materials can produce the desired relaxation moduli by designing microstructure.

In this research, a design methodology based on deep learning is developed to find the microstructure of viscoelastic composites with desired relaxation moduli. The viscoelastic composites are assumed to be composed of periodic unit cells. Various shapes of unit cells are generated as initial data sets by performing topology optimization for either maximizing the bulk modulus, the shear modulus or minimizing the Poisson's ratio. Variational autoencoder (VAE) and generative adversarial network (GAN) are trained by using the initial data set and they generate more diverse microstructures. The relaxation modulus of each microstructure is calculated through the numerical homogenization method. Since the relaxation moduli are time-dependent, it is represented by image data. A deep learning model is developed to find a relationship between the two image data sets which are the microstructure and the relaxation moduli. The deep learning model is constructed based on a convolutional neural network (CNN). Both the homogenization and the inverse homogenization problems can be solved by the proposed deep learning model. A microstructure of viscoelastic composite with desired relaxation moduli can be designed by utilizing the trained deep learning model.

ABSTRACT

Mechanical defects resulting from handling, transportation, and manufacturing significantly impact a material's response to applied loads. Conventional numerical simulations for defect detection face challenges due to computational expenses. In response, our study introduces an innovative methodology seamlessly integrating a Machine Learning-enhanced Model Order Reduction technique with a dedicated search algorithm for efficient defect detection.

The machine learning-enhanced technique incorporates Proper Orthogonal Decomposition (POD) for model order reduction and employs Random Forest for Machine Learning, allowing versatile training for diverse defect scenarios. This non-intrusive approach facilitates real-time displacement prediction with varying parameters. The combined use of model order reduction and the search algorithm, adaptable to defect sizes, locations, and degrees, enables on-the-fly determination of displacements in real-time.

This novel methodology represents a significant advancement in structural health monitoring, providing a swift and online approach to defect detection. Its real-time capabilities empower efficient structure management by facilitating the timely identification and response to hidden defects, ultimately enhancing overall structural integrity.

ADVANCING DIRECTED ENERGY DEPOSITION SIMULATIONS THROUGH OPERATOR LEARNING-BASED REDUCED ORDER MODEL DEVELOPMENT

Dewen Yushu[1]*

[1]Idaho National Laboratory

ABSTRACT

The directed energy deposition (DED) process, a widely utilized additive manufacturing technique, involves intricate physical mechanisms that remain insufficiently understood to this day. Computational tools hold promise for unraveling this complexity and facilitating nondestructive performance evaluations of manufactured parts. A critical challenge in this field lies in the significant space and time scale differences between realistic DED processes and numerical simulations. Current direct numerical simulation approaches struggle to encompass all the intricate physics phenomena across multiple scales within a timeframe comparable to real DED processes. To address this gap, our work focuses on the development of reduced-order models (ROMs) for DED [1-2], based on the Multiphysics Object-Oriented Simulation Environment (MOOSE) framework [3-4]. Notably, machine learning (ML) techniques, which are becoming especially popular in ROM creation, carry the potential for quick, accurate predictions across a diverse range of problems. In the present study, we specifically explore utilization of the operator learning (OL) approach, which enables the learning of a family of differential equations across a broad spectrum of process and material parameters. In addition, we employ deep neural networks (DNNs) and physics-informed neural networks (PINNs) to create ROMs. A comparative analysis of their performance sheds light on the efficacy of these ML approaches in enhancing the speed and accuracy of simulating the DED process. The findings contribute to bridging the gap between realistic DED processes and numerical simulations, showcasing the potential of ROMs and ML techniques to advance our understanding and accelerate simulations in DED.

FULLY ANISOTROPIC MATERIAL MODELS IN ORDINARY STATE-BASED PERIDYNAMICS

Mirco Zaccariotto[*1], Francesco Scabbia[1] and Ugo Galvanetto[1]*

[1]*University of Padova*

ABSTRACT

The need to optimise the use of resources and adapt the performance of materials to the specific requirements of applications has promoted the adoption of materials with anisotropic properties. Several engineering sectors, such as structural engineering, aerospace and bioengineering, are taking advantage of this possibility. Therefore, within the framework of classical continuum mechanics, appropriate constitutive laws have been developed to model the mechanical behaviour of these materials [1]. Unfortunately, the need to simulate material failure and damage propagation requires the adoption of alternative theories to the classical one. Peridynamics (PD) theory [2] has proven particularly effective in simulating the propagation of discontinuities such as cracks, therefore it is crucial to develop constitutive laws for anisotropic materials in PD. For that purpose, the use of bond-based PD is limited by the inherent restrictions on the values of the mechanical properties that can be simulated [2], while the use of non-ordinary state-based PD [3] requires the adoption of strategies to mitigate the problem of zero-energy modes. Ordinary state-based PD, on the other hand, does not suffer from the limitations of the other PD versions. We therefore propose an ordinary state-based PD formulation capable of modelling the linear elastic behaviour of fully anisotropic materials in both 2D and 3D. With the developed strategy, all components of the elasticity tensor of classical continuum mechanics expected for anisotropic materials can be effectively reproduced within the PD framework. To achieve this, two distinct micromoduli were introduced that depend on the orientation of the bonds and were defined to correspond to the classical mechanical properties in the case of an infinite body subjected to homogeneous deformation. The new formulation was applied in several 2D and 3D examples to demonstrate its effectiveness and accuracy.

HYBRID DEEP LEARNING APPROACHES FOR DYNAMIC ANOMALY DETECTION IN BIO-FET BASED BIO-CYBER INTERFACES

Sidra Zafar[*1]*

[1]*Kinnaird College for Women*

ABSTRACT

The Internet of Bio-Nano Things, or IoBNT, is a new paradigm that uses biological transceivers that are nanoscale (~1-100 nm) to gather in vivo signaling data from the human body. The healthcare practitioners are then informed of this information through the Internet. Targeted drug delivery to previously unreachable areas of human tissue is made possible by bio-nano-things (BNT), which allow external actuation of in-body molecular communication (MC). These BNTs are linked to an external ex vivo environment, like the Internet, through bio-cyber interfaces, forming an in body bio-nano network via chemical diffusion channels.

Because of its affordability and non-intrusive design, Bio-Fet bio-cyber interfacing (BFI) has showed promise in the field of IoBNT systems. However, because Internet access exposes interfaces to external threat vectors, the installation of Bio-Fet BFI generates security risks. For effective mitigation, accurate characterization of aberrant BFI traffic patterns becomes essential. Current machine-learning (ML) techniques for anomaly identification, which frequently depend on manually designed features, are constrained by the intricacies of the connections between BFI traffic attributes and their parameters.

In order to overcome these challenges, this work investigates the use of deep learning (DL) methods, which enable dynamic and scalable feature engineering for the purpose of differentiating between typical and abnormal BFI traffic. After a thorough validation process on the created dataset utilizing singular and multi-dimensional models, our hybrid convolutional and recurrent ensemble (CNN + LSTM) outperformed other deep and shallow structures with an accuracy of upto ~83.56%. The incorporation of a hybrid deep learning network enabled the automated extraction of normal and temporal characteristics from BFI data, hence obviating the necessity for manual feature selection and crafting for precise prediction.

Finally, this work advocates for the integration of emerging non-Von Neumann architectures for real-time anomaly detection and suggests implementing the extracted best classifier in traditional intrusion detection systems. This research advances the development of safe and effective IoBNT systems by emphasizing the scalable and dynamic properties of DL algorithms, especially when it comes to Bio-Fet bio-cyber interfacing.

EFFICIENT DESIGN AND SIMULATION OF NONLINEAR METASTRUCTURES USING MAXIMALLY-LOCALIZED WANNIER FUNCTIONS

Sima Zahedi Fard[*1], Parisa Omidvar[1], Paolo Tiso[2] and Marc Serra Garcia[1]*

[1]*AMOLF*
[2]*ETH Zürich*

ABSTRACT

Elastic wave propagation in typical MEMS structures (made of e.g., Silicon or Silicon Nitride) has an extremely low energy dissipation, which makes these structures a promising candidate for metamaterial-based passive (or near-zero power) neuromorphic information processors. However, designing elastic structures that perform computations is a formidable challenge. The reason is that neural networks require a massive number of neurons (in this case, implemented with nonlinear resonators), reaching the limits of direct optimization based on the Finite Element Method. This requires the development of new methods capable of efficiently modelling the nonlinear response of elastic metamaterials.

In this research, we have developed a new model order reduction technique based on the concept of Wannier functions – linear combinations of lattice eigenmodes that are maximally localized at each resonator site. This method draws inspiration from the basis functions used in Density Functional Theory modelling of material responses. In comparison with other reduced order models, this method has two significant advantages: The first key benefit is the sparsity of the reduced nonlinear tensors. The second is the local dependence of each model parameter in one oscillator and its neighborhood, which allows us to extract the effective parameters by repeatedly simulating small clusters of sites instead of the entire lattice. The combination of these two properties allows us to effectively simulate highly complex, non-periodic metamaterials in linear time with the number of sites. In addition to representing the system dynamics using a basis of maximally-localized functions, we use the quadratic manifold technique to statically condense higher-order modes (such longitudinal displacements arising from to geometric nonlinearity), without significantly increasing the computational cost.

The method works in both static and dynamic regime and can capture non-trivial properties such as buckling. We will illustrate the capabilities of our method by designing functional metamaterials (such as logic gates and topological insulators) and validating their performances against high-fidelity simulations.

A P-ADAPTIVE IMPLICIT SHOCK TRACKING METHOD FOR HIGH-SPEED VISCOUS FLOWS

Huijing Dong[1], Masayuki Yano[2] and Matthew Zahr[*1]*

[1]University of Notre Dame
[2]University of Toronto

ABSTRACT

Shock tracking or shock fitting, where the computational mesh is moved to align mesh element faces with discontinuities, represents them perfectly with the inter-element jump in the solution basis without requiring additional stabilization when addressing shocks. In our previous work, we introduced an implicit shock tracking framework that discretizes conservation laws on a mesh without knowledge of discontinuities and solves a PDE-constrained optimization problem over the discrete solution variables and nodal coordinates of the mesh. A Discontinuous Galerkin (DG) discretization of the governing equation is applied and implicit tracking is formulated as an optimization problem constrained by the DG residual to endow the method with desirable properties of DG: consistency, conservation, and stability. The optimization problem is solved using a sequential quadratic programming method that simultaneously converges the mesh and flow solution to their optimal values.

In this talk, we present a p-adaptive implicit shock tracking method aimed at solving steady and unsteady high-speed viscous flows. The polynomial degree is adapted used an indicator based on the enriched residual, which tends to increase the polynomial degree within shocks and boundary layers. A series of shock-dominated numerical experiments demonstrate the potential of the method to efficiently produce accurate solutions to these challenging problems.

MICROSTRUCTURE-BASED FINITE ELEMENT MODELING OF THE STRAIN-RATE-DEPENDENT MECHANICAL BEHAVIOR OF ADDITIVELY MANUFACTURED ALUMINA CERAMICS: TOWARDS COUPLING MULTISCALE MODELING AND DATA-DRIVEN APPROACHES

Zahra Zaiemyekeh[*1], Saman Sayahlatifi[1], Dan L Romanyk[1] and James Hogan[1]*

[1]*University of Alberta*

ABSTRACT

This study develops a microstructure-based finite element (FE) model to predict the strain-rate-dependent mechanical failure behavior of additively manufactured (AM) alumina ceramics towards coupling with machine learning approaches for the development of a data-driven model. AM alumina was first micro-structurally characterized and the data (i.e., grain size distribution, grain crystallographic orientations, and void volume fraction) was used to generate polycrystalline-based representative volume elements (RVEs) of the material. To account for the transgranular failure mechanism, the grains were constitutively modeled by the JH2-V (i.e., a viscosity regularized form of the Johnson–Holmquist-II (JH2) model) model where the strain-rate-dependent behavior of ceramics is accounted for, and this model was implemented by a VUMAT subroutine in Abaqus/Explicit solver. The interfaces between the grains were modeled by the bi-linear cohesive zone model (CZM) approach to account for the intergranular failure mechanism. The microstructure-informed FE model was validated by experimental data derived from rate-dependent testing coupled with ultra-high-speed imaging (e.g., stress-time histories and fracture processes). Here, the evolution history of the failure mechanisms in the model was quantified by the fraction of fully damaged entities (i.e., elements or interfacial nodes) to provide a better understanding of the initiation and growth of the failure in the material. Next, the validated FE model was leveraged to study the effect of microstructural features (e.g., void volume fraction, void size, and interface properties) on the macro scale response of the AM alumina. The current microstructure-based FE model will be exercised to generate datasets for the training and validation of an artificial neural network (ANN) that correlates the mechanical properties of the material (e.g., strength) at the macroscale to the microstructure and strain rate. Such a computationally efficient surrogate model has great potential to be utilized for accelerating the design and optimization of better-performing AM ceramics as future materials.

EXPLORING BIOTRANSPORT IN A POROELASTIC MODEL OF HUMAN VOCAL FOLDS

Rana Zakerzadeh[*1], Isabella McCollum[1] and Manoela Neves[1]*

[1]*Duquesne University*

ABSTRACT

The aim of this study is to analyze the role of porous media in modeling the flow and oxygen transport in the context of human phonation modelling. Poroelastic models are suitable to characterize the biomechanics of the vocal folds as their tissue are composed of dispersed cells separated by connective voids which allow for the flow of nutrients. Considering the interactions between the airflow through the larynx and the deformation of the fluid-saturated poroelastic vocal folds and integrating this fluid-structure interaction (FSI) coupling with mass transport, improves our ability to compute local changes in oxygenation and perfusion within the tissue. Previous experimental observations report contradictory relationships regarding the effects of phonation on the flow within the tissue and the associated oxygen partial pressure. It has been hypothesized that permeability may influence tissue oxygenation, which corresponds with dysfunctions such as hypoxia and localized lesions.
Our prior research studied the liquid dynamics within the vocal folds by considering a biphasic model for the tissue. In this current study, we aim to combine our FSI-porous vocal fold model with a mass transport model to investigate the association of interstitial flow with oxygen transport within the vocal fold, as well as to explore the interplay between permeability and interstitial liquid velocity within the porous structure. A multiphysics coupled mass transport-FSI computational model by considering transient Navier-Stokes equations for the glottal airflow, Brinkman equation for the interporous flow, and advection-diffusion-reaction equation for oxygen transport is developed. Additionally, the tissue dynamics is modeled using the Biot system of equations for a poroelastic medium. This integrated fluido-chemical framework can numerically simulate the complex flow fields, mechanical stresses, and oxygen concentrations. To analyze the significance of physiological features behind biotransport, selected parameters such as tissue porosity and permeability and lung pressure are varied, and coupled biomechanical simulations of transient glottal aerodynamics, vocal fold tissue dynamics, interstitial fluid dynamics, and oxygen flow are performed. The simulation results focusing on the interstitial velocity streamlines and oxygen concentration contours are measured and analyzed. It is found that oxygenation is directly related to permeability, and not noticeably affected by lung pressure. It is also found that interstitial fluid flow is linearly proportional to lung pressure and exponentially related to permeability. Results facilitate a better understanding of the mechanisms behind the role of poroelasticity on biomechanics and biotransport in phonation models.

CONSTRAINED COST-AWARE MULTI-FIDELITY BAYESIAN OPTIMIZATION

Zahra Zanjani Foumani[*1], Amin Yousefpour[1] and Ramin Bostanabad[1]*

[1]*University of California Irvine*

ABSTRACT

Bayesian optimization (BO) is a widely used technique for finding materials with unprecedented properties. However, relying solely on expensive high-fidelity (HF) sources can inflate optimization expenses in complex scenarios. To address this challenge and incorporate known and unknown constraints, we introduce a novel constrained cost-aware multi-fidelity BO (C2-MFBO) framework which a few novelties. Firstly, it uses manifold-embedded Gaussian process (GP) for emulation which handles mixed input spaces and models source-dependent noise and global trends. Secondly, it leverages a composite acquisition function (AF) that quantifies the information value of high- and low-fidelity sources differently and also accommodates source-dependent constraints. Through analytical and real-world examples, we will demonstrate the benefits of our approach which is publicly available via the GP+ package in Python.

NUMERICAL CRACK PATH PREDICTION IN ANISOTROPIC INHOMOGENEOUS MATERIALS

Konstantin Zarjov[*1] and Andreas Ricoeur*[1]

[1]*University of Kassel*

ABSTRACT

Materials and manufacturing processes are being further developed to meet increasing demands on design and energy efficiency. As a result of the addition of additives to composites or the deformation and heat treatment of metals, these materials exhibit anisotropic mechanical properties. Fracture mechanics, with loading quantities such as the J-integral, complements stress analyses with the FEM in the context of least conservative component design. Due to path independence, the J-integral offers the advantage that numerical inaccuracies at the crack tip are avoided. Furthermore, it is suitable for accurately predicting crack deflection and crack paths [1]. The classical J-integral criterion implicitly takes into account the elastic anisotropy, but not the anisotropy of the fracture toughness. The latter, however, has a considerable influence on the crack deflection behavior regardless of its origin, e.g. in fiber composites [2] or in formed aluminum alloys due to the textures of the grain structure [1]. Therefore, a modified anisotropic J-integral criterion is introduced for a reliable prediction of crack paths.

The crack deflection behavior of different materials varies significantly depending on the degree and shape of the anisotropy. In addition, depending on the manufacturing process, materials exhibit local inhomogeneity of anisotropy. Therefore, stochastic aspects must be taken into account in modeling and simulation [2]. A special case of anisotropy is given by imperfect interfaces or bimaterials, as the crack growth resistance within an interface and that of adjacent materials differ in general. In the context of cohesive zones, oftentimes being applied for interface modeling, the J-integral requires an adaptation involving a cohesive interface contour integral, whereby its numerical implementation, based on inaccurate data of field quantities on the crack boundaries of the cohesive zone [3], represents a challenge.

This work aims at demonstrating the influence of various sources of anisotropy on crack deflection behaviors in the context of crack growth simulations. The focus is on bifurcation phenomena, stochastic aspects and the application of the J-integral and its related deflection criterion to interface-matrix crack transition problems. Selected results are finally compared to experiments.

CHALLENGES AND OPPORTUNITIES IN DESIGNING STIMULUS-RESPONSIVE ARCHITECTED MATERIALS WITH HIGH WORK CAPACITY

Phani Saketh Dasika[1], Haohuan Xu[1], Yunlan Zhang[2] and Pablo Zavattieri[1]*

[1]Purdue University
[2]Purdue University, The University of Texas at Austin

ABSTRACT

The field of architected materials, fueled by advances in additive manufacturing, has enabled new materials with new and improved emerging properties. More recent efforts have recently focused on a new family of stimulus-responsive architected materials and structures that are designed to exhibit dynamic and programmable behavior as they respond to external stimuli, such as temperature, light, pH, mechanical stress, etc. making them suitable for sensors, actuators, drug delivery systems, among others. In this work, we introduce new concepts that will enable us to explore new spaces in the material design maps. In particular we are interested in applications related to morphing, actuation, self-deployment/-reconfigurability where relatively high forces are required. Combining insights from previous works on architected material analogs for shape memory alloys and bioinspired materials, we integrate concepts not extensively explored before, with a strong focus on improving the work capacity of the architected material. To mimic the actuation capabilities of traditional shape memory materials, the challenge lies in understanding the forces involved in the mechanisms that take place at the unit cell and how these forces translate into the emergent work capacity of the material. Achieving this with a simple combination of two polymeric materials has been shown to be particularly challenging. In this talk, I will explain the conceptual framework and how these principles are put into practice through architected materials in such a way that these materials can be used for actuation with a focus on improving their work capacity. We will discuss the complexities of ensuring desired stiffness in unit cells at low/high temperatures and explore innovative bistable/monostable designs, crucial for distinguishing our work in smart architected materials.

DE RHAM COMPATIBLE NEURAL NETWORK FEM

Marcello Longo[1], Joost Opschoor[1], Nico Disch[2], Christoph Schwab[1] and Jakob Zech[2]*

[1]ETH Zurich
[2]Heidelberg University

ABSTRACT

Recent years have seen the emergence of methodologies that approximate PDE solutions via neural networks (NNs). These methods minimize a 'physical' loss, such as the PDE residual or the corresponding energy, thereby representing the PDE solution as a NN output. Consequently, understanding the conditions under which network architectures can represent standard, variationally correct, and structure-preserving finite element spaces from numerical analysis is of considerable interest. In this talk, we construct exact NN emulations of all lowest order finite element spaces within the discrete de Rham complex. These include piecewise constant functions, continuous piecewise linear functions, the classical "Raviart-Thomas element," and the "Nédélec edge element," thereby covering a wide range of problems in computational mathematics. Our construction and NN architecture generalizes previous results in that no geometric restrictions on the regular simplicial partitions of the domain are required for NN emulation.

STUDY ON IRRADIATION THERMO-MECHANICAL BEHAVIOR OF SURROGATE FCM PELLETS

Li Zekun[*1], Zhang Jing[1] and Ding Shurong[1]*

[1]Fudan University

ABSTRACT

Fully ceramic microencapsulated (FCM) fuel has good radiation stability and fission product retention ability under accident conditions, which is considered a momentous direction for the development of accident-tolerant fuel (ATF). FCM fuel pellets are composed of TRISO particles randomly dispersed in a SiC matrix, in which TRISO have multi-layered microstructure, including a fuel kernel, a porous carbon layer (buffer), an inner pyrolytic carbon layer (IPyC), a SiC layer, and an outer pyrolytic carbon layer (OPyC). To improve the economy and safety, it is necessary to conduct in-depth research on the irradiation thermo-mechanical behavior of FCM fuel pellets. For individual effect testing and development of the consolidation process, the Oak Ridge National Laboratory replaced the UO2 kernel with ZrO2 to fabricate the surrogate FCM pellets and carried out the irradiation experimental study on them. Surrogate FCM pellets have complex thermo-mechanical behavior under the irradiation environment. The irradiation effect of each part in the pellet is perfectly considered. A three-dimensional mechanical constitutive, calculation method and program are developed based on the theoretical framework of large deformation. According to the experimental result of the interface cracking of the kernel/buffer, the cohesion model, calculation method, and program are developed. The interface cracking numerical simulation in the irradiation experiment is realized. The results show that: i) The interface cracking can occur under very small irradiation doses. The predicted swelling and internal microstructure information of the pellet are in good agreement with the experimental results; ii) The anisotropic irradiation shrinkage of the buffer skeleton has a dominant influence on the thickness change of buffer and the interface gap width, and the skeleton irradiation creep also has an important influence on the size change, porosity, and skeleton stress evolution. In the simulation of the irradiation thermo-mechanical behavior of FCM pellets, it is critical to use a volume growth strain model that takes into account the contribution of irradiation shrinkage and creep of the buffer skeleton. iii) The first principal stress of the SiC layer first increases with the increase of fast neutron fluence, reaches the maximum value at low fluence then decreases with the increase of fast neutron fluence. The experimental observation after irradiation found that there was no damage in the SiC layer, indicating that its tensile strength is particularly high (over 1800 MPa). Thanks for the support of National Natural Science Foundation of China (Nos.12132005,12135008,12102094,), and the support from Shanghai Sailing Program (21YF1402200).

IMPOSING MANUFACTURING CONSTRAINTS USING POLYGONAL PRIMITIVES PARAMETRIZATION

Yakov Zelickman[*1] and James Guest*[1]

[1]*Johns Hopkins University*

ABSTRACT

Topology optimization has been proven to result in efficient designs in many engineering applications. An ongoing challenge remains in realizing optimized design, where manufacturing requirements necessitate manual adjustments and corrections. To deal with this challenge in density-based optimization, where the geometry is implicitly defined, manufacturing constraints are considered through different schemes of filtering and projection. Examples of such constraints include length-scale control, overhang constraints, machining constraints and others. Feature mapping approaches, on the other hand, are characterized by explicit geometrical parametrization, where geometrical primitives are explicitly parametrized and projected on a fixed background mesh. This explicit parametrization facilitates convenient imposition of geometrical constraints. However most existing studies are limited to shapes that have analytical singed distance function (SDF), and thus offer limited geometrical freedom. Recently, a new polygonal primitive (PP) was introduced that can have any number of sides, can form both convex and non-convex shapes, thereby offering great geometrical freedom. At the core of the formulation of the PP is an approximated SDF that is analytical and explicit in terms of the vertices' coordinates.
In this study, we leverage the rich and explicit shape parametrization, as well as the explicit SDF of the PP to impose different manufacturing constraints. The results show that manufacturing constraints that would have been difficult to impose using density-based optimization or traditional feature mapping approaches can be readily handled with polygonal primitives.

A PHASE-FIELD FRACTURE MODEL FOR BRITTLE MATERIALS SUBJECTED TO THERMAL SHOCKS

Bo Zeng[*1] and John Dolbow[1]*

[1]*Duke University*

ABSTRACT

The modeling of brittle materials fracturing under thermal shocks presents a number of challenges. Shock conditions are characterized by rapid temperature increases, such as from room temperature to over 1000 Celsius degrees in tens of microseconds. This can give rise to large thermal strains and stress gradients that exceed the strength of the material, eventually giving rise to crack formation. This study looks to reproduce a series of fracture tests for sintered ceramics subjected to thermal shocks, with the aid of a thermomechanical model coupled with phase-field fracture. In particular, to model the fracturing in the bulk material, a phase-field model that explicitly incorporates material strength as a nucleation criterion is adopted. We will show that with a controlled perturbation to the system, the model is able to reproduce various experimental observations.

COMPRESSIBLE EULER FLOW COMPUTATIONS AND AERODYNAMICS USING THE SHIFTED BOUNDARY METHOD

Xianyi Zeng[*1] and Guglielmo Scovazzi*[2]

[1]*Lehigh University*
[2]*Duke University*

ABSTRACT

In this talk we present the Shifted Boundary Method (SBM) for inviscid compressible flows on complex and deforming domains with aerodynamic applications. The Shifted Boundary Method belongs to the class of unfitted finite element methods. It reformulates the original boundary value problem over a surrogate (approximate) computational domain that does not have to be conformal to the true geometry; and accuracy is maintained by modifying the original boundary condition using Taylor expansions. Because SBM avoids integration over cut cells, it does not suffer from small time-step issues and allows efficient explicit time integration. Previously the SBM has been applied to solve the Poisson equations, Stokes flow equations, and viscous incompressible flows on complex domains, and in this talk we detail the derivation of SBM for more complex wave structures for Euler equations.

In addition to the general methodology derivation and numerical verification, we also discuss the advantages the SBM offers in avoiding spurious numerical artifacts in two scenarios: (a) when curved boundaries are represented by body-fitted polygonal approximations and (b) when additional condition needs to be enforced at a geometrical singularity, such as the Kutta condition at the trailing edge of an airfoil. Lastly, we investigate how these advantages enable SBM to perform efficient and reliable aerodynamics computations to problems like flow past a flapping airfoil.

DATA-DRIVEN UNCERTAINTY QUANTIFICATION AND PREDICTION FOR MODELS WITH HIGH-DIMENSIONAL DEPENDENT PARAMETERS

Xiaoshu Zeng[*1] and Roger Ghanem*[1]

[1]*University of Southern California*

ABSTRACT

Complex physical systems often involve high-dimensional parameter spaces, particularly when dealing with uncertainty quantification (UQ) and response prediction. Exhaustively exploring the entire parameter space is impractical due to the computational cost associated with accurate high-resolution models. In such scenarios, UQ and prediction tasks encounter two significant challenges: the curse of dimensionality and the intricate dependency structure among the parameters. Recent work by the authors introduced a data-driven Projection Pursuit Adaptation (PPA) method within the framework of polynomial chaos expansions. This method utilizes independent Monte Carlo samples to identify an optimal low-dimensional parameter space adapted to the quantities of interest. By reducing parameter dimensionality, PPA efficiently constructs accurate surrogate models for UQ and prediction, even with a limited number of samples. In this study, we extend PPA to handle dependent parameters. While Rosenblatt transformation is commonly employed to decouple input parameter dependencies, it necessitates knowledge of the joint parameter distribution, which can be data-intensive to estimate. Therefore, we propose using multivariate Regular Vine (R-vine) copulas to capture parameter dependency structures, which are typically more accessible to estimate from available data. R-vine copulas contain the necessary joint distribution information and can be integrated into the Rosenblatt transformation to decouple dependent parameters. We combine R-vine copulas with the PPA method to establish a unified data-driven framework for surrogate modeling of complex physical systems with high-dimensional dependent parameters. This approach relies on a minimal number of independent Monte Carlo samples to construct accurate UQ and prediction models. The method has been tested on both a borehole model and a space structure, demonstrating its significant potential in accurate surrogate modeling.

ABSTRACT

Friction depends on geometries of both surfaces of a contact pair, yet numerical or analytical studies involved in two rough surfaces are limited. In this study, we revisit the Cattaneo-Mindlin problem for the contact between two elastic or elasto-plastic spheres with isotropically fractal roughness generated based on ultra-high degree Spherical Harmonics. Transverse contacts are simulated by finite element method (FEM), which is validated by the extended Cattaneo-Mindlin solution to full slip regime for smooth sphere contacts. Gigantic parameter studies, including material properties, intrinsic friction coefficient, normal contact distance, relative roughness, fractal dimension, and wavelength range, in the FEM simulations show that: (1) the newly extended Cattaneo-Mindlin solution can approximately predict the macro contact response between two rough spheres except for extremely high relative roughness and narrow wavelength range; (2) departures induced by roughness of macro normal and frictional forces from smooth sphere contacts can be neutralized by plasticity, deep normal contact interference, and higher intrinsic micro friction coefficient; and (3) considering the realistic values of the two factors adequately quantifying the multi-scaled rough grain topology, fractal dimension impacts frictional contacts less than root mean square roughness. The main cause of these phenomena can be credited to the underlying microscale contact information; distributions of contact areas and stresses and their evolutions provide concrete evidence of the observed behaviour. Our results provide a pathway for applying computational contact mechanics to many geophysical fields involving frictional contacts, such as the asperity model in earthquake engineering and the mechanics of granular materials.

TENSION-COMPRESSION ASYMMETRY OF NICKEL ALLOY VIA ATOMISTIC SIMULATIONS

Haifei Zhan[1,2], Bin Dong[1] and Chaofeng Lü[3]*

[1]*Zhejiang University*
[2]*Queensland University of Technology*
[3]*Ningbo University*

ABSTRACT

Nickel-based single crystal alloys exhibit significant tension-compression asymmetry during service [1,2], and a thorough analysis of their underlying mechanisms is crucial for optimizing its design and predicting its service performance. In this study, the collective variable hyperdynamics (CVHD) method was employed to investigate the vacancy diffusion in nickel under different pressures and temperatures through molecular dynamics simulations [3]. Our simulation revealed that the vacancy diffusion rate in nickel decreases as hydrostatic pressure increases. When uniaxial stress is applied, both tension and compression stress states accelerate the total diffusion rate and introduce anisotropy in diffusion. Additional investigation indicates that size significantly influences its mechanical properties. The initial dislocation evolution during the elastic stage and the dislocation non-uniformity caused by lattice rotation during plastic flow play crucial roles in tension-compression asymmetry.

DEVELOPMENT OF GPU ACCELERATED KINETIC MODELING CODES IN FUSION PLASMA PHYSICS AND GAS DYNAMICS

Chonglin Zhang[*1], Gerrett Diamond[2], Cameron Smith[3] and Mark Shephard[3]*

[2]*MathWorks*
[3]*Rensselaer Polytechnic Institute*

ABSTRACT

Kinetic theory studies the physical system from the microscopic descriptions of atoms, molecules, ions, electrons, and their interactions. Kinetic modeling represents a more accurate description compared to the continuum approach. The governing equation of kinetic theory is the Boltzmann equation. To solve this integro-differential equation accurately and efficiently, particle-based simulation methods are being widely used in kinetic modeling. Owning to their unique properties, particle methods can largely benefit from the advancement in GPU accelerated high performance computing [1, 2].

We discuss recent work developing two GPU accelerated particle simulation codes, XGCm [3] and Comet. XGCm is a gyrokinetic particle-in-cell (PIC) code used in fusion plasma physics. Comet is a direct simulation Monte Carlo (DSMC) code used in hypersonic flow and rarefied gas dynamics, including micro and nanoscale flows. Despite the distinct application areas, they are rooted in the same kinetic modeling framework. Both codes use distributed unstructured mesh and mesh-centric data structure for particle operations. They employ several open source libraries to interact with GPUs and perform parallel operations, including Kokkos, Omega_h, Cabana, PUMIPic, and PETSc.

We first briefly discuss the numerical methods and algorithms used to perform particle operations on the GPUs. We then present code validation studies. In XGCm, the circular geometry cyclone base case is used and the calculated turbulence growth rate shows excellent agreement with existing simulation results. In Comet, simulation results of hypersonic rarefied gas flows are compared with existing experimental data. Finally, we show the parallel performance of the two codes, particularly the excellent weak scaling of XGCm on Summit supercomputer at the Oak Ridge National Laboratory.

ELECTROMAGNETIC COILGUN LAUNCH OF HIGH-TEMPERATURE PROJECTILE CONSIDERING THERMAL EFFECT

Chunyang Zhang[*1], Jun Liu[1] and Zongxing Liu[1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

Blade containment of turbine engines is a long-term concern. The blades are always exposed to high temperatures and high energy, which causes fatigue damage to the material and produces high-velocity debris impacting the engine casing. The casing needs to contain debris to prevent it from penetrating, otherwise it will be a serious safety hazard to the flight.

Most studies on blade containment are ballistic impact tests with air guns. The combination of the projectile and the sabot needs to cling to the gun barrel during the air gun launch. If a high-temperature projectile is launched, it will produce a strong heat conduction with barrel, which will affect the working life of the barrel. Moreover, it takes a long preparation time for air gun launch, which leads to a long cold contact time and a large heat loss of the high-temperature projectile. Therefore, it is difficult to launch projectiles at high temperature, and the impact resistance of casing at high temperature is mostly tested only by heating the target.

The idea of loading a high-temperature projectile using an electromagnetic coilgun was proposed. The electromagnetic coilgun is quite different from an air gun because of its short preparation time, high launch efficiency and accuracy, and no contact between the projectile and the gun barrel. Therefore, a preheated high-temperature projectile can be dropped into the barrel through heat insulation, and then directly launch. Heat is lost during dropping and launching, but the current induced by the conductors in electromagnetic fields also causes thermal resistive of the projectile, which can be calculated separately in theory. In this paper, a theoretical model of the dynamic response of the projectile during electromagnetic launch is established, and the movement and temperature changes of the projectile are analyzed. The theory can provide technical support for electromagnetic coilgun launch of high-temperature projectiles. On this basis, the feasibility of carrying out the research on high-temperature blade containment based on electromagnetic coilgun launch is prospected.

APPLICATION OF MATERIAL POINT METHODS TO OBJECTS WITH COMPLEX GEOMETRIES

Duan Zhang[*1], Kyle Perez[1], Paul Barclay[1] and Jiajia Waters[1]*

[1]Los Alamos National Laboratory

ABSTRACT

We use the material point methods (MPM) to overcome many difficulties related to numerical simulation of objects with complex geometries subjected to extreme deformations and stresses. These issues include complex geometries of 3-D printed materials, mesh or material point generation from CT-scanned images, and distortion of elements in typical Lagrangian methods. Different form many other mesh-based methods, in MPM we can use positions of material points to accurately represent the location and shape of an object. The material points can be generated from stereolithography (STL) files commonly used in advanced manufacturing and computer aided design applications. The background mesh in material point method calculations is not required to be body conforming. The efficiency, accuracy, convergence, and convenience of the method are illustrated using examples.

For the pre- and post- processing of the numerical results, we benchmark the significant efficiency improvements of a new material point generation method and then discuss the presentation of numerical results using the STL file format on material surfaces. Traditionally, the material points are generated based on the computational meshes. With the new efficient material point generation technique, the material points can now be generated independent of the mesh. This new capability causes a new issue related to different numbers of initial material points in adjacent cells. An efficient numerical algorithm has been developed to address the issue. With the algorithm, we will also show the freedom gain of using material point methods.

This work is sponsored by ASC, C2, and LDRD programs of Los Alamos National Laboratory under auspices of U.S. Department of Energy.

COUPLED HYDRO-THERMO-MECHANICAL MODELING CONSIDERING PHASE TRANSITION FOR SC-CO2 FRACTURING IN FRACTURED ROCKS

Haitao Yu[1], Gai Zhang[1] and Xiao Yan[1]*

[1]Tongji University

ABSTRACT

Abstract: Supercritical carbon dioxide (Sc-CO2) fracturing is a developing fracturing technology in the unconventional reservoir stimulation due to its potential to increase production, reduce water requirements, and minimize environmental impacts. With the injection and transport of cold CO2 in geological fractured reservoirs, the elevated reservoir pressure and thermal effects mutually lead to rock deformation and fracture propagation. Once the fracture dynamically propagates, a large void volume would be instantly created causing Sc-CO2 expansion at the fracture tip and inducing the phase transition within the fracture. The phase transition would have a significant influence on the distribution of pressure and temperature, as well as the fracture deformation. However, the phase transition effect is commonly neglected within the fracture in previous numerical studies.

In this study, a coupled hydro-thermal-mechanical model considering phase transition in fractured media was developed to investigate multi-phase flow, heat transport, the CO2 phase transition as well as the fracture deformation and propagation during Sc-CO2 fracturing process. The Span-Wagner equations and the transport equations were introduced to determine the variations of CO2 properties. The modified specific heat capacity, as the characteristic quantity of phase transition, was used to describe the interphase heat transfer. Mixture fluid flow in the rock matrix and fracture was governed based on the modified Darcy law. Heat exchange between fluid and rock matrix obeyed the local thermal non-equilibrium principle. In addition, the effective stress theory and thermal strain effect were taken into account in the stress equilibrium equation of porous rock matrix. The damage of element nodes was judged by the maximum tensile stress failure criterion and Mohr-Coulomb failure criterion according to the continuum damage mechanic model.

The commercial software COMSOL and MATLAB were coupled to solve the multi-field equations. The accuracy and reliability of the numerical method are evaluated and confirmed by the published results. The spatiotemporal evolution of CO2 phase state within the fracture was revealed, and the effects of SC-CO2 phase transition on the coupling characteristics of temperature field, pressure field and deformation field were discussed.

This developed numerical framework and analysis results are expected to provide insight into the effect of phase transition during SC-CO2 fracturing, thereby laying theoretical base for evaluating fracture morphology and fracturing effect.

BANDGAPS IN ACOUSTIC METAMATERIALS: DESIGN AND UNCERTAINTY QUANTIFICATION INCLUDING STOCHASTIC GEOMETRIC DEFECTS AND MATERIAL PROPERTIES

Han Zhang[*1], Rayehe Karimi Mahabadi[1], Cynthia Rudin[1], Johann Guilleminot[1] and Catherine Brinson[1]*

[1]*Duke University*

ABSTRACT

Acoustic metamaterials are a subject of increasing study and utility. Through designed combinations of geometries with material properties, acoustic metamaterials can be built to arbitrarily manipulate acoustic waves for various applications. Despite the theoretical advances in this field, however, acoustic metamaterials have seen limited penetration into industry and commercial use. A significant bottleneck is the difficulty of manufacturing the required intricate geometries and the sensitivity of metamaterial designs to material batch variability and manufacturing defects. Capturing the effects of stochastic material properties and geometric defects requires empirical testing of manufactured samples, which is prohibitively expensive with high precision requirements or with an increasing number of input variables. Through the application of uncertainty quantification techniques, sampling needs can be greatly reduced for characterizing acoustic meta- material dispersion characteristics. For the case of stochastic material properties and geometry, two to three orders of magnitude sampling reductions were achieved in a 7D input space scenario with polynomial chaos expansion and spectral projection, combined with a novel method of encoding geometric defects with a scalar parameter.

Remarkably, this reduction in sampling was possible while preserving accurate output probability distributions of the metamaterial performance characteristics (bandgap size and location). Ongoing work focuses on enhancing metamaterial design iteration efficiency and inverse design capabilities by leveraging the latest advances in deep learning techniques.

UNSUPERVISED-MACHINE-LEARNING ASSISTED TOPOLOGY OPTIMIZATION FOR MULTIFUNCTIONAL STRUCTURE WITH BIONIC STRUCTURAL GENE

Heng Zhang[*1], Sen Kong[1] and Xiaohong Ding[1]*

[1]*University of Shanghai for Science and Technology*

ABSTRACT

As we know many bionic structures show excellent multifunctional mechanical performance, for example, the honeycomb structure has better high stiffness lightweight, and good energy absorption performance, and the bone trabecula also shows similar performance. To integrate these bionic structure genes into the structural topology optimization. This study proposes an unsupervised-machine-learning assisted new topology optimization method for multifunctional structure design[1]. To embed the bionic structural gene into the design, a neural style transfer technique is adopted for measuring and generating the prior knowledge from a reference bionic structure image with the concerned functional gene. The new structure obtained by combining the traditional topology-optimized structure and the given biological structure features not only maintains the original mechanical performance of the topology-optimized structure, but also obtains the special performance of the biological structure, for example, energy absorption. Firstly, the pre-trained VGG19 convolutional neural network(CNN) is selected as a feature extraction tool[2], and the CNN is used to extract and quantify the structural features from biological structures and topology-optimized structures. The total loss function is established by style and content loss. Secondly, taking the total loss function as a constraint, after the neural network reaches a certain number of learning times in each step of the optimization process, the total gradient value obtained from the neural network is used as the sensitivity of a single optimization step, and the total loss constraint and the sensitivity are added into the MMA optimizer for optimization. Finally, the typical design examples in the field of shock absorption and buffering are studied[3]. The results show that after adding the honeycomb structural gene into the optimization, the optimized structure obtains the hole features of the honeycomb, there are dense holes in the internal solid material of the structure, and it is found that the energy absorption effect per unit volume of the structure integrated with biological features is significantly improved than that of the original structure.

3D MESOSCALE FRACTURE INVESTIGATION OF ULTRA HIGH PERFORMANCE CONCRETE CONSIDERING FIBRE ORIENTATION CHARACTERISTICS

Hui Zhang[*1], Chao Gao[2] and Yu-jie Huang[1]*

[1]North University of China
[2]Zhejiang Province Institute of Architectural Design and Research

ABSTRACT

Ultra high performance fibre reinforced concrete (UHPFRC) is composed of fibres, mortar, fibre-mortar interfaces, and pores randomly distributed in space. The damage and fracture of ultra high performance fibre reinforced concrete (UHPFRC) is inherently dependent on fibre orientation and distribution [1]. This work first carried out uniaxial tensile tests of UHPC where the fibres were oriented by an external magnetic field [2]. The fibres were thus subjected to the electromagnetic force and underwent directional distribution, i.e. along the magnetic field direction. Three groups of fibre orientation were used: parallel to the tensile direction, perpendicular to the tensile direction, and no magnetic field applied. This resulted in three groups of specimens termed aligned-UHPC (AUHPC), perpendicular-UHPC (PUHPC), and UHPC, respectively. The effects of fibre orientation on cracking processes and stress-strain curves of UHPC under tension are studied using image analyses and digital image correlation techniques. Secondly, a 3D mesoscale finite element model was developed, in which cohesive elements were pre-inserted in the mortar to simulate the energy dissipation in the fracture process zone and the opening/closing of discrete cracks [3]. Different fibre orientation distribution in AUHPC, UHPC, and PUHPC was generated using a random algorithm. The fibre-mortar interaction was equivalently modelled through fibre constitutive laws, which were curve-fitted from the pullout force-slip relations extracted from single fibre pullout tests for various inclination angles. The proposed model was validated by single fibre pullout tests and direct tensile tests. The mesoscale influencing factors on complex multiple cracking and fibre bridging mechanisms were also quantified.

ABSTRACT

Uncertainty in digital twins is inevitable due to modeling assumptions, inherent randomness in the loads, sensor noise etc. The uncertainty must be quantified to ensure reliable predictions, but many of the sources of uncertainty lack an obvious parametric form. The stochastic projection-based reduced-order model (SPROM) [1] is a non-parametric approach for reducing and quantifying uncertainty in the digital twin via probabilistic model learning from sensor data. This talk presents the steps required to train a load parametrized SPROM for predicting the dynamic response of an indoor footbridge with quantified uncertainty. The input to the digital twin is a set of "what-if" loading parameters, or live measurements of the 6 strain gauges on the bridge, from which the loads can be inferred. The output is a probabilistic prediction of the physical structure's response under the specified loads, including quantities and regions of interests that are not directly monitored with sensors. Since the SPROM is a model updated from strain data, it captures the response and the associated uncertainty of a “healthy” structure. Hence the SPROM provides a baseline against which future changes in the structure can be reliably quantified and diagnosed. This is a unique advantage compared to alternative approaches (e.g., Kalman Filter) which forecast the immediate future state of the system. The contribution of this work lies in: 1) training an SPROM for a physical structure under complicated loads, and 2) using live monitoring data collected while the structure is fully operating. A key challenge is that the live loads producing the strain measurements are entirely random and not known in advance. To this end, we first leverage cameras installed on the bridge to extract 200 "events" of a single person crossing the bridge over 3 days. Second, we use a parametrized projection-based ROM to infer the walking loads for each event, the details of which are presented in a separate talk submitted to this mini-symposium. Third, we use stochastic gradient descent to optimize the "randomness" of the SPROM such that we maximize the likelihood of observing the strain measurements. Our initial results demonstrate the viability of the approach, even with “gappy” sensor data due to partial corruptions by unexpected bursts of electromagnetic interference.

ABSTRACT

Complex civil structures such as bridges, towers, and buildings, are frequently monitored with a network of sensors that collect extensive physical and environmental data. This data is crucial in assessing the structural health and state, and in evaluating both short and long-term behaviours. Improved interpretation of monitoring data can be achieved by coupling it with digital twins—virtual replicas of physical systems. Digital twins can serve as essential tools for facilitating maintenance and operational tasks for civil structures, including health monitoring, fault detection, and performance evaluation. To utilize sensor data effectively, relevant knowledge for each specific digital twin should be extracted from raw data using sensor fusion. Sensor fusion involves the intricate process of mixing, augmenting, and filtering data from traditionally disparate sensors to obtain a comprehensive view of a system's state. For example, the excitation of the first mode of vibration in a bridge under moving traffic loads can be derived from displacement or strain data obtained from at least two sensors installed at distinct locations along the bridge. Neural Networks have shown promise in extracting knowledge from various sources, including images, texts, and graphs, by discerning patterns and rules within a learning process. In this study, we leverage real-world sensor data and exploit neural network capabilities to introduce a model for knowledge extraction from sensor data installed on civil structures. Specifically, we adapt UNet[1]—a convolutional encoder-decoder model with residual connections—to detect and parameterize walking loads on a pedestrian bridge. The model utilizes strain gauge data from three locations along the bridge and distinctively identifies walking events by precisely determining their start (when the pedestrian enters the bridge) and end (when they leave) times. Next, an encoder convolutional model is trained on the data to ascertain walking load parameters such as speed, step frequency, and load magnitude. Our results show that neural networks, if carefully tuned and trained, can serve as versatile sensor fusion tools capable of identifying a structure's state with a minimum number of sensors, potentially reducing the cost and complexity of sensor systems on civil structures.

UNDERSTANDING NEURODEVELOPMENTAL DISORDERS USING ISOGEOMETRIC ANALYSIS, THB-SPLINES AND ADAPTIVE DOMAIN EXPANSION

Jessica Zhang[*1] and Kuanren Qian*[1]

[1]*Carnegie Mellon University*

ABSTRACT

In the US, neurodevelopmental disorders (NDDs) have emerged as the most prevailing chronic medical conditions in the pediatric population, with a notable increase from 6.3% in 1997 to 10.8% in 2021. Comprised of a diverse group of diseases such as autism spectrum disorder (ASD), attention deficit hyperactivity disorder (ADHD), and epilepsy, NDDs are characterized by substantial impairments to cognitive, speech, memory, motor, and other neurological functions, exerting life-long detrimental effects on patients. These symptoms arise due to disruptions of the neurodevelopmental process, leading to severe adverse impacts on the growth of neurons and the formation of vital central and peripheral nervous systems. However, the heterogeneous nature of NDDs presents formidable challenges in identifying the underlying etiology, facilitating accurate diagnosis, and administering the necessary treatments. A competent computational neuron growth model holds immense potential to advance our understanding of multifaceted factors behind the growth process, contribute to the development of potential treatments, and identify the underlying root causes. In this study, we introduce a novel 3D neuron growth model utilizing the phase field method and isogeometric analysis (IGA) to model intricate neurite outgrowth. Leveraging adaptive domain expansion, our model can efficiently expand the domain as needed based on neurite outgrowths to lower computational costs by minimizing the degrees of freedom. With truncated hierarchical B-splines (THB-splines), our model can adeptly simulate complex neurite structures on coarse mesh while preserving accuracy by applying multiple levels of local refinements. Extending beyond the computational model, we conduct comprehensive investigations of neurodevelopmental disorders using the computational model to unveil the effect various factors have on the growth process.

HYBRIDOCTREE_HEX: HYBRID OCTREE-BASED ADAPTIVE ALL-HEXAHEDRAL MESH GENERATION WITH JACOBIAN CONTROL

Jessica Zhang[*1] and Hua Tong*[1]

[1]*Carnegie Mellon University*

ABSTRACT

We present a new software package, “HybridOctree Hex,” for adaptive all-hexahedral mesh generation based on hybrid octree and quality improvement with Jacobian control. The proposed HybridOctree Hex begins by detecting curvatures and narrow regions of the input boundary to identify key surface features and initialize an octree structure. Subsequently, a strongly balanced octree is constructed using the balancing and pairing rules. Inspired by our earlier preliminary hybrid octree-based work, templates are designed to guarantee an all-hexahedral dual mesh generation directly from the strongly balanced octree. With these pre-defined templates, the sophisticated hybrid octree construction step is skipped to achieve an efficient implementation. After that, elements outside and around the boundary are removed to create a core mesh. The boundary points of the core mesh are connected to their corresponding closest points on the surface to fill the buffer zone and build the final mesh. Coupled with smart Laplacian smoothing, HybridOctree Hex takes advantage of a delicate optimization-based quality improvement method considering geometric fitting, Jacobian and scaled Jacobian, to achieve a minimum scaled Jacobian that is higher than 0.5. We empirically verify the robustness and efficiency of our method by running the HybridOctree Hex software on dozens of complex 3D models without any manual intervention or parameter adjustment. We provide the HybridOctree Hex source code, along with comprehensive results encompassing the input and output files and statistical data in the following repository: https://github.com/CMU-CBML/HybridOctree_Hex.

[1]*Beijing Normal University*
[2]*Villanova University*
[3]*University of British Columbia*
[4]*Virginia Tech*

ABSTRACT

Traumatic brain injury (TBI) is a significant health concern, with rotation-induced TBI being particularly severe. To gain a deeper understanding of this issue, we have developed a finite-element code to simulate the impact dynamics in a simplified setup. The model involves a spherical hydrogel ball, representing the soft brain matter, suspended in a fluid within a transparent cylinder. The hydrogel ball is treated as a poroelastic material infused with fluid, and its interaction with the surrounding fluid is managed using an arbitrary Lagrangian-Eulerian method. Our simulations reveal that the contrast in density between the ball and the fluid, as well as the difference in rotational velocity, are key factors in the deformation of the ball due to centrifugal forces.

To validate and further explore these findings, we conducted experiments where the hydrogel ball was subjected to controlled rotation within a water bath, which emulates the cerebrospinal fluid (CSF). Measurements of the cylinder and ball velocities, along with the deformation of the ball over time, were taken. Our experimental results corroborate the computational findings, showing that phases of acceleration and deceleration are most likely to cause damage to the brain model.

This combined numerical and experimental approach provides valuable insights into the role of CSF in transmitting impact from the skull to the brain, contributing to our understanding of brain injuries. It may also portend the development of preventive measures and improved treatment strategies.

AN OPTIMAL IMPLICIT SINGLE-STEP SINGLE PARAMETER TIME INTEGRATION METHOD FOR STRUCTURAL DYNAMICS

Jie Zhang[1]*

[1]*Jinan University*

ABSTRACT

A comprehensive study of the implicit second-order-type time integration methods for structural dynamics analysis is presented. An analytical accuracy framework for algorithm design, convergence, and optimization is developed, where the obstacles encountered in algorithms design, convergence accuracy, algorithms equivalence, accuracy measurement, and accuracy optimization in traditional accuracy frameworks are addressed. An Optimal linear multistep method Equivalent Single-step method with a Single parameter (OESS) is revealed, where the controllable parameter can provide desirable performance on the low-frequency accuracy and high-frequency numerical dissipation properties. The OESS methods is second-order accurate, unconditionally stable, overshooting acceptable, and equivalent to an optimal route between the Houbolt method and the trapezoidal rule.

ON IRRADIATION-INDUCED MULTI-SCALE DEFORMATION BEHAVIORS OF ACCIDENT TOLERANCE MULTI-LEVEL COMPOSITE FUELS

Jing Zhang[*1] and Shurong Ding[1]*

[1]*Fudan University*

ABSTRACT

FCM(Fully Ceramic Microencapsulated) fuel pellet is a potential accident tolerance multi-level composite nuclear fuel, which consists of dispersed TRISO(Tri-structural Isotropic) fuel particles embedded within the SiC matrix. TRISO fuel particle in the FCM fuel has a multi-layered structure, and the innermost fuel layer called Kernel is coated by four functional layers, namely the porous pyrolytic carbon (Buffer) layer, the inner dense pyrolytic carbon (IPyC) layer, the silicon carbide (SiC) layer, and the outer dense pyrolytic carbon (OPyC) layer. Owing to the excellent fission product retention capacity of TRISO particles and the strong stability of the SiC matrix, FCM fuel pellet is suitable for many advanced nuclear reactors and is an important development direction of advanced fuel. In order to perform the manufacturing and optimal design of FCM fuel as well as ensure its safety and cost-effectiveness for practical use in reactors, it's necessary to study the irradiation-induced thermal-mechanical coupling behaviors of FCM fuel.
FCM fuel exhibits more complex irradiation-induced thermal-mechanical coupling behaviors than conventional nuclear fuel owing to its multi-level composite structure. Kernel can produce complicated fission gas-thermal-mechanical coupling behavior. The porous Buffer layer also undergoes multi-scale thermal-mechanical coupling behavior due to the interaction of multiple physicochemical processes. The IPyC layer and OPyC layer have anisotropic irradiation deformations. The irradiation swelling and creep deformation occur within the SiC layer and matrix under irradiation conditions. Meanwhile, thermal-mechanical interactions also appear between each layer, as well as between TRISO particles and matrix. It can be concluded that FCM fuel produces complex multi-scale thermal-mechanical coupling behaviors.
In this study, the irradiation effects of each part of the material are comprehensively considered, and then the multi-scale correlating irradiation-induced thermal-mechanical constitutive models, calculation methods and subroutines are developed. The numerical simulation of multi-scale deformation behaviors of FCM fuel is performed more accurately. Based on the obtained evolution rules, the safety of FCM fuel during reactor service is analyzed. The influence of particle coating layer thickness on the multi-scale deformation behaviors in FCM fuel is also investigated, and the optimization of structural design parameters is proposed in view of ensuring economy and safety. This study can put forward a theoretical basis and technical support for the optimal design and advanced manufacturing of FCM fuel pellets.

RESEARCH ON THE ANALYSIS OF MOTION STATE IN ORBIT AND ORBIT KEEPING CONTROL OF TETHERED SATELLITE SYSTEM

Juan Zhang[*1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

Tethered Satellite Systems (TSS) have significant research and application value in areas such as artificial gravity, space elevators, gravity stabilization, orbit transfer, and tether formation flying. Due to the unique spatial structure of TSS, its dynamic behavior exhibits high nonlinearity. This paper investigates the on-orbit dynamics and orbit control problem during the state maintenance phase of a two-body TSS. Firstly, the TSS is modeled as a "double mass point with a mass elastic rod" system, and the general form of the dynamic equations for the five degrees of freedom is established based on Lagrange's equations. Taking into account the J2 perturbation, the dynamic equations for the five degrees of freedom under the influence of Earth's oblateness are derived. Next, the geostationary satellite orbit is taken as the reference baseline for the system's center of mass orbit, and the effects of the J2 perturbation on both the five-degree-of-freedom and three-degree-of-freedom TSS are analyzed using numerical methods. The results show that the J2 perturbation causes periodic variations in the height of the system's center of mass, with a maximum deviation of approximately 1 km. However, its impact on the system's true anomaly, in-plane and out-of-plane attitude angles, and tether length is minimal, although it follows certain patterns. Finally, two classical PID control methods are selected to primarily maintain control over the height of the center of mass in the three-degree-of-freedom system. Control rates are proposed, and the results demonstrate that the position-based PID controller can compensate for the influence error of the J2 perturbation on the system's center of mass orbit. However, its control performance in terms of maximum deviation and oscillation is average. On the other hand, the incremental PID controller can achieve the desired orbit maintenance effect. It exhibits smaller maximum deviation, shorter control adjustment time, and fewer oscillations compared to the position-based PID controller, resulting in significant improvements in control performance indicators. In conclusion, this study provides valuable insights for the research on orbit control of nonlinear Tethered Satellite Systems.

A FINITE-DIFFERENCE APPROACH FOR MEMBRANE VISCOSITY IN CAPSULE DYNAMICS SIMULATIONS

Ping Li[1], Ali Rezghi[1] and Junfeng Zhang[*1]*

[1]Laurentian University

ABSTRACT

The dynamics motion, deformation and interaction of biological and artificial capsules in flows, as well as the suspension rheology, are of great interest for biomedical research and applications. When undergoing a strain change, viscous stress is resulted in the capsule membrane, and such viscous behaviors have been noticed decades ago. To model the membrane viscosity, several numerical methods had been developed; however, serious concerns are noticed in these methods, such as physical misrepresentation, mathematical inconsistency and numerical complexity. In this presentation, a simple and efficient algorithm is proposed for calculating the membrane viscous stress for simulating capsule dynamics in fluid flows. The method was developed by applying finite-difference approximations, and rigorous validations have been performed to demonstrate its accuracy, efficiency and stability. This method has been employed in several studies of red blood cell behaviors in various flow situations. Application examples will also be presented.

AN IMPLICIT-EXPLICIT TIME INTEGRATION FOR DAM-FOUNDATION INTERACTION BASED ON OCTREE MESH USING SCALED BOUNDARY FINITE ELEMENT METHOD

Junqi Zhang[*1], Pengcheng Liu[1], Mi Zhao[1] and Xiuli Du[1]*

[1]*Beijing University of Technology*

ABSTRACT

In this study, we propose a novel implicit-explicit time integration scheme for dynamic analysis of dam-foundation interaction. In engineering practice, it is necessary to model the dam using a refined mesh with elements smaller than a meter in size, while the foundation, encompassing the larger geological region and underlying soil, is typically represented with a mesh using elements of ten meters or greater. This nonuniform mesh usually leads to difficulties in numerical modeling and analysis. In explicit time integration, the critical stable time step is governed by the smallest elements in the dam, while the implicit scheme consumes excessive memory and computational power. To address these challenges, we propose a hybrid time integration scheme, in which the dam's dynamic behavior is calculated using the implicit method, while the surrounding foundation is calculated using the explicit method with a larger time step. A specially designed overlapping layer is devised to facilitate data communication between the implicit and explicit regions. To this end, we employ the octree algorithm to generate the mesh automatically, exploiting its distinct advantages in rapid mesh size transition and high element quality. The polyhedral elements in the octree mesh are formulated using the scaled boundary finite element method, without necessitating any special treatment. Numerical examples are presented to demonstrate the efficiency and effectiveness of the proposed method.

PHASE FIELD MODELLING OF ELECTROCHEMICALLY DRIVEN VOID EXPANSION AND SPONGE FORMATION IN SILICON ELECTRODES OF LITHIUM-ION BATTERIES

Xiong Yang[1], Bo Lu[1], Ying Zhao[2] and Junqian Zhang[1]*

[1]Shanghai University
[2]Tongji University

ABSTRACT

Recent experimental studies have shown that the silicon electrodes of lithium-ion batteries undergo microvoid expansion and merging during electrochemical cycling, forming sponge-like internal channels, which then penetrate the original surface of the silicon material and further form new surfaces. This microstructural change leads to irreversible deformation of the silicon electrode, which has a significant negative impact on the mechanical integrity and cyclic stability of the cell.
In order to understand this unexpected microstructural evolution, we develop a theoretical model of mechanical-electrochemical coupling based on the phase field method to predict the annihilation, expansion, merging, and surface instability of microvoids. The electrochemical cycle simulation reveals the following microstructure evolution mechanism and images: the surface pits continue to expand on the surface, the internal microvoids expand and move towards the surface of the electrode material, and the microvoids expand in the direction of mutual proximity, resulting in the merge of the voids, the formation of internal channels, and the penetration of the surface. Further, we found that this undesirable spongy microstructure, which is detrimental to battery performance, can be suppressed by mechanical stress.

LIFTING TO HIGHER DIMENSIONS — ALTERNATIVE WAY FOR MULTISCALE COMPUTING

Lei Zhang[*1]*

[1]*Shanghai Jiao Tong University*

ABSTRACT

Most multiscale computing techniques are based on dimension reduction. In this talk, I will present an alternative approach for multiscale computing by lifting problems into higher dimensions. Through a few examples, including periodic/quasiperiodic homogenization, quantum algorithms for multiscale PDEs, etc., I will demonstrate how lifting into higher dimensional spaces can enable accurate and efficient multiscale modeling and simulation.

NUMERICAL INVESTIGATION ON THE MODULATION OF WRINKLING IN TENSEGRITY-MEMBRANE STRUCTURES

Zigang He[1], Liang Zhang[1] and Shaofan Li[2]*

[1]Chongqing University
[2]University of California, Berkeley

ABSTRACT

Tensegrity-membrane structures are potential to be lightweight gossamer spacecraft (e.g., solar sails, radar antennae, solar module), and the dynamics of deployment has been studied in the past studies where the membranes were usually modeled as a flat panel without wrinkles. However, the attitude control of membrane as well as the flatness are critical to the functionality of gossamer spacecraft. The paper proposes a numerical investigation on the modulation of wrinkling in tensegrity-membrane structures. The kinematic and deformation description are based on the co-rotational finite element method (FEM), while the wrinkling of membrane is modeled by Tension Filed Theory (TFT). The numerical method is validated by an illustrative experiment, and then used for a surrogate model-based optimization design, in which clustered actuation is responsible for the attitude control of membrane, while classical actuation accounts for the suppression of wrinkles. An interesting tensegrity-membrane "Sunflower" is presented to show the result of optimization, where "Sunflower" can follow the sunlight Angle accurately and freely control the orientation of "corolla" while maintaining its daylighting surface quality. This study provides effective means for the numerical simulation and optimization design of tensegrity-membrane structures, especially when the attitude and wrinkling of membranes must be considered.

[3]*IBM*

ABSTRACT

Deep neural networks, such as neural operators, have emerged as powerful tools for learning and predicting the response of a complex physical system solely from observational data. This is evident in material modeling problems, where the neural operator approach learns a surrogate mapping from the loading field to the corresponding material response field. It can be seen as learning the solution operator of a hidden Partial Differential Equation (PDE), where the microstructure and mechanical parameters of material specimens correspond to the (potentially heterogeneous) parameter field within this PDE. Consequently, the predictive material modeling problem becomes akin to a forward problem for PDEs.

However, amidst this progress, the discovery of hidden physical properties and the physical interpretation of these data-driven material models remain less explored. To address this gap, we propose to discover the latent representation and causal relationships behind neural operators, effectively solving an inverse problem for PDEs. In particular, we introduce a novel hyper neural operator architecture to learn and extract latent representations from neural network parameters. To enhance the interpretability of these latent representations, we incorporate a Structural Causal Model (SCM) that captures the underlying causal mechanism governing the hidden physical process. Experiments show that CausalNO, our proposed approach, can effectively learn interpretable and generalizable representations from both simulated and real mechanical testing data.

STRUCTURES AND DYNAMICS OF HETERO-INTERFACES BASED ON UNDERLYING MICROSTRUCTURE

Luchan Zhang[*1]*

[1]*Shenzhen University*

ABSTRACT

The hetero-interfaces are commonly formed between different materials or different phases to accommodate the lattice misfit between the adjacent materials.
The structure and dynamics of hetero-interfaces strongly affect the mechanical, electronic and plasticity properties of the composite materials and alloys. The structure of a hetero-interface is a network of dislocations and disconnections, together with the inclination and misorientation of the interface. The motion of the hetero-interface, such as the precipitation inα/βtitanium alloys and martensitic transformations, is also controlled by the interface network structure of disconnections. We present continuum models for the structure and dynamics of hetero-interfaces based on the continuum distribution of these line defects on them.

EXPLORING MULTI-PHYSICAL COUPLED FRACTURE IN POLYMERS THROUGH PHASE-FIELD MODELING

Lu-Wen Zhang[*1]*

[1]*Shanghai Jiao Tong University*

ABSTRACT

Polymers have emerged as key materials for achieving structural-functional integration in marine engineering owing to their remarkable properties such as chemical corrosion resistance, damping characteristics, high specific strength and fatigue resistance. However, prolonged exposure of these materials to the marine environment exposes them to a variety of complex environmental and mechanical loads, resulting in nonlinear, multi-process coupled fracture phenomena. In response to this challenge, we have developed phase field models and efficient finite element programs to systematically investigate the thermodynamic processes associated with moisture diffusion-thermo-mechanical coupled fracture in polymers and composites in high-moisture environments. Our research focuses on the transient two-way coupling behavior between moisture diffusion and crack propagation in composites, providing a comprehensive understanding of the intricate interactions. The investigation of the moisture absorption-induced damage mechanism offers in-depth insights into the degradation process. Our methodology demonstrates its capability to accurately track experimentally consistent crack nucleation and propagation, regarding a wide range of strain rates and cyclic impact loading conditions.

CHARACTERIZING STEEL CORROSION IN CONCRETE USING X-RAY COMPUTED TOMOGRAPHY AND MACHINE LEARNING TECHNIQUES

Mingyang Zhang[1] and Weilun Wang*[1]

[1]*Shenzhen University*

ABSTRACT

The corrosion of steel in concrete has been regarded as one of the most predominant factors for the degradation of reinforced concrete (RC) structures. The accurate predictions of corrosion damages are the basis for the safety assessment of in-service structures and the enhancement of new structure designs. X-ray computed tomography (XCT), known for its non-destructive capabilities, has been widely utilized to understand the corrosion process inside the concrete, offering three-dimensional (3D) visualization and aiding in the identification of steel corrosion [1]. This study uses U-Net, a deep learning network, to detect various phases of steel corrosion evolution in concrete, including the identification of rebar, corrosion products, pores, cement mortar, and corrosion-induced cracking. A galvanostatic accelerated corrosion test was performed to simulate rebar corrosion within the concrete. The XCT test was performed, producing a series of XCT images that reveal the corrosion-induced cracks in the concrete. This set of images formed a comprehensive training database for the U-Net model. The performance of the model was significantly improved by data augmentation within the training dataset, thereby enabling it to recognize corrosion-induced cracking and pores. The U-Net model proved effective in accurately segmenting the XCT images into different phases, demonstrating high accuracy on the test dataset. This significant advancement has automated the process of visualizing and 3D reconstructing the steel corrosion process inside the concrete.

ABSTRACT

Predicting the infiltration of Glioblastoma (GBM) from medical MRI scans is crucial for understanding tumor growth dynamics and designing personalized radiotherapy treatment plans. Mathematical models of GBM growth can complement the data in the prediction of spatial distributions of tumor cells. However, this requires estimating patient-specific parameters of the model from clinical data, which is a challenging inverse problem due to limited temporal data and the limited time between imaging and diagnosis. This work proposes a method that uses Physics-Informed Neural Networks (PINNs) to estimate patient-specific parameters of a reaction-diffusion PDE model of GBM growth from a single 3D structural MRI snapshot. PINNs embed both the data and the PDE into a loss function, thus integrating theory and data. Key innovations include the identification and estimation of characteristic non-dimensional parameters, a pre-training step that utilizes the non-dimensional parameters and a fine-tuning step to determine the patient specific parameters. Additionally, the diffuse domain method is employed to handle the complex brain geometry within the PINN framework. Our method is validated both on synthetic and patient datasets, and shows promise for real-time parametric inference in the clinical setting for personalized GBM treatment.

STOCHASTIC SUBSPACE VIA PROBABILISTIC PCA FOR CHARACTERIZING AND CORRECTING MODEL ERROR

Akash Yadav[1] *and Ruda Zhang**[1]

[1]*University of Houston*

ABSTRACT

Complex engineering systems give rise to high-dimensional computational models that resolve multi-physics coupling and multi-scale processes, pushing the ever-expanding limit of computing power. Yet errors in system input, model parameters and model representation limit the predictive value of such models. Such model error shall be quantified and adjusted based on experimental measurement data, for predictive modeling and digital twinning. A seminal work [1] on this topic proposed a stochastic surrogate model that consists of projection-based reduced-order models (ROM) derived from a high-dimensional model, where the reduced-order bases are randomized. The use of ROM allows tractable uncertainty quantification, while learning a probabilistic model for the basis can improve model accuracy. We follow this strategy and design new probabilistic models for stochastic ROM.

Specifically, we propose a probabilistic model of subspaces based on the probabilistic principal component analysis (PCA). Given a sample of system state vectors, commonly known as a snapshot matrix, this method uses quantities derived from the PCA to construct distributions of the sample matrix as well as subspaces of all dimensions of the state space. It is applicable to projection-based reduced-order modeling methods, such as proper orthogonal decomposition and related model reduction methods. The stochastic subspace thus constructed can be used, for example, to characterize model error in computational mechanics. With experimental validation data, the stochastic subspace model can be adapted in a Bayesian approach to correct model error and improve accuracy.

The proposed method has multiple desirable properties:
(1) it is naturally justified by a probabilistic interpretation of PCA, and in some cases has analytical forms for the induced probabilistic models on related matrix manifolds;
(2) it satisfies linear constraints, such as boundary conditions of all kinds, by default;
(3) it has only one hyper-parameter, which dramatically simplifies the training procedure;
(4) its algorithm is very easy to implement.
We compare the proposed method with existing approaches [1,2] visually in a low-dimensional example, and demonstrate its performance in modeling the dynamics of a space structure.

POLYNOMIAL CHAOS REPRESENTATION OF NON-GAUSSIAN RANDOM FIELDS BASED ON THE OPTIMAL TRANSPORTATION

Ruijing Zhang[*1] and Hongzhe Dai*[1]

[1]*Harbin Institute of Technology*

ABSTRACT

In this paper, we develop a methodology for constructing polynomial chaos (PC) representation of non-Gaussian non-stationary random field by optimal transportation theory. Firstly, non-Gaussian field samples, which is generated by the simulation technique proposed by current author, are represented by the truncated Karhunen-Loeve (KL) expansion. Then, the transformation from standard Gaussian variables to KL coefficients is directly constructed from the samples of KL coefficients by using optimal transportation. With the transformation from Gaussian to KL coefficients, the Hermite PC coefficients are further determined by using least square regression. Since the optimal transportation enables to move the source measure to target measure without requiring the absolute continuity of the target, the transformation from standard Gaussian to KL coefficients can be readily constructed from samples of KL coefficients, by passing the curse of dimensionality encountered in constructing PC representation by Rosenblatt transformation. Moreover, the current work generalizes the PC representation of random fields from translation-based one to more general non-Gaussian cases. Three numerical examples demonstrate the application of the developed method.

DEM STUDY ON EVOLUTION OF SOIL ARCHING IN GROUND WITH TUNNEL

Ruixiao Zhang[*1], Dong Su[1], Xingtao Lin[1] and Xiangsheng Chen[1]*

[1]*Shenzhen University*

ABSTRACT

The effects of existing tunnels on the evolution of soil arching require further investigation. In this study, trapdoor models with different distances between the trapdoor and tunnel are examined via discrete element method simulations after a numerical model is established based on experiments. The results show that as the distance between the tunnel and trapdoor (L) increases, the minimum soil arching ratio, ultimate soil arching ratio, and load recovery decrease, thus indicating that the shadowing effect of the tunnel becomes less distinctive. The stress ratio in the region near trapdoor first decreased significantly and then gradually, followed by a gradual decrease as the trapdoor displacement increased, before reached an ultimate value. The reverse trend is observed when L exceeds 150 mm, which is similarly observed in regions L2 and L3. The displacement of particles above the tunnels was confined because of the shadowing effect caused by the tunnel, where the displacement was much lower than the displacement on both sides and above the weakly affected zone, and the particle displacement resulted in a flow around the tunnel. Two distinct types of soil-arching structures are identified for interaction and independent arches. The displacement of the trapdoor increased the anisotropy of the contact forces within the soil mass.

NON-PARAMETRIC GEOMETRY PATCHING TECHNIQUE FOR MMC TOPOLOGY OPTIMIZATION

Shengqi Zhang[*1], Weisheng Zhang[1], Sung-Kie Youn[2] and Xu Guo[1]*

[1]*Dalian University of Technology*
[2]*KAIST*

ABSTRACT

MMC is one of the topology optimization methods that provides explicit boundary description of the optimized topology. However, due to the inherent nature of MMC, the obtained geometry could exhibit distinct local singularities. To cope with this issue, a non-parametric geometry patching technique for MMC is developed. A moving-node patching technique for both two-dimensional and three-dimensional cases is developed in conjunction with MMC to obtain structures with smooth boundaries. Numerical examples in two-dimensional and three-dimensional are presented to demonstrate the effectiveness of the proposed approach.

NUMERICAL ANALYSIS OF FUNCTIONALLY GRADED MAGNETO-ELECTRO-ELASTIC PLATES AND SHELLS

Shun-Qi Zhang[1]*

[1]*Shanghai University*

ABSTRACT

Magneto-electro-elastic (MEE) materials combine properties of magnetostrictive and piezoelectric effects, which can realize positive or reverse magnetoelectric conversion effectively. As a new type of advanced functional composite material, its appearance has set off a wave of MEE materials research. MEE materials have higher electromagnetic coupling performance than pure piezoelectric or piezomagnetic composites. The modelling and simulation techniques for such multi-physics coupled problems are still of great challenge. This paper intends to develop a finite element (FE) model coupled with magneto-electro-elastic fields for static and dynamic analysis of FG-MEE plates and shells. The FE model is derived by using the first-order shear deformation hypothesis with consideration of linear multi-physics coupled constitutive equations. Eight-node quadrilateral plate/shell elements are proposed for FG-MEE structures, including five mechanical DOFs at each node, one electric and magnetic DOF at each MEE layer of elements. The model is first validated by MEE laminated plates and shells, later applied to parametric study of FG-MEE structures with functionally graded electric and magnetic properties.

NATURE-INSPIRED GENERATIVE DESIGN RULES FOR ADDITIVE MANUFACTURING

Wei Zhang[*1]*

[1]*University of Exeter*

ABSTRACT

This work presents a nature-inspired generative design methodology to support innovation-driven design for manufacturing. It allows designers to create unpredicted but valuable components that can be directly integrated by modern manufacturing methods such as additive manufacturing. In this approach, the design of components is redefined as a series of elemental design instructions and emergence mechanisms that react to the design environment to generate innovative designs. Inspired by plant intelligence in nature, a set of “Design Genes” and “Design Hormones” are proposed which influence “design growth and development” through analogues of biological mechanisms. The design grows and develops from the actions of the genes and hormones, which do not know anything about the emergent shape or form of the design, they simply respond to the engineering environment. The hormones are encoded with genes in a “Design Seed”, and different designs can emerge from the same seed in response to different environments based on their influence on the seed. A practical algorithm is then presented to implement the emergence of design from a simple seed. A range of examples are tested to demonstrate the effectiveness of the proposed approach. This work contributes foundational nature-inspired generative design theory and processes to promote innovative design integrated with manufacturing systems moving from Industry 4.0 to 5.0.

MACHINE LEARNING POWERED SKETCH AIDED DESIGN VIA TOPOLOGY OPTIMIZATION

Weisheng Zhang[*1] and Xu Guo[1]*

[1]*Dalian University of Technology*

ABSTRACT

Structural topology optimization is an important design tool in the conceptual design phase of a product. However, the current topology optimization design is mostly driven strictly based on mathematical and mechanical models. Although the innovative design can be automated, it mostly lacks effective manual experience guidance. To improve the efficiency of computer-aided structural design models, this work proposes a sketch-guided topology optimization approach based on machine learning. Using neural network-based style transfer techniques, computer-digitized/hand-drawn sketches are explicitly incorporated into topology optimization in the form of constraint functions. The obtained optimization results not only satisfy the requirements of optimal mechanical properties, but also fully demonstrate the design intention and requirements of designers. Numerical examples show that the proposed approach can effectively compensate for the lack of manual experience guidance for topology optimization.

A FAST CALCULATION METHOD FOR PREDICTING STEADY STATE ABLATIVE MORPHOLOGY OF C/C COMPOSITES

Weixu Zhang[*1]*

[1]*Xi'an Jiaotong University*

ABSTRACT

Gasification-type ablative composites, typical ablative thermal protection materials, convert the absorbed heat into an outward mass flux through physical or chemical processes during ablation, which cause surface recession and the formation of steady surface morphology of the materials. The variations lead to the structural change and surface roughness increase, which affect the flight trajectory and attitude-control characteristics of the aircraft and even aggravates the aerodynamic heating behavior. Therefore, predicting the surface morphology of materials during steady-state ablation is important.

When designing ablative materials, a huge number of calculations are required for analyzing surface morphology. To effectively design these materials and reduce experiments, a fast effective and simple calculation method is required. Up to date, most of the computational methods for predicting ablative morphology are complex and time-consuming. A quick and effective prediction of the ablation morphology remains a challenge. We discovered an angular relationship between the local ablation velocity at each point of the material and the global ablation velocity. Then, a fast, effective, and simple numerical calculation method for steady-state ablation is proposed.

When taking the carbon/carbon composite as example, we show that the predicted morphology is consistent with the experimental observation. The calculation time- consuming is significantly reduced. In addition, our method is found to be useful for analyzing the physical and chemical properties and surface roughness of the material. This calculation method is suitable for the prediction of the steady state ablative morphology of gasification-type ablative composites with arbitrary cross-section shapes. Furthermore, it can improve the understanding of the interaction between composites and their surrounding environments and provides a guidance for the structural design of gasification-type ablative thermal protection materials.

VISCOUS AND CAPILLARY EFFECTS IN THE SHOCK INDUCED BREAKUP OF CYLINDRICAL DROPLET: A NUMERICAL STUDY

Wenbin Zhang[1], Stefan Adami[1] and Nikolaus Adams[1]*

[1]*Technical University of Munich*

ABSTRACT

The high-speed aero breakup of a liquid droplet extensively exists in engineering applications and academic researches, such as dissemination of bulk liquid medium, and secondary atomization in turbomachinery. In addition, the fuel droplets are directly shattered by the standing shocks in the scramjet engine. In above scenarios, the essential flow features can be modeled as shock induced droplet breakup (SIDB).

In the previous studies [1], five different breakup regimes are recognized based on Weber number We=(ρ_g u_g^2 d_0)⁄σ. With the increase of the We, various regimes are respectively vibrational, bag, bag-and-stamen, stripping, and catastrophic. Later, the breakup mechanism is regrouped into two regimes [2], namely Rayleigh-Taylor piercing (RTP) and shear-induced entrainment (SIE). Meanwhile, influence of the viscosity is further considered through Ohnesorge number Oh=μ_l⁄sqrt(ρ_l d_0 σ). Although lots of experimental and theoretical works have been done on this problem, a deeper understanding of the droplet breakup, especially the droplet size distribution in the later stage, is still necessary. On the other hand, due to the difficulties on algorithm, numerical simulations of SIDB considering both surface tension and viscous effects are seldom carried out.

In this work, by employing the recently developed tangent of hyperbola for interface capturing (THINC) method [3], we conduct a systematically numerical study on the two-dimensional SIDB. The shock Mach number is fixed to Ms=1.47, while the Weber number and Ohnesorge number are altered, in order to investigate the capillary and viscous effects on the droplet breakup process. Specifically, We ranges from 10 to 103, and Oh ranges from 10-2 to 102.

In addition to the droplet morphology and unsteady drag properties, we also focus on the droplet size distribution after the disintegration. The droplet size distribution is characterized by using the spatial Fourier transform of volume fraction field as
α̂(k)=∫α(x) e^(-ikx) dx
With the obtained volume fraction spectrum, we attempt to analyze the characteristics of the droplet size distribution for the typical breakup regimes, and unravel how the surface tension and viscosity influence the final state of the shattered droplet.

ABSTRACT

While experimental evidence indicates that all cardiovascular soft tissues exhibit some degree of viscoelasticity, the effects of viscoelasticity on the functional properties of soft tissues are not well understood. Most computational models for cardiovascular soft tissue ignore viscoelasticity and assume hyperelasticity. This is due to challenges associated with developing viscoelastic constitutive models and the computational expense associated with viscoelastic simulations, which grows O(N^2) in time and O(N) in memory for storing the strain history. More recently, fractional viscoelasticity has increased in popularity and has been shown to successfully model a number of soft tissues.

We have developed a computationally efficient fractional viscoelastic framework with a similar computational cost to conventional hyperelastic models and demonstrated its efficacy in several applications. This includes a viscoelastic model for the human myocardium, where we examined its physiological implication in a computational model of an idealized left ventricle and circulatory system [1]. The importance of viscoelasticity during passive filling was demonstrated by examining ventricular motion and regional fiber strain and stresses [2]. We also introduced a new viscoelastic constitutive model for the human femoropopliteal artery (FPA) grounded in its microstructure. We analyzed the contributions of each intramural component to the overall viscoelastic response, where the viscoelasticity of the passive smooth muscle cells (SMCs) was twice that of the collagen fibers [3]. We further extended this model to evaluate the effects of aging between thoracic aortas (TA) and FPA in 18 subjects between 13 and 73 years old. The results matched well with the structural density measured from bidirectional histology. The results further show that the viscoelasticity of the SMCs in the FPA was twice that of the TA but remained stable with age, like those of the collagen. Fractional viscoelastic modeling is a valuable tool for studying the mechanophysiology of biological soft tissues and investigating the effects of pathological factors and aging. This will improve the fidelity of computational simulations investigating device-tissue interactions and contribute to improving their physical accuracy.

PROGRAMMING THERMO-ACTIVE METAMATERIALS WITH TEMPERATURE-SENSING ADAPTIVE RESPONSES

*Xiaojia Shelly Zhang**[1]

[1]*University of Illinois Urbana-Champaign*

ABSTRACT

Plants can change their morphology upon environmental variations such as temperature. We envision programmable matters that can alter their physical properties in desirable manners based on user input or autonomous sensing. This vision motivates the pursuit of mechanical metamaterials that interact with the environment in a programmable fashion. Here, we use multi-physics topology optimization and hybrid fabrication to systematically create soft metamaterials with arbitrarily programmable temperature-switchable morphing shapes and nonlinear mechanical responses under large deformations. We explore both temperature-sensing passive [1] and active [2] materials, such as liquid crystal elastomers. We demonstrate that the programmed metamaterials can accurately morph into a wide range of complex target shapes and curvatures as well as realizing maximized spontaneous area expansion, precisely programmable area change, and temperature-switchable nonlinear force-displacement behaviors. The computational inverse design technique holds promise for a wide array of applications requiring function- and performance-driven design of active materials with freely tunable thermally adaptive behaviors.

CONTINUOUS SIMULATION OF THE FIBRE-CRACK BRIDGING MECHANISM WITH IMPLICIT MODELLING OF THE FIBRE-MATRIX INTERFACE USING A PHASE-FIELD BEAM MODEL

Xin Zhang[*1] and Zhenyu Wang*[1]

[1]*Zhejiang University*

ABSTRACT

The fibre-crack bridging mechanism is a critical phenomenon in fibre-reinforced concrete, wherein the crack growth is hindered by the presence of fibres. The understanding of this mechanism is essential for the design and optimization of fibre-reinforced concrete. However, simulating the complex interactions between fibres and cracks remains a challenge due to the presence of multiple physical scales and interfaces involved.

In this study, we propose a phase-field beam model to integrate the fibre and the fibre-matrix cohesive-frictional interactions in single constitution. Fibre elements are fully coupled with the matrix mesh, assuming no relative movements between fibres and matrix, which reduces the model complexity and increases the simulation efficiency and robustness. Since the the relative movement between fibres and matrix is excluded, the beam elements cannot represent the exact position and deformation of the fibres. Therefore, in addition to the displacement field of the beam elements, the virtual strain phase-field and its gradient are introduced to regularize the position and deformation of real fibres. The energy dissipation functional due to fibre-matrix de-bonding and slipping, as well as the stored energy functional, are characterized by a fibre strain distribution function and the energetic degradation function, Key parameters calibrated according to fibre pullout test.
The proposed model is validated through simulations of multi-angle fibre pullout tests, direct tensile tests, splitting tests, and three-point bending tests of steel fibre reinforced concrete. The simulated results are well aligned with the experimental results in terms of load-displacement curves, crack patterns, and fibre stress-strain states. Compared to existing simulation approaches, such as direct methods that explicitly model fibres and interfaces, and indirect methods that embed fibres with equivalent stress-strain accounting for fibre-matrix debonding and slipping in the matrix, the proposed model exhibits advantages in computational efficiency and robustness (compared to direct methods) and mechanical interpretability (compared to indirect methods).

PHYSICAL FIELDS LEADING STRUCTURE DESIGN STRATEGY FOR META-FIBER REINFORCED HYDROGEL COMPOSITES BY DEEP LEARNING

Xingyu Zhang[1], Chuanzhi Liu[2], Xia Liu[1] and Qingsheng Yang[1]*

[1]*Beijing University of Technology*
[2]*Huazhong University of Science and Technology*

ABSTRACT

Fiber-reinforced hydrogel composites are widely employed in many engineering applications, such as tissue engineering, drug release, and flexible electronics, with more flexible mechanical properties than continuous hydrogel materials. Comparing to the hydrogel strengthened by continuous fiber, the meta-fiber reinforced hydrogel provides stronger individualized design ability of deformation patterns and tunable stiffness, especially for the elaborate applications in joint, cartilage and organ. In this paper, a novel structure design strategy based on deep learning algorithm is proposed for hydrogel reinforced by meta-fiber to achieve a targeted mechanical property, such as stress and displacement fields. A solid mechanic model for the meta-fiber reinforced hydrogel is firstly developed to construct the dataset of fiber distribution and the corresponding mechanical properties of the composite. A deep learning algorithm, generative adversarial network (GAN), is then trained to characterize the relationship between the input data, namely stress or displacement field, and the output data, namely meta-fiber distribution. Based on the algorithm, the inverse design strategy is proposed to determine the meta-fiber distribution in the hydrogel composites, with targeted stress or displacement fields. The proposed GAN-based inverse structure design strategy is implemented to design meta-fiber reinforced hydrogel composite structure under specific operation conditions. The results show that the deep learning method may efficiently predict the structure of the hydrogel composite with satisfied confidence, under the premise of given stress or displacement field and has great potential for applications in drug delivery and flexible electronics.

HYPERELASTIC MATERIAL CRACK SIMULATION WITH PERIDYNAMICS UNDER COMPLICATED NEUMANN BOUNDARY CONDITION

Zhixin Zeng[1] and Xiong Zhang[1]*

[1]Tsinghua University

ABSTRACT

Hyperelastic materials are frequently observed in the natural world and engineering applications such as rubbers and animal soft tissues[1][2]. Modeling large deformation and progressive fracture of these materials under complicated loading condition is challenging for numerical simulation. In this work, we propose a novel ordinary state-based Peridynamics (PD) model to simulate the large deformation of hyperelastic material. To simulate the progressive fracture, we propose a critical stretch calculation method for hyperelastic material in peridynamics, which gives accurate relatives between the critical stretch and the surface energy release rate. A virtual stress field is proposed to apply the nonconforming Neumann boundary condition for peridynamics. Instead of applying the boundary force on boundary particles directly, we define a virtual stress field on the material body to implicitly apply the Neumann boundary condition. With the virtual stress, the complex boundary representation and tracking is avoided. Furthermore, to obtain better computational efficiency, we perform an efficient adaptive refinement by splitting a parent particle into several child particles directly which does not require any information from its adjacent particles. The state variables and neighbor list of the child particles can be obtained directly from their parent particles, so that the proposed adaptive refinement method is very efficient and can be easily applied in both 2D and 3D cases without complex adjacent particle list building. The numerical results show that the proposed method can simulate the crack growth in hyperelastic material under complicated Neumann boundary condition with great efficiency and accuracy.

AN ENRICHED IMMERSED FINITE ELEMENT METHOD FOR THREE-DIMENSIONAL INTERFACE PROBLEMS

Xu Zhang[*1]*

[1]*Oklahoma State University*

ABSTRACT

Interface problems arise in many applications in science and engineering. Partial differential equations (PDEs) are often used to model interface problems. Solutions to these PDE interface problems often involve kinks, singularities, discontinuities, and other non-smooth behaviors, which often pose challenges in obtaining satisfactory solutions. The immersed finite element method (IFEM) is a class of numerical methods for solving PDE interface problems with unfitted meshes.

In this talk, I will present recent advances in the development and analysis of IFEM for solving 3D interface problems with general non-homogeneous jump conditions. The proposed method can be utilized on interface-unfitted tetrahedral and cuboidal meshes, even if the 3D interface surface has an arbitrary shape. Distinguished from many unfitted-mesh methods in the literature, our method follows the homogenization idea, and the enrichment functions are immediately determined by the jump data, which does not introduce any additional degrees of freedom to the system, but still leads to optimal convergence. The resulting homogenized IFE space is isomorphic to the standard finite element space on the same mesh, and the isomorphism is stable with respect to the interface location. This feature leads to the optimal h^2 conditioning independent of interface location, which allows us to build an efficient multigrid grid solver. Numerical examples will be provided not only to validate our theoretical results, but also to demonstrate the applicability of the method when dealing with some real-world 3D interface models.

A DOMAIN-INDEPENDENT INTERACTION ENERGY INTEGRAL IN NON-HOMOGENEOUS MATERIALS CONTAINING COMPLEX INTERFACES UNDER TRANSIENT THERMAL LOADING

Yanyan Zhang[1], Fengnan Guo[2], Yaoming Fu[1], Jun Luo[1] and Zengtao Chen[3]*

ABSTRACT

Nonhomogeneous materials have been widely used in aeronautics, astronautics, microelectronics, and medical fields. The complex service environments in those materials may affect material failure. Fracture failure is one of the typical failure modes during the service process of nonhomogeneous materials. The interaction energy integral method [1-3] is a direct method for solving fracture problems, which introduces a designable auxiliary field into the traditional J-integral. In this paper, a thermomechanical problem of a nonhomogeneous material with complex interfaces under transient thermal loading is solved using the domain-independent, interaction energy integral method. Combined with the Newmark integral method, the transient temperature field is analyzed first using the non-Fourier heat conduction model. Then the transient thermal fracture problem in the non-homogeneous material with complex interfaces is solved, and the mixed-mode, thermal stress intensity factors are obtained. It can be proved that the validity of the new integral is not affected by the material discontinuity at the interfaces. The overshooting phenomenon of transient temperature occurs in non-homogeneous materials based on the non-Fourier heat conduction theory, which must be considered in engineering applications of these materials under extreme thermal environments.

NUMERICAL INVESTIGATION ON HYDRODYNAMIC CHARACTERISTICS OF FLOATING OWC BREAKWATERS BASED ON MULTI-PHASE ASR-SPH METHOD

Yifan Zhang[*1], Can Huang[2] and Fang He[1]*

[1]*Zhejiang University*
[2]*North China University of Technology*

ABSTRACT

The oscillating water column (OWC) breakwaters have superior performances in wave reduction and energy extraction, which has been proven nearly a decade ago. However, few scholars have used SPH method to investigate their pneumatic and hydrodynamic characteristics comprehensively, because the significant difference between aerodynamic scale near the chamber orifice and hydrodynamic scale of the wave tank leads to great particle numbers and unacceptable computational cost. In this work, GPU acceleration technique together with adaptive spacing resolution (ASR) is applied to multi-phase SPH method to simulate the floating OWC breakwaters. Three numerical cases, including wave interaction with box-type floating breakwaters, dam-breaking flow impacting on an elastic plate, and wave interaction with a fixed OWC structure, are simulated to validate the numerical models. Then, a floating OWC breakwater with the elastic plate is investigated by multi-phase ASR-SPH. A series of simulations are conducted under different wave conditions to discuss the performances of OWC devices and the dissipation characteristics of wave energy. Results show that the valley value of wave transmission coefficient and the peak value of wave energy extraction capability occur at the same relative width position, indicating that the wave energy extraction of the floating breakwater has a great effect on its wave protection performance. Also, as the length of the elastic plate increases, the shear behavior of water at the end of the elastic plate is significantly enhanced, leading to a significant increase in vortices.

ABSTRACT

Architected cellular materials exhibit exceptional mechanical properties, such as ultralight, ultrastiff, and even respond to external stimuli through tailoring geometry and topology rather than changing composition. Such materials have the potential to be applied in the aerospace industry, automotive and mechanical engineering, and energy sectors, which usually require them to perform under high-temperature environments. Despite this, limited research investigated the performance of architected cellular materials under high temperatures. To address this gap, our study utilizes recent advances in additive manufacturing to create a series of heat-resistant alloy honeycomb structures using ABD-900AM. This research focuses on the processing, characterization, and analysis of the deformation behavior of these metallic honeycomb structures at both room temperature and 900°C. Through a combination of experiments and simulations, we have gained a comprehensive understanding of the deformation mechanisms and their interaction with damage pathways across various temperatures. Additionally, we explored the effects of oxidation and the intrinsic ductility of the material.

THE RELATIONSHIP BETWEEN MICROSTRUCTURES AND MECHANICAL PROPERTIES IN ADDITIVE MANUFACTURING

Zhao Zhang[1], Yifei Wang[1], Lichao Zhang[1], Xiang Gao[1], Hongshan Zhou[1] and Jingyuan Chen[1]*

[1]*Dalian University of Technology*

ABSTRACT

The formation of microstructures determined by the high cooling rate is the key reason for the mechanical properties in additive manufacturing. The relationship between microstructures and mechanical properties is necessary to be established for the design of mechanical properties based on the control of the microstructural evolutions. Here Monte Carlo model and phase field model are used to determine the grain morphologies in additive manufacturing and a dislocation evolution model is integrated with the crystal plasticity model to calculate the mechanical properties of additively manufactured specimens. The relevance between the process parameters and the microstructures is studied and then the relationship between microstructures and mechanical properties is investigated. Experiments are carried out for the validation of the proposed model. The yield strength can be decreased in high temperatures, which is caused by the synergies of grain globularization and vacancy concentration in high temperature states.

A SECOND-ORDER HYBRID IIM-PFEM METHOD FOR TWO-DIMENSIONAL MOVING CONTACT LINE PROBLEMS

Zhen Zhang[*1]*

[1]*Southern University of Science and Technology*

ABSTRACT

We develop a second-order Cartesian grid based numerical method to solve two-dimensional moving contact line problems, which are modeled by the incompressible Navier-Stokes equations with the Navier-slip condition and the contact angle condition (CAC). The solutions of the flow field and the interface motion are decoupled in an alternating way. For a given interface, the velocity field is solved via a pressure Poisson equation formulation of the incompressible Navier-Stokes equations, which is numerically discretized by the immersed interface method. Once the velocity field is obtained, the interfacial kinematics together with the CAC is reformulated into a variational system, which is solved by the parametric finite element method (PFEM). With this hybrid method, we detect topological changes in the interface by the inconsistency of neighboring normal vectors, which are directly computed through the parametric FEM. Second-order accuracy of the proposed method in both the interface and the contact line positions before and after topological changes has been numerically validated. Moreover, with the help of the numerical method, the merging and collision dynamics of droplets on the substrates are easily investigated.

ADAPTIVE ALARM SYSTEM FOR PREDICTIVE MAINTENANCE OF ELECTRIC MOTORS

Zhengyu Zhang[*1], Dongyan Shi[1], Renjie Huang[1], Yongran Yin[1], Yubo Gao[1] and Yuguang Zhong[1]*

[1]Harbin Engineering University

ABSTRACT

Electric motors are widely used in various fields such as production lines, robots, ships, and electric vehicles. They are one of the most fundamental and critical actuators in the field of industrial automation. However, if mechanical faults in motors are not detected and addressed promptly, it can affect the performance and lifespan of the motors, leading to issues such as production equipment downtime, decreased product quality, and energy waste. Therefore, this paper presents an adaptive alarm system for predictive maintenance of motors based on machine learning.

The system autonomously collects vibration data from motors and utilizes the random forest algorithm and the WDCNN deep convolutional neural network model to establish a comprehensive predictive model for data analysis and processing. Through machine learning, the system predicts the fault type of new input data and promptly issues an alarm signal. The system employs the Adam optimization algorithm with adaptive learning rates to improve the accuracy and reliability of the model. The results of cross-validation and testing experiments demonstrate that the proposed adaptive alarm system can achieve predictive maintenance of motors, effectively enhancing their reliability and safety. The predictive model exhibits good robustness and generalization ability, enabling it to adapt to different types and degrees of mechanical faults.

Keywords: motor fault diagnosis, deep learning, adaptivity, alarm system, predictive maintenance.

ABSTRACT

Laser Powder Bed Fusion (LPBF), a 3D printing technology, can produce parts with complex geometries that are typically difficult to create using conventional manufacturing techniques. However, the complex phenomena related to the melting and solidification of powder particles pose significant challenges for both experimental and numerical tools in terms of investigating and, furthermore, controlling the print quality. In this work, the evolution of the melt pool in ceramics LPBF is observed at the Tomcat beamline of the Paul Scherrer Institute using operando high-speed tomographic microscopy. As a Lagrangian and particle-based discretization technique, the smoothed particle hydrodynamics (SPH) method [1] provides distinct advantages in handling large deformations and capturing moving interfaces encountered in LPBF simulations [2]. We present a particle-based SPH solver to simulate the LPBF process and test its validity by comparing the simulation results with experimental data concerning melt pool size. Subsequently, by combining the experimental observations with high-fidelity simulations, we characterize the evolution of melt pools in situations with varying laser power, laser speed and laser spot size, while explaining the formation of either deep or shallow melt pools. The initial development of the melt pool under the influence of a laser heat source is further studied, with a close analysis of the factors affecting the formation of the melt pool. Finally, several keyhole modes in ceramics LPBF are identified, a discovery that proves valuable for enhancing the quality of manufactured structures.

*[1]Institute of High Performance Computing (IHPC), Agency for Science Technology and Research (A*STAR)*

*[2]Institute of Materials Research and Engineering (IMRE), Agency for Science Technology and Research (A*STAR)*

ABSTRACT

In the realm of Cold Spray Additive Manufacturing (CSAM), metal powder particles are propelled by pre-heated, high-pressure gas through a converging-diverging nozzle, reaching velocities beyond the critical range of 500m/s to 1000m/s, depending on the material type. This acceleration results in the particles impacting the substrate, allowing for material deposition and the construction of parts at a high volume rate. A key metric in CSAM, Deposition Efficiency (DE), plays a pivotal role in determining the quality and production costs of the process. DE can be influenced by various process parameters including gas pressure, pre-heating temperature, nozzle design, nozzle impingement angle, powder size distribution and more. Experimental data has shown that DE significantly affects the properties of the deposited materials, such as microstructures (including grain size and dislocation densities), hardness, porosity, and adhesive and cohesive bonding strength. To gain a comprehensive understanding of the factors influencing DE and to enhance the predictability and control of DE in CSAM processes, we have developed a multiphysics and multiscale computational modeling and simulation platform. This includes the utilization of Molecular Dynamics and Finite Element Method (FEM) modeling for single particle impact simulations to fundamentally understanding bonding mechanism and establish bonding criteria in CSAM. Furthermore, a data-driven model has been constructed based on the bonding criteria, enabling the identification of bonding and rebounding scenarios for individual particles varying in size, temperature, and velocity. The dynamics of gas flow, as well as the velocity and temperature of tens of thousands of in-flight particles, are studied using a multiphase Computational Fluid Dynamics (CFD) model, further enhanced by a serial CFD-FEM coupling model for more accurate particle temperature analysis. This integration of the data-driven model with CFD simulation results allows for the prediction of DE under various CSAM process conditions. To validate the model's accuracy, experiments were conducted, focusing on in-flight particle velocities and the DE of Ti-64 CSAM processes. The impact of DE on deposit properties such as surface morphology, porosity, and residual stresses has been illustrated through both computational modeling and experimental studies, highlighting its crucial role in CSAM.

MACHINE LEARNING MODEL FOR CORRELATING MICROSTRUCTURAL FEATURES AND MACROSCOPIC PROPERTIES OF HETEROGENEOUS COMPOSITES

Chengcheng Shen[1] *and Haifeng Zhao**[1]

[1]*University of Chinese Academy of Sciences*

ABSTRACT

In the traditional micromechanics context, the size and volume fraction of inclusions in heterogeneous composites are considered the primary microstructural parameters for controlling macroscopic properties, rather than other factors. Challenges persist in accurately predicting effective properties due to a limited understanding of extensive multi-scale microstructural data using micromechanics-based methods such as homogenization and finite element analysis.
In this research, both supervised and unsupervised learning approaches are employed to explore the limits of artificial intelligence comprehension. In the case of supervised learning, analysis of scanning electron microscope (SEM) images of nickel-based superalloys from a high-throughput experiment involves defining 23 microstructural descriptors to correlate with the hardness. Subsequently, 10 descriptors are selected to reduce the computational cost of the deep neural network (DNN) with the support of the shallow neural network (SNN). Additionally, in order to enhance DNN accuracy, new training sets are proposed by incorporating these 10 descriptors along with two additional ones: area distribution and one heat treatment parameter - cooling rate. In conclusion, it is demonstrated that the supervised learning approach surpasses the predictive capabilities of existing physics-based constitutive models.

In the case of unsupervised learning, the prediction of the effective thermal conductivity of thermal insulation composite materials is achieved through the utilization of a convolutional neural network (CNN). The CNN model is trained and validated using fibrous and particulate composites images generated from numerical approaches as input data and the conductivities predicted by the Lattice Boltzmann Method (LBM) as output data. Subsequently, the CNN predictions are compared to experimental results as well as those obtained from analytical and computational micromechanics methods. It is worth noting that the proposed CNN model demonstrates accurate prediction of the thermal conductivity for materials featuring novel microstructures that were not part of the training set.

In summary, harnessing artificial intelligence to capture the scattering characteristics of heterogeneous materials enables both DNN and CNN models to achieve more efficient predictions compared to traditional methods. This highlights the potential of machine learning in advancing materials science and expediting the development of materials with desired properties.

GENERAL NUMERICAL FRAMEWORK TO DERIVE STRUCTURE PRESERVING REDUCED ORDER MODELS FOR THERMODYNAMICALLY CONSISTENT REVERSIBLE-IRREVERSIBLE PDES

Zengyan Zhang[1] *and Jia Zhao**[1]

[1]*Binghamton University*

ABSTRACT

In this presentation, we propose a general numerical framework to derive structure-preserving reduced-order models for thermodynamically consistent PDEs. Our numerical framework has two primary features: (a) a systematic way to extract reduced order models for thermodynamically consistent PDE systems while maintaining their inherent thermodynamic principles and (b) a strategic process to devise accurate, efficient, and structure-preserving numerical algorithms to solve the forehead reduced-order models. The platform's generality extends to various PDE systems governed by embedded thermodynamic laws. The proposed numerical platform is unique from several perspectives. First, it utilizes the generalized Onsager principle to transform the thermodynamically consistent PDE system into an equivalent one, where the transformed system's free energy adopts a quadratic form of the state variables. This transformation is named energy quadratization (EQ). Through EQ, we gain a novel perspective on deriving reduced-order models. The reduced order models derived through our method continue to uphold the energy dissipation law. Secondly, our proposed numerical approach automatically provides numerical algorithms to discretize the reduced-order models. The proposed algorithms are always linear, easy to implement and solve, and uniquely solvable. Furthermore, these algorithms inherently ensure the thermodynamic laws. Our platform offers a distinctive approach to derive structure-preserving reduced-order models for a wide range of PDE systems abiding by thermodynamic principles.

ELECTROHYDRODYNAMIC EFFECTS ON VISCOELASTIC DROPLET DEFORMATION IN SHEAR FLOWS

Jiachen Zhao[1], Vedad Dzanic[1], Zhongzheng Wang[1] and Emilie Sauret[1]*

[1]*Queensland University of Technology*

ABSTRACT

Abstract

The droplet-based microfluidic technologies in a confined shear flow configuration have evolved rapidly in the past decade and have shown tremendous potential in many industrial and commercial applications, such as food processing, pharmacy, and materials synthesis [1]. For many of these applications, the droplet exhibits non-Newtonian viscoelasticity, whose dynamical behaviour differs significantly from the Newtonian counterpart. The size and morphology of droplets play a crucial role in determining the mechanical properties and rheology of the resulting system. Therefore, an efficient and effective manipulation of the droplet size and morphology is of paramount importance to ensure accurate control over the dynamics of the process. It has been shown that additional stresses can be generated at the fluid interface in the presence of an electric field (electrohydrodynamics) [2], thereby significantly altering the flow behaviours. In this study, the dynamics of viscoelastic droplets under the combined action of electric field and shear flow are investigated by using a hybrid lattice Boltzmann model (LBM) and finite difference method (FDM), where the hydrodynamic field is simulated by LBM and the electric and polymer field (viscoelasticity) are solved by FDM. Both the droplet and the surrounding medium are considered to be leaky dielectric fluids. The effects of the conductivity and permittivity contrast between the fluids and the electric field strength on the viscoelastic droplet deformation and morphology are studied. The results show that in the presence of an external electric field, the deformation of the droplet can be suppressed or promoted, and the droplet inclination angle can be aligned or opposite to the shear flow direction depending on the electrical properties of the two fluids.

DYNAMICS AND HETEROGENEITY OF PARTICLE NETWORK IN COMPOSITE ELECTRODES OF LI-ION BATTERIES

Kejie Zhao[1]*

[1]*Purdue University*

ABSTRACT

We use a data-driven approach to assess the heterogeneous electrochemistry and mechanics in composite cathodes. We visualize the morphological defects at multi-scales ranging from the macroscopic composite, particle ensembles, to individual single particles. Particle fracture and interfacial debonding are identified in a large set of tomographic data. The mechanical damage of active particles is highly heterogeneous. The difference originates from the polarization of the electrolyte potential, various local conducting environments, and thus the non-uniform distribution of the activation energy for the charge transfer reaction. We model the kinetics of intergranular fracture and interfacial degradation to assess the heterogeneous mechanical damage in composite electrodes using microstructure-informed mechanics modeling. We quantify the influence of the mechanical damage on the metrics of battery performance. More interestingly, the interfacial failure reconstructs the conductive network and redistribute the electrochemical activities that render a dynamic nature of electrochemistry and mechanics evolving over time in the composite electrodes.

A UNIFIED MIXED METHOD FOR THE FLUID-STRUCTURE INTERACTION

Lina Zhao[*1]*

[1]*City University of Hong Kong*

ABSTRACT

In this talk we propose and analyze a staggered DG method free of stabilization in stress-velocity formulation for fluid-structure interaction. A unified formulation is employed for the Stokes equations and the elastodynamic equations. The symmetry of stress is strongly imposed and equal order polynomials are employed for all the variables. The proposed scheme yields divergence-free fluid velocity. In particular, the transmission conditions can be incorporated naturally without resorting to additional variables or Nitsche-type stabilization owing to the bespoke construction of the discrete formulation. Moreover, the dynamic coupling interface condition is satisfied strongly in the definition of the approximation space. Optimal convergence for all the variables can be obtained. Furthermore, the pressure-independence, and the robustness with respect to fluid viscosity and the Lam\'{e} constants are investigated. The proposed scheme is hybridizable and the globally coupled unknowns only involve the normal trace of stress. Importantly, the resulting matrix is shown to be symmetric positive definite, rendering the scheme computationally attractive. Several numerical experiments are presented to verify the proposed theories.

THREE-LAYER HELE-SHAW PROBLEM DRIVEN BY A SINK

Meng Zhao[*1]

[1]*Huazhong University of Science and Technology*

ABSTRACT

We investigate a sink-driven three-layer flow in a radial Hele-Shaw cell performing numerical simulations. The three fluids are of different viscosities with one fluid occupying an annulus-like domain, forming two interfaces with the other two fluids. Using a boundary integral method and a semi-implicit time stepping scheme, we alleviate the numerical stiffness in updating the interfaces and achieve spectral accuracy in space. The interaction between the two interfaces introduces novel dynamics leading to rich pattern formation phenomena, manifested by two typical events: either one of the two interfaces reaches the sink faster than the other (cusp-like morphology) or they touch each other (interface merging). In particular, the inner interface can be wrapped by the other to have both scenarios. We find that multiple parameters contribute to the dynamics including the width of annular region, the location of the sink, and the mobilities of the fluids.

HIERARCHICAL MULTISCALE MODELING OF FLUID-SOIL INTERACTIONS FOR LARGE-DEFORMATION PROBLEMS

Zhang Cheng[1], Shiwei Zhao[1] and Jidong Zhao[1]*

[1]Hong Kong University of Science and Technology

ABSTRACT

Large deformation problems in fluid-saturated granular media are of significant concern in areas such as natural geohazards and engineering applications. The multiscale nature of granular media has gained increasing recognition with advancements in experimental and numerical tools. In this study, we propose a novel multiscale hydro-mechanical approach that couples the double-point Material Point Method (MPM) with the Discrete Element Method (DEM). To capture the complexities of the system, we employ an explicit double-point MPM with two-phase media. This approach enables the description of soil-water interactions, the transition from free water to groundwater, as well as the fluidization and sedimentation behavior of soil. Additionally, DEM is utilized to simulate the response of a representative volume element (RVE), which acts as a surrogate for the conventional constitutive model at a material point. This allows for adaptability to complex loading conditions. To validate the accuracy of our method, we compare the results to analytical solutions of consolidation theory. Subsequently, the method is employed to simulate various dynamic experiments, including the collapse of submerged granular-liquid mixtures and the generation of water waves caused by the collapse of dry granular materials into water. Furthermore, we enhance the computational efficiency of the numerical simulations by employing hybrid OpenMP and GPU-based parallelization. This approach offers an efficient and effective pathway for addressing large-deformation problems involving complex hydro-mechanical coupling in granular media. Overall, our proposed multiscale, hydro-mechanical approach, combining the double-point MPM with DEM, demonstrates promising capabilities in accurately capturing and simulating large-deformation phenomena in fluid-saturated granular media.

EXPERIMENTAL AND NUMERICAL STUDY ON CRACK PROPAGATION OF CONCRETE AFTER LOW-CYCLE RECIPROCATING LOADING

Wenhu Zhao[*1] and Yi Li*[1]

[1]*Nanchang University*

ABSTRACT

Concrete structures usually contain cracks or micocracks that directly weaken concrete strength and structure's stability. To fully understand the fracture behaviour of concrete with initial micocracks or damage, a series of concrete specimens are split using an improved wedge splitting device after low-cycle reciprocating loading. Due to the additional springs on the device, the complete stress-strain curves representing concrete fracture are measured and recorded, including the evolution of micro-cracks, damage accumulation, and ultimate fracture stages. Compare to the results of normal tests, the differences on the fracture toughness and fracture energy are analyzed and calculated with the double-K fracture model. The measured values of the initiation force, the initiation toughness and the unstable toughness increase slightly because the weaker bond zones have accomplished fracture, and the rest performance of concrete specimen is mainly determined by the properties of coarse aggregates. The results show that the reciprocating loading changes the failure pattern and that more failures occur around the coarse aggregates, causing the relative ratio up to over 160%. Meanwhile, a numerical simulation of crack propagation is carried out based on the scaled boundary finite element method (SBFEM). An equivalent stress intensity factor (eSIF) is proposed to determine the crack propagation for concrete with damage. Finally, the performance of the proposed method is verified by several numerical examples. The numerical results agree well the experimental ones and the proposed critical eSIF has high accuracy in solving the mode I and II stress intensity factors as well as simulating the internal crack growth path of materials.

STUDY ON THE INFLUENCE OF VALLEY WIDTH DEFORMATION ON THE SAFETY OF HIGH ARCH DAM CONSIDERING UNSATURATED SEEPAGE

Yin Zhao[*1], Changhong Xin[1] and Xuan Wu[1]*

[1]*Hohai University*

ABSTRACT

Abstract: The effect of valley width deformation during the initial impoundment stage on the subsequent working behavior and the long-term safety of an arch dam has become an increasingly important challenge faced by dam engineering and academia. This study aims to analyze the sensitivity of valley width deformation to the absorption curve of fractured rock mass to address the challenge of valley width reduction during impoundment of the Jinping Ⅰ arch dam in China. The methods of unsaturated seepage analysis theory and nonlinear finite element numerical analysis were applied to study the law of valley width deformation during unsaturated seepage process. The influence of valley width deformation on the displacement and stress of the dam was analyzed. The results showed that the slope on both sides of the valley deformed towards the center under the action of the unsaturated seepage field. The deformation of valley width upstream exceeded that downstream. The valley width deformation increased with an increasing elevation
of the water level, and maximum valley width reduction occurred in the saturated seepage field. The distribution of displacement and stress of the dam changed little during the unsaturated seepage process. However, the maximum longitudinal displacement and the minor principal stress of the dam decreased gradually with increasing elevation of the water level. There was a gradual increase in the major principal stress. However, the valley width deformation resulting from the seepage field had a limited effect on the displacement and stress of the dam, which would not affect the overall stability of the dam.

Key words: unsaturated seepage; absorption curve; valley width deformation; high arch dam

PHASE-FIELD FORMULATION FOR PREDICTING VOID EVOLUTION AT THE LI-ELECTROLYTE INTERFACE IN ALL-SOLID-STATE BATTERIES

Ying Zhao[1], Emilio Martinez-Paneda[2] and Runzi Wang[2]*

[1]*Tongji University*
[2]*University of Oxford*

ABSTRACT

All-solid-state batteries are among the most promising energy storages, because they use unflammable solid electrolyte in substitution of organic liquid electrolytes, thus reducing safety hazards. Moreover, they can potentially allow for the employment of Li metal electrode that can significantly enhance the energy densit. However, void and dendrite formation at the interface between the Li-metal anode and the solid electrolyte are hindering the viability of all-solid-state Li-metal batteries.

In this presentation, we develop a phase-field formulation for predicting void evolution in the Li metal electrode during the charge and discharge of all-solid-state battery cells [1]. This formulation can predict vacancy annihilation and nucleation, and track of the void-Li metal interface. This is coupled with a viscoplastic description of Li deformation, to capture creep effects, and a mass transfer formulation accounting for substitutional (bulk and surface) Li diffusion and current-driven flux. Moreover, we incorporate the interaction between the electrode and the solid electrolyte, resolving the coupled electro-chemical-mechanical problem in both domains. This enables predicting the electrolyte current distribution and thus the emergence of local current ‘hot spots’, which act as precursors for dendrite formation and cell death. The theoretical framework is numerically implemented, and single and multiple void case studies are carried out to predict the evolution of voids and current hot spots as a function of the applied pressure, material properties and charge (magnitude and cycle history). For both plating and stripping, insight is gained into the interplay between bulk diffusion, Li dissolution and deposition, creep, and the nucleation and annihilation of vacancies. The model is shown to capture the main experimental observations, including not only key features of electrolyte current and void morphology but also the sensitivity to the applied current, the role of pressure in increasing the electrode–electrolyte contact area, and the dominance of creep over vacancy diffusion.

AN EFFICIENT MULTISCALE SIMULATION FRAMEWORK OF ADS COMPOSITE FUEL BY INCORPORATING AN INTERPRETABLE DEEP-LEARNING-BASED SWELLING MODEL

Yunmei Zhao[*1] and Yiqun Dong*[2]

[1]*Tongji University*
[2]*Fudan University*

ABSTRACT

Numerical analysis of nuclear fuel composites is a classic engineering problem with multiphysics and multiscale nature. Owing to the complicated mechanical, thermal effects, and multiscale irradiation damage effects, the modeling framework usually suffers from limited applicability in engineering practice. In this study, a novel framework for the multiscale analysis of the ADS (Accelerated driven system) fuel composite is proposed, in which a deep learning surrogate is employed to describe the hydrostatic-pressure-dependent swelling behavior, circumventing the difficulties associated with conventional approaches. The surrogate model was trained by a Long Short-Term Memory (LSTM) deep learning model that excels at processing the sequential nature of the swelling evaluation with irradiation burnups. The model was further incorporated within the stress update algorithm in UMAT/ABAQUS. During the FE solution, the surrogate receives the key history features of temperature, hydrostatic pressure, and swelling deformation at the Gauss integration points and returns the predicted swelling strain to advance the computation. The applicability and capacity of the machine-learning-assisted framework were demonstrated by analyzing three simulation cases, in which different loading conditions and irradiation effects were considered. It was shown that the framework can reproduce satisfactory solutions without resorting to any constitutive theory. Furthermore, the use of the DL model not only avoids the stress integration of the conventional FE analysis but also leads to better computational efficiency.

ROBUST TOPOLOGY OPTIMIZATION FOR STRUCTURES WITH SPATIALLY BOUNDED GEOMETRIC UNCERTAINTY

Jing Zheng[*1] and Chao Jiang[1]*

[1]*Hunan University*

ABSTRACT

In structural topology optimization design, a series of robust topology optimization methods have been developed considering the uncertainties related to material properties and applied loadings. In addition, manufacturing errors or measurement errors often lead to the uncertainty of structure boundaries. The structural design may be very sensitive to the small fluctuation of the boundary. On the one hand, it is difficult to obtain the probability distribution of the boundary uncertainty due to the high-cost experiment or limited data. On the other hand, structural boundary uncertainty is generally uncertain but spatially bounded. In this work, the interval field is used to measure the geometric uncertainty, and an efficient robust topology optimization method based on Chebyshev polynomial expansion is developed. Firstly, the boundary disturbance of the structure is described by modelling the projection threshold variable in the Heaviside filter as an interval field, and a robust topology optimization model under the worst case is then constructed. Secondly, based on the interval KL (Karhunen-Loève) expansion, the interval field is approximately discretized into finite interval variables, and the robust objective function and constraint are evaluated using the Chebyshev polynomial expansion method. Thirdly, the sensitivities of the robust objective function and constraint with respect to the design variables are derived, and the gradient-based optimization algorithm is used to update the topology design variables. The analysis results of numerical examples show that the geometric uncertainty fluctuation of the structural boundary has an important impact on the structural performance. Compared with the topology optimization design under the deterministic boundary, the robust topology optimization design considering uncertainty has better robustness when considering the fluctuation of the structural boundary.

TOPOLOGY OPTIMIZATION-BASED DESIGN METHOD FOR LOW-PROFILE HIGH-GAIN ENDFIRE CIRCULARLY POLARIZED ANTENNAS

Junfeng Zheng[*1], Qi Wang[1], Renjing Gao[1] and Shutian Liu[1]*

[1]*Dalian University of Technology*

ABSTRACT

Metallic antennas with excellent properties (single feed, broadband, endfire radiation, high gain, and circularly polarized) are attractive for modern wireless communication systems. However, the complex radiation is extremely challenging for conventional parameter optimization-based design methods. In particular, when the profile of the antenna is lowered, it is difficult to achieve circularly polarized waves because of the mismatch between the profile and cross-sectional dimensions, which imposes stringent requirements on the design of the antenna configuration. To overcome this difficulty, a topology optimization approach is introduced for the design of a low-profile, high-gain end-fire circularly polarized antenna. The objective of the design problem is to maximize the gain of the metallic antenna while maintaining a circularly polarized wave around the direction of the endfire radiation. The material distribution approach is adopted to search for the optimal distribution of metal materials, and the material resistance is chosen to be interpolated with the design variables to differentiate between metallic conductors and nonconductors. Since the metallic antenna radiation performance is sensitive to the gray elements, to obtain a discrete solution, the design variable is iteratively projected using a smoothed Heaviside projection function during the optimization process. For the zig-zag boundary and the leftover gray elements, a Bessel curve-based shape optimization approach is proposed to reoptimize the topological conceptual configuration, thus antenna with smooth boundaries can be obtained.

SPECIMEN-SPECIFIC FINITE ELEMENT MODELLING OF CARTILAGE MECHANICS: A NEW PARADIGM IN LINKING TISSUE ULTRASTRUCTURE TO ITS MICROMECHANICS

Keke Zheng[*1], Jingrui Hu[2] and Junning Chen[2]*

[1]*Heriot-Watt University*
[2]*University of Exeter*

ABSTRACT

The architecture of collagen network plays the dominant role in determining the biomechanical behaviour of articular cartilage, which exhibits strong directionality and anisotropy [1]. Several theoretical material models have been developed to study the micromechanics of cartilage [2], but few have been capable of capturing the specimens-specific heterogeneity in the organisation of the fibrous network across multiple length scales. Polarisation-resolved Second Harmonic Generation (pSHG) microscopy is an emerging technique that allows the principal orientation and the molecular order (dispersion) of collagen fibre networks to be probed below the optical diffraction limit [3]. These data await to be incorporated into image-based finite element (FE) simulations to study cartilage mechanics in a specimen-specific manner. This study aims to establish a framework for combining the collagen network architecture quantified by pSHG and FE analysis, to establish a link between the ultrastructural parameters and the micromechanics of the tissue, therefore inferring the mechanobiological environments of cells within. A multiphasic material model was developed to govern the interaction among different major constituents, including the non-fibrillar extracellular matrix (ECM), the fibrillar collagen network, the osmotic pressure, and the interstitial fluid. The pixel-based fibril orientation information from pSHG images was then assigned to the elemental material properties in the FE model. The fibrillar stress and pore pressure were quantified for the cartilage in the sagittal plane which had three zones of distinct collagen organization. Under a uniaxial compression loading, three different zones respond differently. It is not only due to the different fibrillar orientation, but also because the deformation of the chondrocyte varies across three zones. In addition, the mechanical response showed discrepancies between the territorial and inter-territorial matrix. The cartilage model presented in this study incorporated the local fibrillar orientation information to link ultrastructure to its micromechanics, and results implied that heterogeneity of fibrillar structure affects the local biomechanical behaviours of cartilage, not revealed in the theoretical models before.

UNIFYING THE DESIGN SPACE AND OPTIMIZING LINEAR AND NONLINEAR TRUSS METAMATERIALS BY GENERATIVE MODELING

Li Zheng[*1], Konstantinos Karapiperis[1], Siddhant Kumar[2] and Dennis Kochmann[1]*

[1]*ETH Zurich*
[2]*TU Delft*

ABSTRACT

The rise of machine learning has fueled the discovery of new materials and, especially, metamaterials—truss lattices being their most prominent class. While their tailorable properties have been explored extensively, the design of truss-based metamaterials has remained highly limited and often heuristic, due to the vast, discrete design space and the lack of a comprehensive parameterization. We here present a graph-based deep learning generative framework, which combines a variational autoencoder and a property predictor, to construct a reduced, continuous latent representation covering an enormous range of trusses. This unified latent space allows for the fast generation of new designs through simple operations (e.g., traversing the latent space or interpolating between structures). We further demonstrate an optimization framework for the inverse design of trusses with customized mechanical properties in both the linear and nonlinear regimes, including designs exhibiting exceptionally stiff, auxetic, pentamode-like, and tailored nonlinear behaviors. This generative model can predict manufacturable (and counter-intuitive) designs with extreme target properties beyond the training domain.

STRICT UPPER AND LOWER BOUNDS ON QUANTITIES OF INTEREST FOR TRANSIENT DYNAMICS

Qisheng Zheng[*1], *Li Wang*[1] *and Jike Liu*[1]

[1]*Sun Yat-sen University*

ABSTRACT

This work proposes a guaranteed error estimator for linear transient elastodynamics, accounting for both time- and space-discretization errors. The key lies in the definition of a novel dynamic constitutive relation error formulation, which is proven to be the strict bound of the discretization error. Moreover, based on the established dynamic constitutive relation error and the goal-oriented error estimation framework, strict upper and lower bounds on quantities of interest are also obtained. Numerical examples are conducted to verify the proposed strict bounds and to explore the potential application of these bounds to adaptive time-stepping and mesh-refinement.

FRACTURE PREDICTION OF HYDROGEL USING MACHINE LEARNING AND INHOMOGENEOUS MULTISCALE NETWORK

Shoujing Zheng[1], Hao You[1], K.Y. Lam[1] and Hua Li[1]*

[1]*Nanyang Technological University*

ABSTRACT

Hydrogels are soft polymeric materials with promising applications in biomedical fields. Understanding their fracture behavior is crucial for optimizing device design and performance. However, predicting hydrogel fracture is challenging due to the complex interplay between material properties and environmental factors. In this study, we present a machine learning (ML) approach to predict hydrogel fracture behavior. A multiscale hydrogel fracture model is developed to generate simulation data, which is used to train a predictive neural network model. The ML model utilizes a hierarchical architecture of convolution long short-term memory units to capture spatial and temporal dependencies in the data. Model predictions are found to closely match simulation results with high accuracy, demonstrating the ability to learn complex fracture processes. Comparison of crack lengths shows the model can generalize across different material parameters. This work highlights the potential of ML for advancing the understanding of hydrogel fracture and soft matter failure. The presented approach provides an efficient framework for predicting fracture in complex materials and systems.

PHASE-FIELD TOTAL LAGRANGIAN MATERIAL POINT METHOD FOR FRACTURE IN SOFT MATERIALS

Yonggang Zheng[1], Zijian Zhang[1], Hongfei Ye[1] and Hongwu Zhang[1]*

[1]*Dalian University of Technology*

ABSTRACT

Fracture problems of soft materials under large deformation exist widely in nature and engineering areas. Predicting the facture behaviors is of great importance for the structural design and safety assessment of many soft materials based devices. However, effective and accurate prediction of these behaviors remain challenging due to the coupled nonlinear mechanical responses of large deformation, contact and fracture. To address these problems, we have recently developed an explicit phase-field total Lagrangian material point method. In this method, the phase-field model was introduced to describe the cracks and the governing equations of the dynamic system were derived via the Lagrangian equation. Considering the massive deformation of soft materials, the TLMPM discretization was then developed for the displacement and phase field governing equations. To deal with the contact during the dynamic process, a particle-based contact algorithm was also proposed for both contact and self-contact problems within the total Lagrangian framework. Furthermore, with the consideration of the weak compressibility of series soft materials, the proposed method was developed to avoid the volumetric locking for near-incompressible materials by introducing a pressure field. Several complicated problems, including the impact of a metal ball on a soft membrane, the compression of soft blocks and the out-of-plane tearing of gels were presented to illustrate the performance of the proposed method for the dynamic fracture of soft materials in practical applications. These works were supported by the National Natural Science Foundation of China (Nos. 12072062, 12072061 and 11972108).

GLASS COMPRESSION CREEP TEST MODELLING

Zheming Zheng[*1]

[1]*Corning Incorporated*

ABSTRACT

Three modelling/analysis approaches are developed to study the glass compression creep test process, including analytical analysis based on Navier-Stokes equations, viscous fluid finite element analysis (FEA) modelling and viscoelastic solid finite element analysis (FEA) modelling. It is confirmed that the three methods generate the same result under the ideal condition. Impact of process parameters, like temperature, slip condition, is studied. Viscoelastic model study shows that the viscoelasticity impacts the result only to a small scale, and only at around or sub glass transition temperature Tg.

VIBRATIONAL CHARACTERISTICS OF SP3 CARBON NANOSTRUCTURES

Zhuoqun Zheng[*1]

[1]*Nanjing University of Aeronautics and Astronautics*

ABSTRACT

In past years, nanoelectromechanical systems (NEMS) attract interest from broad fields. The excellent vibrational properties of low-dimensional nanomaterials are crucial, which allows the detection of minute frequency shift under external perturbations. Recently, low dimensional sp3 carbon nanostructures have attracted increasing attention, due to their unique properties.
Targeting the ultra-sensitive sensing applications, this presentation contains a comprehensive study on the vibration properties of several novel low dimensional sp3 carbon nanomaterials, such as carbon nanothreads (NTH), diamane and its analogues [1-3]. Size effect is observed in transverse free vibrations of NTHs. The modified couple stress theory (MCST) based Timoshenko beam model is utilized to quantify such effects. Based on molecular dynamics simulations and continuum mechanics model, the natural frequencies and corresponding modal shapes of diamane are investigated. The results show that the Kirchhoff plate model can reasonably predict the vibration properties of diamane. Furthermore, the vibrational characteristics of the diamane's analogue - twisted bilayer graphene with interlayer-bonding (TBGIB) are studied. It is found that the interlayer shear modulus plays an important role in the natural frequencies of TBGIBs.
This work provides a comprehensive understanding of the vibration properties of carbon nanaothreads, diamane and its analogues, which should be beneficial to the tuning of ultrasensitive nano resonators.

GRAPH NEURAL NETWORKS FOR ACCELERATING THE DISCRETE ELEMENT SIMULATION OF GRANULAR FLOW

Peng Zhi[*1] and YuChing Wu*[1]

[1]*Tongji University*

ABSTRACT

Granular flow is a phenomenon widely presented in both the natural and engineering fields. Here granular materials could be either solid particles, e.g. rocks, soil, and grains, or liquid particles, e.g. mud and fresh concrete mortar. Soil landslides, particle transport, and grain accumulation have been edge-cutting hot research topics. Discrete Element Method (DEM) has been regarded as one of the most important methods to simulate granular flows and to investigate discontinuous and large deformation problems. The basic principle of DEM was to view the simulated object as consisting of discrete particles, to define specific constitutive relationships for the particles, and to study the macroscopic properties of the simulated object from a microscopic perspective based on the interactions between particles. However, DEM simulations usually consume very high computational cost for particle contact searching and detection. To accelerate the computational process of discrete element simulation, the Graph Neural Network (GNN) based deep learning model was proposed in this paper. In GNNs, graph nodes and graph edges represent the particles and their interactions. The training and testing datasets were generated using an open-source software named YADE, while the neural network model was constructed using PyTorch and Deep Graph Library (DGL). Replacing the direct calculation of particle collisions in DEM with the trained neural network model, the state of the particles at the next moment could be predicted based on the current state of the particles. It significantly increased computational speed. The proposed technique was applied in various examples, such as particle stacking and drum rotation. Its accuracy and efficiency were demonstrated to be superior to other deep learning methods. This study established a solid foundation and provided robust support for further research and applications of granular flow simulation.

A THERMO-CHEMO-MECHANICALLY COUPLED PERIDYNAMICS FOR INVESTIGATING CRACK BEHAVIOR IN SOLIDS

Zheng Zhong[*1]*

[1]*Harbin Institute of Technology*

ABSTRACT

In engineering applications, the phenomenon of cracking is often accompanied by a coupled multiphysics effect. Peridynamics (PD) is an effective approach for solving cracking problems, but currently, no general PD model accounts for the coupling of multiple physical fields. In this work, we develop a PD model of coupled deformation, heat conduction, species diffusion, and chemical reactions. First, we establish the equations for mass, linear momentum, and energy. Then we establish fully coupled constitutive laws that interpret the interactions between the various fields and formulate evolution equations that govern the flux of species and heat. These laws and equations are developed based on the inequality of energy dissipation and the principles of chemical kinetics. Species diffusion and chemical reactions are treated as separate processes to study their effects on the Helmholtz free energy density of solids and the subsequent formation and propagation of cracks. In addition, certain coupling coefficients are calibrated by equating the corresponding physical quantities in the PD model with those in continuum mechanics. Four specific cases are simulated to validate the model, including redistribution of vacancies in ceramics, hydrogen traps,and embrittlement in metals.

AN EFFECTIVE ALGORITHM BASED ON SIX-EQUATION DIFFUSION INTERFACE MODEL FOR SIMULATING CONDENSED PHASE DETONATION

Biao Zhou[*1], Yiqing Shen[1] and Baolin Tian[2]*

[1]*Chinese Academy of Sciences*
[2]*Institute of Applied Physics and Computational Mathematics*

ABSTRACT

We propose an effective algorithm for simulating the interaction between condensed-phase explosives and inert materials. The augmented Euler system (with an equation evolving the mass fraction), which can preserve the conservation property, is applied to model the mixture of explosive and its products, and a six-equation multi-phase diffusion interface approach is adopted to resolve the interaction between explosive mixtures and immiscible inert materials. Similar to the work of Saurel et al.[1], the Newton iteration nonlinear equation system of pressure relaxation terms is derived by combining the energy balance equation and the thermal equilibrium between explosive mixtures. And an effective root-finding process is developed by the initialization with the preliminary equation solutions. Several detonation examples are simulated to validate the robustness and efficiency of the new algorithm, and the comparisons to the algorithm based on the five-equation model[2] are also presented.

MULTISCALE MIXED METHODS WITH IMPROVED ACCURACY: THE ROLE OF OVERLAPPING AND SMOOTHING

Dilong Zhou[*1] and Luis Felipe Feres Pereira*[1]

[1]*The University of Texas at Dallas*

ABSTRACT

Multiscale mixed methods based on non-overlapping domain decompositions have been carefully studied in recent years. Linear solvers for porous media flow problems based on these methods are naturally parallelizable in multi-core computers and can handle efficiently the solution of large problems in very heterogeneous formations of interest to the industry.
Efficiency in the numerical solutions is dictated by the choice of interface spaces that are selected: the smaller the dimension of these spaces, the better, in the sense that fewer multiscale basis functions need to be computed and smaller interface linear systems need to be solved. Thus, in the solution of large computational problems, it is desirable to work with piecewise constant or linear polynomials. In these cases, it is well known that the flux accuracy, when computed in terms of fine grid solutions, is of the order of 10^-1.
In this work, we focus on the development of a practical, efficient, and accurate solver for large problems. We consider subdomains with small overlapping regions, and we introduce the concept of a smoothing step, to handle small-scale errors in the multiscale solution. Moreover, we introduce novel informed spaces for the calculation of multiscale basis functions.
Several numerical studies are presented to illustrate the good properties of the new solver. We consider initially a problem with an analytical solution followed by a careful study of two-dimensional solutions of several layers of the permeability field of the SPE 10 project.

A MODEL ON STRESS ANALYSIS OF ADHESIVE LAYER IN PLATED BEAM

Fen Zhou[*1]*

[1]*Hunan University*

ABSTRACT

The prediction of stresses in an adhesive layer is helpful in revealing the mechanism of debonding failure in plated beams. This study proposes an improved analytical model for the stress analysis of an adhesive layer in a plated beam. The beam and the soffit plate are individually modelled as a single Timoshenko sub-beam with separate rotations, while the adhesive layer is modelled as a two-dimensional elastic continuum in plane stress, which considers different adherend-adhesive interface stresses. The internal forces of the adhesive layer are assumed to satisfy the Timoshenko beam theory, and the shear deformation and bending moment of the adhesive layer can be considered. The internal forces and displacements of the adhesive layer are fully considered in the displacement compatibility equations, and deformable interfaces are assembled so that the effect of interface stresses on local deformation is captured. Based on equilibrium equations and displacement continuity, the governing differential equations of beam forces are derived, and then the analytical solutions of interface stresses and stresses along the thickness of the adhesive layer are obtained. Comparisons of the results of the finite□element analysis and the existing four-parameter model solutions show that the present model is reasonable. The influence of adhesive thickness on stress distributions in adhesive layers is also investigated.

EXPLORING COMPLEX ENVIRONMENTAL FLOW PHENOMENA WITH THE LATTICE BOLTZMANN METHOD

Qi Zhou[*1]

[1]*University of Calgary*

ABSTRACT

This presentation combines findings from three distinct studies, each leveraging the lattice Boltzmann method (LBM) to investigate various aspects of environmental fluid dynamics:

1. Rayleigh–Taylor instabilities under granular suspensions: The first study delves into Rayleigh–Taylor instabilities at the interface between a granular particle suspension and a clear fluid [1]. Employing a combination of lattice Boltzmann and discrete element methods, this research focuses on the instabilities' growth rate and average wave number. It examines the impact of the solid fraction of the suspension and the solid-to-fluid density ratio, shedding light on the dynamics of interfacial granular RTI and the potential of continuum-based linear stability analysis in such contexts.

2. Simulation of stratified plane Couette flows: The second study uses LBM to model stratified plane Couette flows, evaluating LBM's capacity for directly simulating wall-bounded, sheared turbulence under stable stratification [2]. The study presents a complete analysis of turbulence statistics by drawing comparisons between LBM outcomes and direct numerical simulations executed via the conventional pseudo-spectral method. It highlights the importance of selecting appropriate grid spacing in LBM to achieve accurate resolution in stratified wall-bounded turbulence scenarios.

3. Self-organization in stratified turbulence: The third study probes into the self-organization of strongly stratified turbulence, focusing on a local critical state within numerically simulated stratified turbulent flows. The approach [3] involves separating the turbulent flow field into large and small scales for an examination of energy transfer dynamics. The study delves into the possibility of flow self-organization under the influence of intense stratification, offering new perspectives on the behaviour of stratified turbulence.

The presentation aims to underscore the innovative use of LBM in environmental fluid mechanics, showcasing its versatility and effectiveness in unravelling the dynamics of fluid flows in natural and engineered systems.

FIBER HYBRIDIZATION EFFECTS ON RESISTANCE TO REPEATED LOW-VELOCITY IMPACT OF MG-BASED FIBER METAL LAMINATES

Xia Zhou[*1], Wogayehu Worku Tegegne[1] and Guohui Qu[2]*

[1]*Dalian University of Technology*
[2]*Dalian Xinzhong Group Co., LTD.*

ABSTRACT

In order to investigate fiber hybridization effects on repeated low-velocity impact response of novel fiber reinforced AZ31B magnesium alloy laminates (Mg-FMLs)，the theoretical and numerical analyses of single and repeated low velocity drop weight impact tests on Mg-FMLs reinforced with pure glass fiber (GF) and carbon fiber (CF) and their hybrids were conducted. The simulation predictions are also compared with the existing experimental results [1]. On the basis of the verification of the simulation model, the impact resistance of hybrid CF and GF reinforced Mg-FMLs with different layups was also simulated. This study provides a reasonable basis for the accurate evaluation of the impact behavior and performance optimization of lightweight Mg-FMLs [2].
The Mg alloy, the interfacial delamination between two neighboring layers and the fiber/epoxy composites in the fiber/AZ31B Mg laminates were modeled by using an anisotropic plastic constitutive model, an exponential cohesive zone model, and 3D Hashin failure criteria incorporated with the stiffness reduction of failed elements, respectively. In addition，the numerical analyses of low-velocity impact for different fiber/Mg laminates were carried out by using ABAQUS /Explicit with a user-defined subroutine VUMAT to predict the dynamic impact response and delamination as well as damage evolution rules under conditions of different low-velocity impact loadings. Meantime, the variations of impact force, deformation and energy absorption with impact number for various Mg-based FMLs were also analyzed.

The results show that impact response predictions of GF/Mg alloy laminates are in agreement with the existed experimental data under different impact energies. The repeated low-velocity impact resistance of CF reinforced Mg-FMLs can be improved by the incorporation of GF at suitable lay-up locations. For the hybrid fiber reinforced Mg-FMLs with 3/2 lay-up configuration, the hybrid laminates have the strongest resistance to repeated impact when the glass fibers are laid at the second layer of the hybrid fiber composite layers due to the larger impact contact force, smaller deformation deflection and proper energy absorption as well as higher delamination resistance.

VOID AND HELIUM BUBBLE INTERACTIONS WITH DISLOCATIONS IN AN FCC STAINLESS STEEL ALLOY: ANOMALOUS HARDENING AND VOID CROSS-SLIP LOCKING

Ryan B. Sills[1], Xiaowang Zhou[2] and Michael E. Foster[2]*

[1]Rutgers University
[2]Sandia National Laboratories

ABSTRACT

The critical stress for cutting of a void and He bubble by edge and screw dislocations has been determined for FCC Fe0.70Cr0.20Ni0.10—close to 300-series stainless steel—over a range of bubble spacings, diameters, pressures, and glide plane positions. The results exhibit anomalous trends with spacing, diameter, and pressure when compared with classical theories for obstacle hardening. These anomalies are attributed to elastic anisotropy and the wide extended dislocation core in low SFE metals, indicating that caution must be exercised when using perfect dislocations in isotropic solids to study void and bubble hardening. In many simulations with screw dislocations, cross-slip was observed at the void/bubble surface, leading to an additional contribution to strengthening. We refer to this phenomenon as void cross-slip locking, and argue that it may be an important contributor to void and bubble hardening.

RESEARCH ON HEAT DISTRIBUTION DESIGN OF CARBON CERAMIC BRAKE DISCS AND SHAPE OPTIMIZATION OF RIB FOR HIGH-SPEED TRAIN

Yili Zhou[*1] and Shuguang Yao*[1]

[1]*Central South University*

ABSTRACT

High speed and lightweight are the development trends of high-speed trains in the world. Air braking technology is the last line of defense to ensure the safety and reliability of trains. The complex working environment and huge braking power put forward higher requirements for brake disc configuration and material. Carbon-ceramic composite materials have the characteristics of large specific heat capacity, thermal shock resistance, lightweight and high temperature resistance, and are considered to be high-performance friction materials. By imitating the distribution of animal and plant nutrients transportation pipelines, a carbon-ceramic composite brake disc structure with #-shaped heat dissipation ribs was designed that take into account the anisotropy of the thermal conductivity of carbon-ceramic composite materials. The branched rib structure realizes rapid heat transmission in the disc material, thereby achieving high efficiency and uniform temperature distribution, prevents the concentration of heat generated by friction, which can reduce the maximum temperature value under braking conditions. Then combined with the shape optimization and size optimization design of the local heat dissipation ribs of the brake disc, Further research on the uniform temperature performance and pump wind effect under emergency braking conditions of 400km/h was carried out. The Kriging model was used to analyze the different outlet angle, inlet angle and number of the cooling ribs in the same reference flow field. By comprehensively considering parameters such as the average maximum temperature, convection heat transfer coefficient, and pumping efficiency, an optimal design that balances cooling efficiency and aerodynamic loss is obtained.

ANALYTICAL SOLUTION OF THE GENERALIZED PROBABILITY DENSITY EVOLUTION EQUATION WITH MULTIDIMENSIONAL RANDOM VARIABLES: THE CASE OF EULER-BERNOULLI BEAM

Yongfeng Zhou[*1] and Jie Li*[1]

[1]*Tongji University*

ABSTRACT

The analytical solution of the generalized probability density evolution equation not only holds significant theoretical value, but also serves the purpose of validating numerical solutions and subsequently calibrating the errors in numerical algorithms. In a general sense, the generalized probability density evolution equation has an analytical solution. However, limited by its form - multidimensional integration containing Dirac functions, the analytical solution for this equation is limited to a small number of simple systems under a single random variable. Therefore, according to the basic idea of converting multidimensional integration into one-dimensional integration, taking the Euler-Bernoulli simply supported beam as an example, the analytical solution of the generalized probability density evolution equation corresponding to the mid-span displacement response of the beam under forced vibration is derived. The solutions include those under non-stationary and non-Gaussian random excitations (involving 2-dimensional random variables) as well as those considering both the randomness of excitations and structural parameters (involving 2-dimensional, 4-dimensional and 5-dimensional random variables, respectively). The analysis results indicate that the real evolution of probability density is a highly intricate process. This advancement can provide a foundational aspect for further in-depth research into the theory of probability density evolution.

APPLICATION OF COMPUTATIONAL DAMAGE MECHANICS IN THE DEVELOPMENT OF DOWNHOLE COMPLETION TOOLS

Zhong Zhou[*1], Allan Zhong[1], Gordon McLeary[1] and Stephen Maddux[1]*

[1]*Halliburton Energy Services*

ABSTRACT

Material modelling is crucial for predicting material behaviors and for improving the robustness of product designs. Specifically, the incorporation of damage mechanics and fracture mechanics principles through finite element analysis (FEA), has become indispensable in achieving these objectives for many applications. Accurately predicting material damage is difficult especially in the complex conditions encountered in the energy industry.

Damage mechanics provides insights into the evolution of material degradation. The widely adopted Johnson-Cook plasticity and damage model offers a sophisticated representation of material response under complex loading conditions and enables a realistic simulation of both plastic deformation and damage accumulation. On the other hand, fracture mechanics focuses on the initiation and propagation of cracks, a critical aspect in predicting failure in engineering applications.

In the context of oil and gas well completion tool design, we often deal with release mechanism where controlled failure is desirable. The traditional approach uses iterations of engineering calculations and physical tests. FEA is a powerful virtual testing ground, allowing for the numerical study of the intricate interplay between material properties, geometric complexities, and loading conditions. A Johnson-Cook damage model for ductile fracture is integrated into the nonlinear FEA, which enables the visualization of stress distribution, potential failure modes, and associated failure mechanisms. This analysis enables an improved design.

This work presents two cases studies demonstrating the effectiveness of this numerical method in tool design for the energy industry. The first study involves the design of a 6061-T6 aluminum shear pin. FEA predicted a shear value below the target load and this prediction aligned closely with test data. FEA, confirmed with test results, recommended decreasing the shear pin's inner diameter to achieve the desired load. The second study investigated the design upgrade of a retention U-Clip. The Johnson-Cook plasticity and damage model constants of 22Cr stainless steel were calibrated using material test data. FEA was validated against component test results from earlier designs, revealing the failure mechanism, and yielding identical failure load as the test. The validated FEA was used to optimize a new design for a higher failure load, meeting the upgraded operation conditions.

In summary, the synergistic application of damage mechanics, fracture mechanics, and FEA in product development provides a holistic understanding of material responses to real-world operating conditions. This approach reduces development time and costs by offering virtual insights into material behavior and failure modes, enabling more efficient and optimized product designs.

VISCOUS FLOW OF EVOLVING FILM WITH ARBITRARY SHAPE AND TOPOLOGY

Cuncheng Zhu[*1], Albert Chern[1] and David Saintillan[1]*

[1]*University of California, San Diego*

ABSTRACT

The dynamics of evolving fluid films in the viscous Stokes limit is relevant to various applications, such as the modeling of lipid bilayers in cells. While the governing equations were formulated by Scriven in 1960, solving for the flow of a deformable viscous surface with arbitrary shape and topology has remained a challenging task. In this study, we present a straightforward discrete model based on variational principles to address this long-standing problem. The contribution is two-fold. First, we replace the classical equations, which are expressed with tensor calculus in local coordinates, with a simple coordinate-free, differential-geometric formulation. This allows us to gain a fundamental understanding of the underlying mechanics. For a general embedded surface, the velocity field is a section of the pullback bundle from the tangent bundle of the ambient space via the embedding. Through the pullback connection, the strain rate tensor is derived from the derivative of the velocity field. This coodinate-free abstraction directly leads to a discretization for the strain rate tensor on discrete meshes. Second, we construct a discrete analogue of the system using the Onsager variational principle, which, in a smooth context, governs the flow of a viscous medium. According to this principle, the velocity of the viscous film minimizes a dissipation measure known as the Rayleighian, which is a function of the strain rate tensor. In the discrete setting, instead of term-wise discretizing the coordinate-based Stokes equations, we construct a discrete Rayleighian for the system and derive the discrete Stokes equation via the variational principle. This approach results in a standard linear saddle-point problem that can be efficiently solved using the augmented Lagrangian method.

A NEW FINITE ELEMENT METHOD FOR SIMULATING WAVE PROPAGATION ON GRAPHENE SHEETS

Jichun Li[1], Li Zhu[2] and Todd Arbogast[3]*

[1]University of Nevada Las Vegas
[2]Portland State University
[3]The University of Texas at Austin

ABSTRACT

This presentation introduces an innovative variational approach tailored for simulating the propagation of surface plasmon polaritons on graphene surfaces. The methodology treats graphene as a current-conducting thin sheet, employing an effective conductivity model. For the first time, a novel finite element time-domain method is proposed and analyzed specifically for solving this graphene model. The presentation includes rigorous demonstrations of discrete stability and error estimations for our method. Additionally, numerical findings are showcased to highlight the efficacy of this graphene-based model in accurately simulating the propagation of surface plasmon polaritons on graphene sheets.

A DAMAGE MODEL OF COUPLED SWELLING AND LOAD-INDUCED DEFORMATIONS IN DOUBLE-NETWORK HYDROGELS AND ITS APPLICAITON ON BUCKLING ANALYSIS

Pingping Zhu[*1] and Zheng Zhong*[1]

[1]*Harbin Institute of Technology*

ABSTRACT

Double-network (DN) hydrogels have attracted a most attention among various synthetic tough hydrogels. As high load-bearing candidates, the Mullins effect and buckling instability are two frequent phenomena that may occur simultaneously in slender DN hydrogel structures. The swelling/deswelling degree of the DN hydrogel affects the coupling phenomena. A deep understanding of the interplay between these behaviors is essential. We propose a physically based damage constitutive model for a DN polymer under water-diffusion equilibrium and cyclic loadings. By fitting the experimental data of a freely swollen DN hydrogel under cyclic compression, the model shows good capability in capturing the Mullins effect and the swelling ratio. Based on the damage constitutive model and determined parameters, we investigate the Mullin effect on the buckling instability of DN hydrogel beams. Via the analytical formula of incremental modulus, we depict the global stability diagrams of the virgin DN hydrogel beam and damaged DN hydrogel beams with five historically compressive stretches. The influences of stress softening, strain stiffening and chemical potential on buckling conditions for compressive stress and slenderness ratio are thoroughly analyzed. It is found that the stress softening is dramatically against the stability of the beam, but the strain-stiffening effect would conversely help widen the stable range. Besides, it sees that a DN gel beam immersed in a sufficient low chemical potential environment has better buckling stability. These theoretical results are valuable in the preparation and structural design of DN hydrogels for repeated use purpose.

DEVELOPMENT OF HIGH-STRENGTH WOODEN PALLETS UTILIZING LOCAL TIMBER FROM EHIME PREFECTURE

Xia Zhu[1], Akira Ochi[1], Tsubasa Kaneko[1], Daiki Ito[2] and Hiromichi Toyota[1]*

[1]Ehime University
[2]Ito Wood Co., Ltd.

ABSTRACT

In this study, we focus on developing a new pallet structure utilizing Hinoki and Sugi woods from Ehime Prefecture, aiming to achieve a strength comparable to that of the foreign Bay Pine. The main goal is to design a pallet that balances high strength and rigidity with cost-effectiveness. We conducted tests on single-sided, two-way entry flat pallets, conforming to the JIS 0604-1989 standard [1], using Bay Pine for the standard pallets and the local woods for the new design. The pallets measured 1100mm by 1100mm by 144mm and had a maximum load capacity of 2 tons. Through bending and compression tests adhering to JIS Z 0602 – 1988 standards [2], we assessed the strength and rigidity of both the conventional and new pallet types. Additionally, considering the anisotropy inherent in wood's structure [3], we performed a finite element analysis, incorporating custom calculation codes for elastoplastic analysis. This led to a proposed pallet structure that improved bending strength and rigidity, as well as leg compressive strength and rigidity, validated through pallet testing. The findings indicate that the new pallet design, leveraging local timber, is effective in terms of strength and cost, contributing to the advancement of regional forestry.

MACHINE-LEARNING-BASED ASYMPTOTIC HOMOGENISATION AND LOCALISATION AND DESIGN OF SPATIALLY-VARYING LATTICE CONFIGURATION

Yichao Zhu[*1]*

[1]*Dalian University of Technology*

ABSTRACT

In this talk, we introduce a general framework, with the use of traditional asymptotic homogenisation approaches and the emerging machine learning tools, for the (CAD-inspired) representation, (CAE-inspired) analysis and (CAD-CAE integrated) design of smoothly-varying lattice configurations. Asymptotic analysis serves to identify the expressions for key quantities of interest, such as the (nonlinear) overall compliance, the sites and the magnitude of the maximum tensile stress, etc., in a scale-separated manner. Machine learning method is employed to embody those implicit interrelationships that are confirmed with asymptotic analysis. A number of simulation examples will be presented to show the balanced accuracy and efficiency of the proposed method. The presentation concludes with mathematical analogy to generalise the method used for analysing the behaviour of other multiscale systems.

A FAST PARALLEL SOLVING METHOD FOR THERMAL CONDUCTION-POISSON EQUATIONS BASED ON FAST FOURIER TRANSFORM

Jiang Zichao[*1], Huang Bohua[1], Wang Zhuolin[1] and Yao Qinghe[1]*

[1]*Sun Yat-sen University*

ABSTRACT

In the field of incompressible fluid dynamics and numerical heat transfer, the solution of Poisson and thermal conduction equations is usually one of the computational bottlenecks. To address this issue, this study introduces an innovative solution algorithm based on Fast Fourier Transform (FFT). The core of this algorithm is a FFT-based approach coupled with a variable reordering strategy, which transforms the global Poisson and thermal conduction equations into a series of sub-equations with a uniform structure. This enables compatibility with parallel computing architectures and significantly reduces computational complexity. Furthermore, the study has developed transformation algorithms suitable for Dirichlet, Neumann, and periodic boundary conditions. Numerical results indicate that our proposed method, when dealing with three-dimensional problems on a million-grid scale, surpasses traditional iterative methods by achieving more than a hundredfold acceleration. Additionally, the algorithm has been employed for direct numerical simulations of complex incompressible fluid and heat transfer problems, including vortex ring interactions, demonstrating its extensive applicability and high efficiency in practical scenarios.

TRANSIENT RESPONSE OF MAGNETO-RHEOLOGICAL FLUIDS IN HIGH SHEAR RATE REGIME

Sanket Chougale[1] *and Andreas Zilian**[1]

[1]*University of Luxembourg*

ABSTRACT

Magnetic field-responsive fluids are functional materials whose rheological properties can be controlled by an external magnetic field. The magneto-rheological (MR) fluid consists of magnetically soft (magnetizable) micron-sized particles suspended in a low-viscosity base fluid. Without an external magnetic field, MR fluids behave as a Newtonian fluid. On the other hand, the applied magnetic field introduces a rapid and reversible transition of an MR fluid from a free-flowing state to a solid-like behavior.
Understanding the transient characteristics of MR fluids, particularly the hydrodynamic response time of the fluid, is integral to the design of MR dampers. However, there is a scarcity of studies in the literature examining the hydrodynamic response time of magnetorheological fluids (MRFs) and their correlation with fluid properties. The response time of MRFs depends on several factors, such as the magnitude of the applied magnetic field, the dimensions of an MR valve, or the corresponding shear rates of MRFs. Thus, in this work, we investigate the transient behavior of MR fluid for a wide range (very low to high) of shear rates based on advanced constitutive relations for continuum-based fluid models.
Computational fluid dynamics (CFD) analysis has been carried out, and the results indicate that the higher the Bingham number, the lower the hydrodynamic response time of MRF. However, this only applies to low to moderate shear rate regimes, as recently reported in the literature [1, 2]. In the high shear rate regime, for the first time, we report that the response of MR fluid becomes much faster below a critical Bingham number. The observed phenomenon can be described by considering the notion of dwell time [2]. When the dwell time decreases significantly, especially falling below the response time under conditions of high shear rates, the MRF doesn't exhibit resistance to flow as expected for an applied magnetic field but rather only partial resistance. Our analysis implies that one must consider the effect of the dwell time on the response of MR fluid while designing an MR damper dealing with high velocities.

DEEP LEARNING ASSISTED MONITORING INVERSION MODEL FOR GEOLOGIC CARBON SEQUESTRATION

Jonathan Zingaro[*1], Robert Gracie[1] and Yuri Leonenko[1]*

[1]University of Waterloo

ABSTRACT

Geophysical monitoring is an important risk mitigation strategy used to assess the integrity of the subsurface during Carbon Sequestration injection and storage operations. There is a desire to assimilate various sparse geophysical measurements to achieve detailed and high-resolution monitoring of reservoirs. Traditional optimization and stochastic-based methods have been recognized as severely ill-posed and extremely computationally intensive, where real-time simulations are not possible. This work presents a robust deep learning-based inversion approach to model the time-dependent nature of predicting the saturation and pressure fields in the subsurface during CO2 injection and storage operations. This work employs a state-of-the-art, transformer-based deep learning architecture. This architecture utilizes the self-attention mechanism, which effectively learns the long-term dependencies of sequential data without the computational inefficiencies of recurrent hidden layers in Recurrent Neural Networks (RNNs) architectures. The training regime is generated through several high-fidelity simulations using a Finite Element-based quasi-3D vertically averaged multiphase flow simulation combined with a surface uplift geomechanical elasticity model. Multi-Gaussian porosity and permeability fields, varying injection schedules, and heterogeneity in the reservoir characterize the training regime. The performance of the proposed deep learning-assisted inversion model is demonstrated through a problem with highly heterogeneous subsurface permeability and porosity fields. The results show that the transformer-based architecture can accurately and computationally efficiently capture the long-term behaviour for high-dimensional inputs and outputs of nonlinear dynamical systems through the self-attention mechanism.

MULTIPHYSICS MODELING OF PROCESS–STRUCTURE–PROPERTY RELATIONSHIPS IN METAL 3D PRINTING

Aleksandr Zinoviev[1] and Olga Zinovieva*[1]

[1]*University of New South Wales*

ABSTRACT

Enhancing properties of additively manufactured materials requires a comprehensive understanding of AM process-(micro)structure-property (PSP) relationships, which is currently limited. This calls for the development of tools that facilitate deepening this understanding and will support efficient materials engineering for AM.
In response, we have developed the computational suite of robust multi-physics models to support AM PSP research by enhancing the prediction capabilities in this space. This includes melt-pool-scale thermal simulations of metal AM, using the finite difference method, cellular automata simulations to describe the microstructure evolution during printing [1], micromechanical crystal-plasticity-based simulations with finite elements describe the mechanical behaviour of additively manufactured materials as well as the analytical approach to quickly estimate elastic properties of larger volumes [2]. The models have been validated experimentally.
This presentation covers the results of PSP modelling for alloys fabricated by laser powder bed fusion (mostly) and touches upon direct energy deposition. Effects of some process parameters on the microstructure and mechanical behaviour of AM metallic materials are analysed. High performance computing process-structure simulations are discussed. The integrative computational approach not only advances our understanding of AM but also enhances our ability to predict and control the properties of manufactured materials, addressing key barriers to the broader application of AM technologies.

EFFECT OF THE CAPILLARY FORCE ON THE REPOSE ANGLE OF GRANULAR MATERIALS

Wang Ziye[*1] and Tan Yong*[1]

[1]*TongJi University*

ABSTRACT

The angle of repose does affect the behavior of granular materials and has a wide range of applications. The addition of a small amount of liquid can dramatically change the properties of granular media, leading to an increase in the repose angle. This change is mainly attributed to the capillary force resulting from the liquid bridge when the small amount of water was introduced. The capillary force as an attractive force increases the interaction between particles and becomes a dominant factor affecting the angle of repose because it is usually stronger than gravity. In this paper, a new discrete element method (DEM) model was developed in which the capillary force was calculated by the liquid bridge model based on "toroidal approximation"[1]. The developed DEM model linked the microscopic liquid bridge volume to the macroscopic water content and it also considered the effect of liquid bridge breakage and formation on capillary force. The numerical model was first validated by comparing the experimental and numerical results. Then, the effects of surface tension, volume of the liquid bridge, and the contact angle are studied numerically. Finally, the empirical equation between water content and angle of repose is given under the present simulation conditions. This work will provide a deep understanding for the effect of capillary on the angle of repose.

STRUCTURE AND NUMERICAL SOLUTION OF A THERMAL PROBLEM WITH IMPOSED INTERNAL CONDITIONS

Sergio Zlotnik[*12], Mariano Tomás Fernández[12] and Pedro Diez[1]*

[1]*Universitat Politecnica de Catalunya*
[2]*Centre Internacional de Mètodes Numèrics en Enginyeria, CIMNE*

ABSTRACT

Undestanding the current state of Earth requires the knowledge of the location of several interfaces. One the the main ones is the Lithosphere-Asthenosphere Boundary (LAB). This is done via multibservable inversion schemes. One of the key fields to determine is the temperature. It affects almost all the other physical quantities involved (e.g. densities, viscosities, wave propagation velocities, among others).
The LAB affects most of the processes and properties in the Earth structure. Determining its location is one of the goals the inversions. The LAB is usually defined as an isotherm.
The need of determining the thermal field in accordance with a given LAB location leads to a mathematical problem with imposed interior conditions. In particular, the isotherm defining the LAB has to be located in the position tested by the inverse solver.
Here we analyze the mathematical structure of a thermal problem with known interior conditions and then propose several numerical procedures to solve it. The proposed methods are tailored to the geophysical case and are based on the certainty of the different boundary conditions that are imposed in the model. Moreover, because this thermal solver is expected to be used many times within an inverse scheme, we want the numerical mesh to be fixed. The LAB, therefore, will not fit the mesh.

TOWARDS ZERO-POWER SPEECH RECOGNITION: IMPLEMENTING MACHINE-LEARNING MODELS IN MECHANICAL STRUCTURES

Saeed Zohoori[*1], Finn Bohte[1], Théophile Louvet[1], Sima Zahedi Fard[1] and Marc Serra Garcia[1]*

[1]AMOLF

ABSTRACT

Elastic metamaterials, with their minimal energy dissipation during vibration, present a promising solution for ultra-low-power applications like the Internet of Things. However, taking advantage of these unique properties to do information processing tasks (for example, speech recognition for command detection) is a challenging computational design problem. In this talk, I will describe our results regarding the development of a mechanical resonator network capable of performing speech recognition. The design approach we have chosen is based on a proven speech recognition architecture. In our model, a support vector machine (SVM) operates on a set of features obtained from calculating the energy content across various frequency bands. We employ a multi-step procedure to transfer this model into the mechanical domain. First, the model is mapped to a lumped, nonlinear mass-spring model, which is then translated to a device geometry in a second step. A comparison of the mass-spring model to standard benchmarks for few-word classification reveals that, in addition to delivering comparable accuracies to electronic speech recognition implementations, it reduces energy consumption by multiple orders of magnitude.
The mass-spring model is optimized by using adjoint back-propagation in time and then mapped to a geometry by implementing each degree of freedom using structural modes from drums, strings, and cantilever resonators. We subject these components to finite element simulations, optimizing them to exhibit the required dynamic characteristics as designed in the abstract model. Creating neural networks involves thousands of components, which makes simulations and optimizations time-consuming. To overcome this challenge, we use sub-structuring techniques to reduce the size of mass, stiffness, and damping matrices, replacing some of the degrees of freedom in the FEM model with normal modes. We then apply adjoint-based optimization methods to identify the geometric parameters that are most conducive to word classification accuracy.

STABILITY AND CRACK NUCLEATION IN VARIATIONAL PHASE-FIELD MODELS OF FRACTURE: EFFECT OF LENGTH-SCALES AND MULTI-AXIALITY

Camilla Zolesi[*1] and Corrado Maurini*[1]

[1]*Sorbonne Université*

ABSTRACT

Phase-field model for brittle fracture is widely used due to its ability to reproduce complex crack patterns, without ad hoc criteria, and to deal with the behavior of crack formation under tensile loading. However, crack nucleation under multi-axial stress states in phase-field model remains a subject of discussion with several unresolved issues. Among these, we identify the inability to flexibly set the crack nucleation criterion under multi-axial stress states and the difficulty in modeling crack nucleation in materials close to the incompressibility limit. In this contribution, we focus on the evolution of a special class of phase-field models with linear softening [1] in order to overcome the aforementioned limitations. These models provide increased flexibility in adjusting the crack nucleation criterion by allowing the use of different softening laws on the volumetric and deviatoric components of the strain energy density. However, the choice of the softening law has an impact on crack nucleation and reveals the length-scales which influence the stability of the solution. Therefore, we conduct a theoretical and numerical stability analysis, inspired by the work of [2-3]. Through this stability analysis, we establish the limitations of this model in describing crack nucleation in nearly inextensible bars (the 1D version of almost incompressible materials) and under multi-axial stress states and we explain the connection between fracture nucleation and the competition between stored elastic energy and fracture energy.

A LAYERED SOLID FINITE ELEMENT FORMULATION WITH INTERLAMINAR ENHANCED DISPLACEMENTS FOR THE MODELING OF LAMINATED COMPOSITE STRUCTURES

Miklos Zoller[*1] and Brian Giffin*[2]

[1]*Lawrence Livermore National Laboratory*
[2]*Oklahoma State University*

ABSTRACT

Laminated composite materials are widely used in many engineering industries today ranging from aerospace applications, fuel storage pressure vessels, automotives, etc. Their increased usage has motivated the need for improved finite element modeling capabilities to aid in the design and assessment of composite structures. Current modeling approaches for layered composite materials range from homogenized material models in the form of an effective continuum-level anisotropic material model, to finely discretized mutli-scale models wherein each of the individual material plies are discretized at the micro/mesoscale level. Both approaches are subject to different limitations: homogenized material models do not explicitly consider the behavior of individual plies, whereas multi-scale modeling approaches may incur prohibitively high computational costs.

To address the limitations of both ranges of modeling granularity, an 8-node layered solid hexahedral finite element is formulated with the aim of striking an appropriate balance between efficiency and fidelity. The element may be discretized into an arbitrary number of material layers and employs a reduced in-plane integration scheme in each layer for computational efficiency along with supplementary physical stabilization based upon the stabilization scheme of Puso [1]. While many existing solid shell formulations similarly adopt physical stabilization with reduced in-plane integration, the novelty of the proposed approach lies in its use of layerwise enhancements to accurately represent the stabilizing material stiffness contributions from each layer and eliminate various forms of locking phenomena. Additionally, the chosen framework supports the inclusion of interlaminar enhanced displacements to enforce continuity of interlaminar tractions and further reduce locking behavior in general layered composites. The element has been implemented in the ParaDyn finite clement code [2], and its efficacy for modeling laminated composite structures has been demonstrated on a variety of verification problems.

SINDY-RL: INTERPRETABLE AND EFFICIENT REINFORCEMENT LEARNING

Nicholas Zolman[*1], Urban Fasel[2], Nathan Kutz[1] and Steven Brunton[1]*

[1]*University of Washington*
[2]*Imperial College London*

ABSTRACT

Deep Reinforcement Learning (DRL) has shown significant promise for uncovering sophisticated control policies that interact in environments with complicated dynamics, such as stabilizing the magnetohydrodynamics of a tokamak reactor and minimizing the drag force exerted on an object in a fluid flow. However, these algorithms require many training examples and can become prohibitively expensive for many applications. In addition, the reliance on deep neural networks results in an uninterpretable, black-box policy that may be too computationally challenging to use with certain embedded systems. Recent advances in sparse dictionary learning, such as the Sparse Identification of Nonlinear Dynamics (SINDy), have shown to be a promising method for creating efficient and interpretable data-driven models in the low-data regime. In this work, we extend ideas from the SINDy literature to introduce a unifying framework for combining sparse dictionary learning and DRL to create efficient, interpretable, and trustworthy representations of the dynamics model, reward function, and control policy. We demonstrate the effectiveness of our approaches on benchmark control environments and challenging fluids problems, achieving comparable performance to state-of-the-art DRL algorithms using significantly fewer interactions in the environment and an interpretable control policy orders of magnitude smaller than a deep neural network policy.

[2]*Cape Panensula University of Technology*

ABSTRACT

The Stockbridge vibration damper is significantly used in overhead transmission lines to mitigate Aeolian vibration. Aeolian vibrations refer to the oscillations of conductor cables within the frequency range of 3–150 Hz. The effectiveness of the Stockbridge damper is characterized by the number of resonant frequencies. Unlike the basic Stockbridge damper, which features only two resonant frequencies, the asymmetric Stockbridge damper demonstrates the capability to exhibit up to four resonant frequencies. Previous numerical simulations and parametric studies have established a correlation between the increase in natural frequencies and alterations in the counterweight's geometry. In this paper experiments have been conducted on the modified asymmetric damper and an analytical model has been developed. This paper confirms the research that was done by Vaja, Barry, and Tanbour.

COARSE-GRAINED MOLECULAR DYNAMICS SIMULATION OF HYDROGEL MICROSTRUCTURES

Ting Zong[*1], Xin Wang[1] and Xia Liu[1]*

[1]*Beijing University of Technology*

ABSTRACT

Hydrogels are composed of cross-linked polymer network wrapped with a large amount of water. It has large deformation, strong toughness, and are currently attracted considerable attention owing to their unique mechanical properties. The microstructure and dissipation mechanism of polymer networks in hydrogels are the basis for their desired properties. Hence, we proposed a practical and efficient data-inspired method for coarse-grained molecular dynamics model with greatly simulation efficiency compared to all-atom molecular dynamics simulation. Furthermore, the correlation between copolymer ion gel components and macroscopic properties was established to explore the relationship between microstructure and tensile properties. We observed and analyzed the viscoelasticity by the coarse-grained hydrogel models with extensive dissipation mechanisms and by uniaxial elongation simulations. The coarse-grained molecular dynamic simulation of hydrogels successfully described the microstructure of hydrogels, explored the strength mechanism of hydrogels, reduced the difficulty of constructing multi-scale models, and expanded the intelligent application of hydrogels.

REDUCED-ORDER MODELING OF UNSTEADY CONVECTION-DOMINATED PROBLEMS BY IMPLICIT FEATURE TRACKING

Victor Zucatti[*1] and Matthew Zahr*[1]

[1]*University of Notre Dame*

ABSTRACT

For convection-dominated problems, failure to build accurate reduced-order models (ROMs) has been mainly attributed to the slowly decaying Kolmogorov n-width of linear subspace approximations. This is also sometimes referred to as Kolmogorov barrier because the error slowly decaying with the dimension of the reduced space limits the achievable accuracy of ROMs in practice and requires a substantial amount of training data, which can be infeasible to collect offline. In this work we propose an arbitrary Lagrangian-Eulerian approach that improves the accuracy of time-dependent conservation laws by implicitly aligning the solutions in the computational domain. The mapping between the fixed (computational) geometry and the physical space are given by Lagrange interpolation functions computed by solving an optimization problem that minimizes the residual. Afterwards, the resulting state solutions and mappings obtained are used in the following to generate projection-based ROMs with improved predictive capabilities. The approach is tested and validated on different convection-dominated problems.

IMMERSED TECHNIQUES FOR SIMULATING FLOW AND TRANSPORT IN FRACTURED POROUS MEDIA

ABSTRACT

The ever-increasing computational power of modern supercomputers enables the numerical simulation of complex and coupled large-scale multiphysics problems, e.g., arising from fluid-structure interaction, or geometrically complex interactions, e.g., in contact mechanics. Common to these coupled and complex problems is the need to transfer data or information between the different models, meshes, or approximation spaces. The transfer of discrete fields, such as stresses, pressure, displacements, or velocities, might be required along surfaces or within volumes. Variational transfer techniques might also play an essential role at the level of the discretization, e.g., within non-conforming domain decomposition or mortar methods for the transfer along surfaces, or on the level of the solution method, e.g., within multigrid or multi-level methods for the transfer between different volume meshes. This talk introduces our parallel variational transfer technique and its application to flow and transport in fractured porous media.

AN EXTENSIVE THERMAL AND STRESS ANALYSIS OF RAILWAY WHEEL-RAIL CONTACT DURING HEAVY BRAKING WITH DISC BRAKE

*Peter T. Zwierczyk**[1]

[1]*Budapest University of Technology and Economics*

ABSTRACT

Railways have become increasingly popular as safe and less polluting forms of traffic both in short and long distances and in passenger and freight transports. More and more new safety features, like the anti-slip WSP - Wheel Slide Protection System, are in service with their development. Still, these developments sometimes cause undesired effects, such as micro-thermal wheel tread cracks [1].

During intensive wheel-braking of railway vehicles equipped with disk brakes, the wheel slides on the rail. While the macroscopic sliding speed is restricted, it is not excluded by the WSP. There is a remarkable heat generation through the frictional sliding process between the parts in contact. This heat may cause micro-cracks on and under the wheel tread.
In earlier publications [2] [3], the modeling method was presented using ANSYS, which provided the opportunity to examine and understand the background of this phenomenon using numerical calculations. Furthermore, using an extended FE model, the effect of the different operation conditions (movement speed, different coefficient of friction, etc.) and the coupled effect of the micro-cracks and the subsurface fatigue cracks could be observed [3].

In the current state of the research, the modeling method was adopted for different vehicles (contact geometries, loading conditions) and operating conditions (such as winter or summer using different frictional environments). These extended analyses provided the opportunity to create widespread trends that show the possible micro-cracking in the function of several operating factors (different frictional environments). The results of these coupled transient thermal and elastic-plastic frictional contact and further crack FE simulations provide the opportunity to understand the limits of these WSP systems. It can help minimize the failures of the wheels and the rail using an appropriate setup of this safety feature.

FLUID-STRUCTURE INTERACTION SIMULATIONS OF NUCLEAR POWER PLANT STEAM GENERATOR TUBES INVOLVING CONTACT

Kevin Zwijsen[*1]*

[1]*Nuclear Research & Consultancy Group*

ABSTRACT

In the evolving landscape of nuclear energy, ensuring the safety and efficiency of nuclear reactors remains paramount, particularly with the increasing demands for energy and a concurrent rise in global temperatures. A significant aspect of nuclear safety and efficiency involves maintaining the structural integrity of the nuclear steam supply system (NSSS). In particular, key NSSS components such as fuel assemblies (FA) or steam generator (SG) tubes are susceptible to flow-induced vibrations (FIV) resulting from the turbulent flow of the coolant. FIV can instigate severe repercussions, including structural damage such as fatigue and wear, caused by the repetitive oscillatory motion of these components and the rubbing or sliding contact between them and surrounding parts. In particular, grid-to-rod-fretting wear (GTRFW) resulting from such vibrations is the cause of 58% of fuel failures in pressurized water reactors [1].

Despite the attention FIV of FA and SG tubes has garnered since the 1950s, conventional semi-empirical methods offer limited predictive accuracy and do not facilitate extrapolations for multi-rod scenarios effectively, while experiments are complex and complicated to perform, not in the last place due to the harsh environment. With the increased computational power available today, numerical methods are more frequently used to estimate the tubes' displacements. The used methods and models have increased in complexity in time, and are generally quite well able to predict the vibration frequency and, to a lesser extent, the amplitude of displacement of the moving tubes. However, they seldomly involve contact between neighboring tubes or between tubes and the fixed surroundings, while this contact causes the wear leading to structural degradation and eventual failure of the component. Such contact also has a significant effect on the vibrational frequency [2].

The current presentation shows initial work done on performing Fluid-Structure Interaction simulations involving contact, using the commercial software Simcenter STAR-CCM+. The case under consideration is that of a cylinder subjected to cross-flow, representative of the U-bend area of a SG tube, the area of most concern for FIV of SG tubes in nuclear power plants. Amongst others, the influence of the inflow velocity and material properties are studied on the observed vibration behavior and resulting contact.
