A FINITE DEFORMATION MICROPOLAR PERIDYNAMIC THEORY AND ITS APPLICATION TO METAMATERIALS

Sajal -[1] and Pranesh Roy*[1]

[1]*Indian institute of Technology (ISM) Dhanbad*

ABSTRACT

Metamaterials with engineered microstructures exhibit exceptional properties such as negative Poisson's ratio, energy absorption, and bandgap. Metamaterials find applications in mechanical filter, vibration isolators, biosensor etc. These materials can prevent propagation of elastic waves in certain range of frequency called bandgap. Researchers have developed various novel unit cell configurations to absorb elastic energy and create frequency bandgap. Golub et al. [1] observed that cracks act as reflectors of elastic waves. The microstructure of these materials affects the overall response of the structures. Microstructures may undergo large rotations and their rotary inertia needs to be considered along with deformation. Micropolar continuum theory is developed to address this issue that considers microrotation independent of displacement degree of freedom. The micropolar continuum considers the effect of microstructure by defining the micro-rotation at every material points. However, it is not suitable to analyze the discontinuities as it involves partial differential governing equations. Peridynamics (PD), a nonlocal continuum theory, has integro-differential governing equations which can handle the discontinuities in the structure. As the metamaterials in the study involve cracks, we developed a finite deformation micropolar PD theory to analyze their response. We proved the variational consistency of the wryness measure in an alternative way than the one proposed by Pietraszkiewicz and Eremeyev [2]. A new bond breaking criterion is introduced that uses critical stretch and critical relative rotation. The proposed PD micropolar theory is validated by comparing the results obtained from the boundary element solutions of plate with hole. The response of metamaterials with periodic arrangement of holes and cracks is studied under static and dynamic loads and the results are compared with the nonpolar PD theory.

COMPUTATIONAL APPROACH TO NON-INVASIVELY ASSESS VELOCITY IN ARTERIES FROM CT PERFUSION IMAGING

Anahita Abbasnejad Seresti[1] and Muhammad Owais Khan*[1]

[1]*Toronto Metropolitan University*

ABSTRACT

Introduction
Coronary computed tomography angiography (cCTA) can provide detailed anatomical visualizations of the coronary vasculature to detect diseased coronary arteries (heart vessels). However, not all disease coronary arteries limit blood flow to the heart muscles and thus over-treatment, either with stenting or heart surgery, is common. For targeted treatment, it is necessary to develop methods that can non-invasively detect coronary hemodynamics. One approach to measure blood flow is through CT perfusion imaging, which has conventionally been applied to measure blood flow in the myocardium, but can potentially be used to measure coronary blood flow [1], [2]. Towards this goal, we have developed a computational framework to assess velocity from simulation of contrast perfusion under a range of flow conditions (laminar and quasi-turbulent).

Methods
High-resolution CFD simulations were performed in an idealized, non-axisymmetric stenosis with 75% area reduction. Reynolds number was varied from 100 to 1000 (increment=100) to capture both laminar and turbulent flow regimes. The eccentricity in the stenosis served to destabilize the flow. Advection-diffusion equation was solved with a contrast-bolus curve to simulate the perfusion of contrast into the vessel. Since CT perfusion imaging suffers from coarse spatial resolution and noise, especially near lumen boundaries, it is challenging to estimate the complete three-dimensional velocity field from contrast perfusion. Hence, we assumed unidirectional flow with minimal radial dispersion of contrast to estimate average velocity across the lumen using the following relation: $V=(dC/dt)/(dC/dx)$, where V, C, t and x represent lumen velocity, contrast, time and axial location.

Results
estimated velocity was compared to the assigned mean velocity in the CFD simulations. Error ranged from 0.1 to 9.25 % in the mean velocity for different Reynolds numbers. The contrast transit delay ranged from 46 to 65% of the simulation run-time. The correlation coefficient for estimated velocity vs. calculated velocity was 0.999 and the correlation coefficient between estimated velocity and transit delay is -0.9305.

Discussion and Conclusion
Despite flow-regime dependent errors, our study demonstrates the feasibility of estimating lumen velocity using contrast perfusion imaging. Notably, estimated velocities closely mirror CFD simulations at all Reynolds numbers (errors < 10%). Furthermore, higher Reynolds numbers exhibit shorter simulation times and lower relative errors. This agreement across diverse flow conditions underlines the robustness of our method.

CONVOLUTIONAL VARIATIONAL PHYSICS-INFORMED NEURAL NETWORKS TO SOLVE A FINITE ELEMENT FORMULATION

Mohammed Abda[*1], Elsa Piollet[2], Christopher Blake[2] and Frederick Gosselin[1]*

[1]*Polytechnique Montréal*
[2]*Maya HTT*

ABSTRACT

We propose an extension to physics-informed neural networks (PINN) in which the outputs of the network are used to approximate the weak-form residuals of time-dependent partial differential equations (PDE) using convolution operations. PINNs are machine-learning methods that leverage the physics expressed in the PDEs to extract information from high-dimensional data generated through experiments. They received considerable attention in the literature due to their approximation capabilities and effectiveness in solving forward and inverse linear and nonlinear PDEs. Resembling the finite elements method (FEM), the current variational physics-informed neural networks (hp-VPINN) formulate the solution based on domain decomposition and projection onto space of high-order polynomials allowing the network to construct both global and local approximations. The weak-form residuals of the equations of each sub-domain are then approximated using the Gauss quadrature rule sequentially, where the network is trained to minimize those residuals. However, the computation cost of the current hp-VPINN escalates drastically when the domain is discretized into a few sub-domains, not to mention many subdomains. This limits the ability of hp-VPINN to approximate the solutions when dealing with complex problems requiring many elements or sub-domains. Using convolution operations to evaluate the Gauss quadrature sum allows for parallelization in evaluating the weak-form residuals of the sub-domains which significantly improves the computation efficiency. By incorporating customized test functions and the integral weights within the convolution filters and multiplying them across the network outputs to evaluate the weak-form residuals, we demonstrate that convolutional PINNs achieve three orders of magnitude higher precision in predictions than PINNs. Furthermore, they converge nine times faster than hp-VPINN when solving the one-dimensional wave equation. We also show that this extension enables us to use smaller-sized networks, which further improves the computation speed. In addition, we illustrate the efficacy of the convolution PINN in solving inverse problems related to the one-dimensional wave equation and the linear pipe conveying fluid equation. Ultimately, we plan to extend the application of convolution PINN to higher dimensional problems for both the two-dimensional wave equation and the three-dimensional nonlinear pipe conveying equations. This formulation blurs the line between the conventional finite element method and AI methods as it makes use of neural networks to solve an FEM formulation.

PREDICTION OF THE FAILURE BEHAVIOR OF PSEUDO-DUCTILE COMPOSITES USING A MICRO-MECHANICAL FINITE ELEMENT MODEL

Sayyed Behzad Abdellahi[*1], Fatemeh Azhari[1] and Phu Nguyen[1]*

[1]*Monash University*

ABSTRACT

The hybridization technique has recently been used to produce a new generation of composites called pseudo-ductile composites, which have shown higher failure strain compared to conventional composites, minimizing the risks of the occurrence of a catastrophic failure. The pseudo-ductility behavior in these composites is obtained by hybridization of fibers with high and low failure strains.
In this study, a micro-mechanical finite element (FE) model is proposed to predict the failure behavior of pseudo-ductile composites with conventional thickness. A representative volume element (RVE), consisting of randomly distributed fibers, was generated using a Python code. Mechanical properties, including elastic and failure constants, were assigned to the fibers and matrix. To account for fiber failure and ply fragmentation, the tensile strength of fibers was distributed based on the Weibull distribution function. Tensile loading was then applied to the RVE to simulate the composite's mechanical behavior using FE analysis.

To validate the numerical model, an RVE was developed based on the experimental data obtained from a recent research on conventional thickness composites. The numerical results were compared to the experimental data, showing acceptable agreement.

The effect of fiber volume fraction in the low-strain ply on the tensile mechanical properties of pseudo-ductile composites was investigated. In addition, the influence of the Weibull modulus on the composite's mechanical behavior was evaluated through a sensitivity analysis. Lower Weibull modulus values resulted in linear behavior, while higher values yielded nonlinear stress-strain curves. Notably, high Weibull modulus values exhibited a sudden stress drop, indicative of diminished pseudo-ductile behavior.

Overall, this research provides valuable insights into the prediction and analysis of the tensile mechanical response of pseudo-ductile composites. The proposed numerical model showcases promising agreement with experimental results, validating its efficacy. Understanding the impact of fiber volume fraction and Weibull modulus contributes to the optimization and design of these composites, facilitating their implementation in various applications.

ABSTRACT

Finite linear viscoelastic or quasi-linear viscoelastic models are commonly used to model the constitutive behavior of polymeric materials [1]. However, these models' limitations in accurately describing nonlinear viscoelastic phenomena, particularly in capturing strain-dependent viscous behavior, motivate the development of alternative methodologies. In response to this issue, we introduce viscoelastic Constitutive Artificial Neural Networks (vCANNs) [2], a novel physics-informed machine learning framework. vCANNs rely on the concept of generalized Maxwell models with nonlinear strain (rate)-dependent properties represented by neural networks. With their flexibility, vCANNs can automatically identify accurate and sparse constitutive models for a broad spectrum of materials. To assess the capabilities of vCANNs, extensive training was conducted using stress-strain data from synthetic and biological materials subjected to diverse loading conditions, e.g., relaxation tests, cyclic tension-compression tests, and blast loads. The results show that vCANNs can learn to accurately and efficiently represent the behavior of these materials without human guidance. We showcase the seamless integration of vCANNs into existing finite element codes through illustrative examples. This integration underscores the practical applicability of vCANNs in applied mechanics.

MODELING AND SIMULATION OF THERMAL DEGRADATION IN A COMPOSITE MATERIAL SUBJECTED TO HEAT FLUX

Mhadji Abdoussalam[*1], Damien Halm[1], Azdine Nait-Ali[1] and Benjamin Batiot[2]*

ABSTRACT

Keywords: Composite materials, microstructure, pyrolysis, thermal degradation, interface, coupling, gradient-based model, phase field

Composite materials are widely used in structures where weight reduction is crucial while maintaining high stiffness and strength properties. Under strong thermal stress, these materials degrade and alter their physical properties [1]. In order to understand and enhance the fire behavior of these materials, the objective of this study is to establish a numerical model at microstructure scale to simulate the thermal degradation (pyrolysis decomposition) of a composite material subjected to a heat flux. A rigorous thermodynamic approach with internal variables has been adopted to better capture the phenomenon under study. In the literature, the models used to describe this degradation generally do not take into account the influence of microstructural heterogeneity on the decomposition rate, on the degradation kinetics and, consequently, on the propagation of the thermal front decomposition. To consider the variability of the composite microstructure, simulations at the microscale were conducted, involving a strong coupling between the evolution of the thermal degradation rate (which follows an Arrhenius law) and the temperature evolution using the phase-field method. This method is suitable for simulating phase transition phenomena and interface motion in a non-homogeneous material [2][3]. This approach introduces a degradation gradient term to characterize the interface energy between degraded and sound regions, allowing the influence of microstructural fluctuations to be considered.
Experimental tests were conducted to identify the input parameters of the model and to validate it. Firstly, observations using an optical microscope are carried out to reconstruct the microstructure, which is essential for a reliable simulation. Then, a post-processing is performed to delineate the distinct phases of the material. Secondly, characterization tests, such as thermogravimetric analysis (TGA), have been conducted to identify model parameters. Finally, we carried out cone calorimeter tests to compare the results with the numerical simulations. This comparison focuses on the analysis of the degradation kinetics as well as the evolution of the mass loss.

DISCOVERY OF ASYMPTOTIC EXPANSIONS OF MECHANICAL PROBLEMS USING SYMBOLIC REGRESSION

Rasul Abdusalamov[*1], Julius Kaplunov[2] and Mikhail Itskov[1]*

[1]*RWTH Aachen University*
[2]*Keele University*

ABSTRACT

Asymptotic methods play an important role in a wide variety of physical problems, including the analysis of thin plates and shells, the solution of the Navier-Stokes equation, and the propagation of elastic waves in highly inhomogeneous structures, see, e.g., [1,2] and references therein. In many cases, it is challenging to identify the effect of small problem parameters and to derive their asymptotic expansions of the desired solution. Recently, data-driven methods such as symbolic regression have demonstrated their high efficiency in discovering equations and physical relationships [3].

This work proposes a new automatic method for generating asymptotic expansions based on symbolic regression. The goal is to find an asymptotic series in a form that fits the given analytical solution as closely as possible. Therefore, data is generated from analytical solutions for a chosen small or large parameter. First, a two-mass collision problem is discussed for three boundary scenarios. Subsequently, a divergent asymptotic series resulting from the implementation of a viscoelastic Kelvin-Voigt model is investigated. Finally, Lamb waves propagating in an elastic layer are studied. Good agreement between the asymptotic expansions obtained by symbolic regression and the underlying analytical solutions is demonstrated.

ABSTRACT

Ice accretion is the phenomenon that forms an ice layer when supercooled droplets impinge on a body and occurs in several situations in the industrial field. Particularly, icing on aircraft poses a threat to navigation safety because the ice layer can alter the airflow around the wing and deteriorate aerodynamic performance. Given that aircraft are equipped with anti- or de-icing systems to avert serious accidents, accurate prediction of aircraft icing is essential during the design phase of the systems. Despite extensive research, the methodology for the detailed icing simulation has not yet been established due to the challenges posed by multi-physics problems. In addition, under the conditions involving supercooled large droplet (SLD), where the diameter of droplets in the cloud exceeds 40 μm, the splashing and the rebounding of droplets generate secondary droplets. These factors contribute to the increased complexity of the ice shape and render the prediction of icing more challenging. This study suggests a pragmatic simulation approach to address the trade-off issue between high-resolution simulation and computational cost. We utilize a coupling scheme involving grid- and particle-based methods; the grid-based method is employed for computing the flow field and the droplet trajectory, while the particle-based method is utilized for determining the behavior of impinged droplets and the icing process. The particle-based method can reproduce the distinctive phenomena of SLD without relying on empirical models, as it facilitates the direct computation of droplets' impingement behavior. On the other hand, this method incurs significant computational costs when simulating large-scale phenomena with high spatial resolution. Therefore, we propose a method that reduces computational cost with accuracy. This approach minimizes the simulation cost, and the ice shape is extrapolated based on the increasing ice mass ratio. In the computation of the icing process, we accounted for both conductive heat transfer within the ice or water layer and convective heat transfer between the airflow and ice surface. To account for the change of the airflow by ice, we introduced a multi-shot simulation, updating the flow field and the droplet trajectories over time. Employing these methods, we performed a two-dimensional simulation of SLD icing on the NACA0012 airfoil. As a result, the computation for actual scale can describe a more complex ice shape, with the ice mass increasing due to heightened heat flux caused by convective heat transfer. The present method offers a more practical and precise simulation approach for addressing aircraft icing issues.

RATE DEPENDENCY OF INTERFACIAL AND BULK FRACTURE MODELS

Reza Abedi[*1], Giang Huynh[1], Alireza Amirkhizi[2], Colin Furey[3], Farhad Pourkamali-Anaraki[3] and Christopher Hansen[2]*

[1]*University of Tennessee*

[3]*University of Colorado Denver*

ABSTRACT

We will examine the rate dependency of several fracture models from two perspectives: 1) The form of differential equation and damage driving force, especially the temporal derivatives of the equation; 2) Instabilities that arise as damage localizes in 1D to 3D problems. For the first aspect, we present elliptic, parabolic, and hyperbolic forms of a phase field formulation. In a so-called 0D model, we assume that the solution fields do not vary in space. We then demonstrate that maximum stress and fracture energy of the elliptic model are rate-independent. The parabolic and hyperbolic models are both rate-dependent with the difference that the hyperbolic model exhibits a higher sensitivity. We also relate this work to other differential equations that arise in fracture namely bulk and continuum damage models. Using the asymptotic expansion method, we demonstrate that the form of the damage driving function also influences the extent of rate dependency. For example, energy-based models exhibit a lower rate-sensitivity than effective stress-based models.

For the second aspect, i.e. rate-dependency arising from damage localization, we show such effect exists even for the rate-independent 0D model; that is, for the elliptic PDE. We compare the responses of 1D and 0D models as well as hyperbolic / elliptic differential equations with the elliptic equation in 1D. For these 1D fracture simulations, we also examine the effect of material heterogeneities on macroscopic Quantities of Interest (QoIs) such as maximum stress, dissipated energy, and fragment statistics. Finally, we will present machine learning models that are trained to predict these QoIs from key loading and nondimensional material parameters, as well as a low dimensional representation of the underlying heterogeneous material property field.

NATURAL FREQUENCY AND DISPERSION ANALYSIS OF CONTINUOUS AND DISCONTINUOUS GALERKIN METHODS FOR 1D WAVE EQUATION

Erdem Caliskan[1], Ali Heidari Shirazi[1], Ershadul Haque[1] and Reza Abedi[1]*

[1]University of Tennessee, Knoxville

ABSTRACT

This study presents a comparison of the dispersion and dissipation of various 1D finite element formulations for the wave equation. The study includes continuous finite elements (CFEM), Symmetric Interior Penalty Galerkin (SIPG), Nonsymmetric Interior Penalty Galerkin (NIPG), and Incomplete Interior Penalty Galerkin (IIPG) methods. For the Discontinuous Galerkin (DG) methods, three different weak formulations with different primary fields have been considered: displacement, velocity, and two fields simultaneously. In addition, the calculation of the numerical flux is conducted with Reimann, central, and alternating methods. The eigenvalue problem of the free vibration is used for the dispersion analysis using the duality principle [1]. Spectral analysis has been conducted for different polynomial orders and penalty values. The results indicate that the penalty values for the central flux approximation have an optimal value for both primary fields, and the central method provides more accurate results than the Reimann solver when that optimal value is used for the penalty. In addition, DG formulations can have better approximations than the CFEM, depending on the penalty values. Overall, for all the formulations that are considered, increasing the polynomial order also decreases the error. Even though there are some trends observed when changing the penalty values or the polynomial order, the accuracy of a given method highly depends on the wave number, and different methods can have different performances depending on the considered spectral window.

DYNAMIC VIBRATION ABSORBER WITH HYDRAULIC AMPLIFIER AND MECHANICAL INERTER: A NOVEL APPROACH

Mohamed Abido[*1]

[1]*King Fahd University of Petroleum and Minerals*

ABSTRACT

To enhance the performance of the Dynamic Vibration Absorber (DVA) amplification mechanism is proposed to overcome the limitations associated with the mass ratio in passive DVAs with a mechanical inerter which enhances the damping. Traditional lever amplification mechanisms encounter challenges with length ratio and rigidity, especially in large-scale systems. The novelty of the proposed system lies in integrating a DVA with a Hydraulic Amplifier (HA) and a mechanical inerter, exploring various configurations. Additionally, piezoelectric elements for energy harvesting is incorporated. The main issue encountered with HA is fluid friction loss, which is inversely proportional to the diameter of the HA. However, increasing the diameter also escalates weight and cost. To address this, Differential Evolution (DE) optimization to minimize friction loss and pipe weight is developed and implemented. Using a large dataset from optimization runs, an Artificial neural network (ANN) to predict optimal HA dimensions is trained, tested, and validated. Further optimization aims to minimize vibration while maximizing output voltage, using Multi-objective Weighted Sum Particle Swarm Optimization (PSO) and Genetic Algorithm (GA). Our findings indicate that the amplification process not only enhances damping but also broadens the frequency band. PSO solutions generally outperform GA solutions in terms of diversity and quality, although we observe fluctuations in PSO solutions' stability compared to GA solutions under corresponding weight settings.
The proposed model of the DVA with HA and mechanical inerter successfully compensates for the limitation of the mass ratio required to increase the damping and it increases the working frequency band of the DVA. Multi-objective optimization using PSO generally outperforming GA in diversity and quality, although fluctuations in stability have been observed in PSO. The train data was used to select the best dimensions of the HA. HA has advantages over the lever amplification, the flexibility of the alignment of the configuration, and the ability to connect different vibrated systems to a single DVA which consequently increases the energy harvested.

A PHYSICS-INFORMED NEURAL NETWORK FOR INVERSE CHARACTERIZATION OF CONSTITUTIVE MODELS USED IN PROGRESSIVE DAMAGE ANALYSIS OF COMPOSITES

Sahar Abouali[*1], Ehsan Haghighat[2] and Reza Vaziri[1]*

[1]*University of British Columbia*
[2]*Carbon Inc.*

ABSTRACT

Successful simulation of progressive damage and failure response of composite structures relies on accurate characterization of constitutive models that in the macroscopic sense are typically in the form of strain-softening curves. This necessitates conducting high-quality coupon-level experiments coupled with the implementation of efficient inverse strategies for calibration of constitutive model parameters. Conventional inverse methods often involve iterative processes, requiring reruns of numerical models for each parameter update leading to tedious calibration procedures.
This study presents a physically meaningful machine learning approach based on Physics-Informed Neural Networks (PINNs) [1]. PINNs explicitly incorporate the underlying physics of the problem, offering increased interpretability and the ability to train with smaller datasets [2]. We develop a PINN-based framework for characterizing the strain-softening response of composite materials leveraging real-world notched fracture tests. The training dataset for the proposed PINN includes full-field displacement and global force measurements. To overcome the training challenges associated with severe localization in the fracture tests, we design an enhanced architecture by implementing a pipeline of forward and inverse neural networks. The performance of the developed framework is validated using synthetic data obtained from finite element simulations of the fracture tests.
To bridge the gap between theoretical and real-world experiments, our methodology is applied to a series of physical tests on quasi-isotropic IM7/8552 Carbon Fiber Reinforced Polymer (CFRP) composite laminates. Over-height Compact Tension (OCT) [3] and Compact Compression (CC) tests are conducted to promote stable growth of damage in tension and compression, respectively, allowing for the generation of sufficient data in the damage regime of the constitutive model. The full-field displacement data required for PINN training are obtained from experimental measurements using the digital image correlation (DIC) technique. For validation purposes, the PINN-characterized constitutive models are used within the FE simulation of the OCT and CC tests, and the resulting force-POD (pin opening displacement) response curves obtained from the simulations are compared against the corresponding experimental curves.

DETECTING AND QUANTIFYING STRUCTURAL NONLINEARITIES: A SYNERGISTIC APPROACH USING POST-HOC INTERPRETABILITY AND NEURAL NETWORKS ON RESPONSE SIGNAL TIME SERIES

Bayan Abusalameh[*1], Jiawen Wei[1] and Gianmarco Mengaldo[1]*

[1]*National University of Singapore*

ABSTRACT

Abstract:
In the realm of computational mechanics, accurately detecting, characterizing, and quantifying structural nonlinearities remains a pivotal yet challenging endeavor[1]. This study introduces an innovative methodology that synergistically combines post-hoc interpretability[2] with nonlinear parameter estimation via neural networks, leveraging their universal approximation properties.

The robustness and applicability of our method are meticulously validated through a series of numerical test cases, each simulating a single degree of freedom system with inherent nonlinearity.

ABSTRACT

Computational simulations are playing an increasingly important role to improve therapeutics and diagnostics using ultrasound waves. To unleash the full potential of computer simulations, the computational method must strike the right balance between accuracy and speed. We develop a fast pseudodifferential method that takes advantage of the geometric flow of acoustic energy to efficiently handle the highly oscillatory nature of ultrasound waves. Simultaneously, the method accurately incorporates refraction, reflection and attenuation imposed by realistic models of biological media. As a result, simulations of ultrasound wave propagation can be executed orders of magnitude faster than using conventional approaches. Some numerical results will be presented, and limitations discussed.

MODELING TARGETED BONE REMODELING AND VOXEL-BASED COMPUTER SIMULATION

Taiji Adachi[*1], Tsuyoshi Muto[1], Youngkwan Kim[1] and Yoshitaka Kameo[2]*

[1]Kyoto University
[2]Shibaura Institute of Technology

ABSTRACT

Bone with accumulated microdamage due to mechanical loadings is repaired by so-called targeted remodeling. In this process, mechanosensory osteocytes detect the microdamage and signal neighboring cells to activate osteoclastogenesis, initiating resorption-formation-coupled bone remodeling. This process is fundamental to maintaining the mechanical integrity of bone throughout life effectively preventing age- and disease-related loss of bone strength. However, the coupled phenomena of mechanics, such as damage accumulation under loadings, and biology, such as detection and repair of the microdamage by cellular activities, are complex and thus require understanding as a mechanobiological system. In this study, we aimed to model and simulate targeted remodeling by incorporating molecular and cellular mechanisms into the in-silico experimental platform (V-Bone) [1], which enables a voxel-based bone remodeling simulation that incorporates mechanics and biology within a single framework. By introducing a damage variable as a scalar function, microdamage accumulation in the bone matrix under mechanical loadings was modeled, based on damage mechanics, as an evolution equation that depends on the magnitude of local stress. In response to accumulated microdamage, osteocyte number density was modeled as a monotonically decreasing function of the microdamage, expressing osteocytic apoptosis due to microdamage. We hypothesized that the production of receptor activator of nuclear factor-κB ligand (RANKL), a master regulator of osteoclast differentiation, is triggered by osteocyte apoptosis and that RANKL production increases as osteocyte density decreases. In addition, the accumulation of microdamage leads to matrix degradation, which is expressed by a decrease in the elastic modulus of the matrix. Targeted remodeling for a single trabecula and a cancellous bone under uniaxial compressive loadings was simulated, in which the cancellous model was constructed from X-ray μCT data of a mouse femur. Under compressive loading, microdamage locally accumulated according to local trabecular morphology and mechanical conditions, and the corresponding regions were targeted to promote bone resorption by osteoclasts and subsequent new bone formation by osteoblasts. Thus, targeted remodeling under the influence of mechanics was reproduced in silico. The developed simulation method of targeted remodeling will be used as an in-silico experimental tool to investigate the coupled behaviors of mechanical adaptation and damage repair processes by bone remodeling. This study was supported by JST-CREST (JPMJCR22L5) and JSPS KAKENHI (JP20H00659, JP22K03827), Japan. We also thank Koki Fujimoto for technical assistance.

EMPIRICALLY MODELING IONOSPHERIC ELECTRON DENSITY VARIATIONS USING F107 , E107 AND MGII INDICES BASED ON SCATTER RADAR OBSERVATIONS OVER LAGOS, NIGERIA.

Christopher Adeogun[*1]*

[1]*Eko City Polytechnic*

ABSTRACT

Each of three solar flux indices, F107 , E107 , and MgII core-to-wing, has been tested as asolar activity proxy to model empirically electron densityNe measurements made by anincoherent scatter radar during the period of 1976-2001 over the height span of 150-1000km at Lagos, Nigeria. It is found that deviations of model values given by the three indices to the data are practically the same, regardless of altitude, local time, and season,indicating no significant improvements with introducing the newer indices E107 and MgII for empirically modeling long-term Ne data. The long-term behavior of the three indicesare identical. This paper also discusses electron density responses to the solar flux index.

DEVELOPMENT OF DRONE SUBSTITUTE MODEL FOR SURVIVABILITY ANALYSIS OF COLLISION WITH HUMAN HEAD

Hakim Afarsiou[*1], Fabien Coussa[1] and Éric Deletombe[1]*

[1]*ONERA*

ABSTRACT

A collision between drones and human head can have fatal consequences [1]. Considering that the dynamic response of two colliding solids depends on unknown impact conditions, geometry and material properties of each solid, the analysis of these risks turns out to be a very complex problem. The presented research idea is to develop a method derived from data science and AI augmented by physics, to help in the design of future drones (250g-4kg category). The approach proposed here is developed within the theoretical framework of mechanical wave propagation, that considers transient impact loading, contact duration, solid deformation and energy distribution within system. It considers the possible extension of the intrinsic properties of specific solid impedances [2], to more complex situations (multi-body and multi-material impactors, non-linear and dissipative phenomena, rupture) than usual. Simplified UAVs FE models, nevertheless based on shock physics, are used to access quantities relating to potential survivability on impact (forces, accelerations, transmitted energies), as functions of numerous simulation parameters, results which are analysed in relation to survivability envelopes, and reported to generalized design parameters like head/drone impedances.

The research first consists in carrying out numerical analyses to assess the physical basis and possible limits of the modelling proposal, as increasingly complex systems are studied. The contact force, momentum and energy transmitted during collisions between multi-material solids are evaluated (based on ONERA tests or open literature results [3]) and related to specific generalized impedances of impactors and targets. Once the FE substitution models (multi-domain, multi-material) for UAVs have been simplified (human head FE models are studied by an academic partner), the following work consists in carrying out a broad parametric numerical design of experiment (drone, velocity, impact angle, etc.) and in positioning the numerical results/data relatively to the prescribed survivability envelopes. The final stage of the research (perspective of the research) will concern AI-based data processing and comparison between raw (latent) and physically-based analyses.

MACHINE LEARNING HYPERPARAMETERS OPTIMIZATION FOR ENGINEERING PROBLEMS

Mateus Machado[1], Alexandre Souza Jr.[1], Juan Tueros[1], Rafael Santos[1], Ramiro Willmersdorf[1], Silvana Afonso[1], Leonardo Oliveira[1] and Bernardo Horowitz[1]*

[1]Universidade Federal de Pernambuco

ABSTRACT

The flexibility of neural networks is also one of their main disadvantages as there are many hyperparameters to adjust in order to have an efficient architecture. For example, starting from an imaginable network configuration, one can change the number of layers, the number of neurons, the type of activation function to be used in each layer, the type of optimizer to be used, its learning rate, lot size and more (Géron 2023). Therefore, hyperparameter optimization is an effective process in building deep learning models as it consists of finding a good combination of these parameters to improve the model's performance. Exhaustive search and optimization tools are the strategies commonly used to obtain these best parameters. In this context, an initial alternative here was to use the Python Keras Tuner library. Specifically, this library helps with hyperparameter optimization for deep learning models built with TensorFlow and Keras (Géron 2023). When using optimizers, it is necessary to define, in addition to the objective function, to be minimized or maximized, the design variables and constraints. In the hyperparameter optimization problem, these are the design variables of the problem, the objective function is a metric that depends on the problem (classification or regression) and the constraints are of the variable limit type. This falls into a mixed variable optimization problem as it presents more than one type of design variable (integer and continuous). To achieve this, specific algorithms and strategies are needed to solve a problem of this nature. Still in the context of using optimizers to obtain hyperparameters, we investigated the following frameworks here: pymoo (Blank and Deb 2020), Optuna (Akiba, et al. 2019) and Ray Tune (Liaw, et al. 2018). These libraries offer a series of optimization algorithms, as well as tools to evaluate the performance of different algorithms on different problems. Initially, the Fashion-MNIST benchmark presented in (Géron 2023) with some techniques for obtaining the hyperparameters was studied. The frameworks explored here were then applied for an oil reservoir management problem. Results obtained by different frameworks are discussed.

Modeling and simulation of advanced manufacturing processes for metals

MESHFREE COMPUTATIONAL MODELS OF METAL MANUFACTURING PROCESSES: THE GOOD, THE BAD, AND THE REAL WORLD

Mohamadreza Afrasiabi[*1], Zhilang Zhang[2], Christof Lüthi[2] and Markus Bambach[2]*

[1]*Inspire AG/ETH Zurich*
[2]*ETH Zurich*

ABSTRACT

Meshfree discretization methods have emerged as a powerful tool in computational mechanics, particularly in the context of manufacturing and materials processing simulations. The unique suitability of these techniques for multi-scale and multi-physics simulations stems from their efficiency in coupling different physical phenomena in a Lagrangian form and their inherent potential for adaptivity and parallelization, among other advantages. In this work, we present an overview of our recent developments in numerical simulations of various metal manufacturing processes using meshfree methods, with a focus on smoothed particle hydrodynamics (SPH). We examine the capabilities and limitations of our in-house massively parallel SPH code through a series of applications in both subtractive and additive manufacturing domains – see [1-3].

Computational modeling of manufacturing processes without mesh constraints offers attractive opportunities for developing multi-scale simulation approaches that can achieve remarkable efficiency. We demonstrate the ability of SPH to capture detailed thermo-mechanical aspects of metal machining operations, offering valuable insights into understanding processes, optimizing them, and controlling mechanisms. To achieve meaningful SPH simulation results, we emphasize the vital role of numerical stabilization and higher-order corrective terms through comparisons with experimental observations.

Furthermore, we showcase the strength and effectiveness of meshfree discretization techniques in representing the intricate fluid flow and melt pool behavior in metal additive manufacturing processes, such as laser powder bed fusion and cold spray 3D printing. We underscore the critical importance of runtime acceleration for manufacturing process simulation with SPH, highlighting the pivotal role of adaptivity and parallel computing in obtaining reliable numerical predictions.

This research offers a comprehensive examination of the potential benefits and challenges associated with employing meshfree methods, particularly SPH, in simulating metal manufacturing processes. By bridging the gap between theoretical modeling and real-world applications, our work not only lays the foundation for comprehending the key obstacles preventing widespread industrial adoption of meshfree methods but also suggests the necessary steps to take towards exploiting the full potential of these methods in multi-scale and multi-physics manufacturing simulations.

ENHANCING CARDIOVASCULAR CFD SIMULATIONS WITH REDUCED ORDER MODELS

Pasquale Claudio Africa[*1], Pierfrancesco Siena[1], Michele Girfoglio[1] and Gianluigi Rozza[1]*

[1]SISSA

ABSTRACT

Cardiovascular diseases, being major contributors to global mortality, present complex diagnostic and therapeutic challenges, making high-fidelity modeling techniques like Full Order Models (FOMs) essential for detailed hemodynamic analysis. However, the computational demands of FOMs, often built on finite element [1] or finite volume methods, limit their real-time clinical application. The emergence of digital twins as virtual replicas of a patient's cardiovascular system offers a groundbreaking tool in personalized healthcare, facilitating real-time diagnosis, treatment planning, and long-term health monitoring. Within this framework, Reduced Order Models (ROMs) emerge as a strategic solution, providing a streamlined yet accurate representation of these complex models, enhancing computational efficiency without significant loss of critical details.

In this presentation, we will explore how ROMs complement FOMs, creating a more versatile and practical approach to cardiovascular CFD. We will discuss the potential brought by two different approaches, namely traditional intrusive physics-based ROMs and data-driven techniques (particularly those based on machine learning and neural networks), in enhancing the predictive capabilities of these models. This is crucial for developing adaptive models suitable for the variability and complexity of cardiovascular conditions in clinical settings.

A key part of this presentation will be the introduction of a test case for multi-scale hybrid ROM simulations for cardiovascular flows [2]. This case study addresses the challenge of enforcing patient-specific non-homogeneous Dirichlet boundary conditions on pressure within an intrusive ROM framework, employing a lifting function approach. We utilize the Finite Volume (FV) method for simulating multi-scale blood flow in idealized or realistic cardiovascular geometries. The talk will compare two stabilization techniques: one based on supremizers and the other on the Pressure Poisson Equation. Our objective is to enable the incorporation of time-dependent boundary conditions for both velocity and pressure at the reduced level, potentially enhancing the accuracy and efficiency of cardiovascular simulations. This development could lead to more realistic and patient-specific modeling in cardiovascular care.

TDC FOR FINITE ELASTIC DEFORMATION IN SUBMERGED MOORING LINES EXPOSED TO DYNAMIC LOADING

Shagun Agarwal[1] and Oriol Colomés*[1]

[1]*Delft University of Technology*

ABSTRACT

The next generation of offshore and nearshore structures will be focused towards expanding human activities into the ocean waters. These range from power generation using floating solar platforms, aquaculture farms and floating islands for use in farming, housing and production facilities. These structures are expected to have a large waterplane area and a structurally compliant design to enable them to survive the harsh offshore environment. Moreover, these platforms are also expected to require new mooring methods involving flexible synthetic mooring lines, especially for deployment in relatively shallow waters.

These problems require development of models capable of effectively capturing the geometric nonlinearity in the structural deformation associated with large deformations of flexible bodies. In these cases, the equilibrium is satisfied in the deformed configuration, while the problem is often formulated in the presently known undeformed configuration, resulting in a moving boundary problem. Moreover, modelling of structures like mooring lines involve dimensional reduction over curved manifolds, resulting in considerably more involved partial differential equations.

In this work we present a finite-element model for flexible mooring lines, capable of capturing the geometric nonlinearity associated with large deformations. We utilize the Tangential Different Calculus (TDC) method, devised in Fries (2020), for defining the geometric and differential quantities associated with finite strain (large deformation) analysis of mooring lines over curved manifolds. The technique can be applied on parametric and immersed manifolds, thus enabling the application to embedded flexible boundaries. However, this work will present the results only using the parametric manifold approach. The effect of the sea-floor is implemented using a damped spring bed, thus enabling large movement of the touch-down point of the mooring line. Additionally, the effect of the wave and current loading on the mooring line is implemented using Morison’s equation, with slender body approximation. The model is implemented using Gridap (Badia 2020), an advanced FEM library in Julia language. We utilize this model to study the variation in the tension at the fairlead and the anchor of a composite mooring line, comprised of chain and fiber sections, under wave and current loading. The work will highlight the influence of geometric nonlinearity on the tension and the excursion of the floater.

ACCELERATING FRACTURE MECHANICS SIMULATIONS THROUGH MODEL ORDER REDUCTION WITH ENRICHED REDUCTION SPACES

*Konstantinos Agathos**[1]

[1]*University of Exeter*

ABSTRACT

This work introduces a model order reduction method for accelerating the solution of fracture mechanics problems, discretised with enriched finite elements. Projection based approaches, which are the most common among model order reduction methods, rely on the assumption that solutions of high dimensional problems can be accurately approximated in low dimensional spaces, that can typically be obtained from solutions to similar problems. In fracture mechanics problems however, the presence of evolving localised discontinuities, in the form of cracks, significantly limits the effectiveness of such bases. As a result, most existing model order reduction methods for such problems are either limited with respect to the damage configurations that can be represented or require frequent solutions of the full order problem to update the low dimensional spaces used, in order to account for crack propagation, thus reducing efficiency. In the proposed approach, low-dimensional spaces, constructed for undamaged systems, are adaptively enriched with selected columns of the flexibility matrix of the system, allowing to represent arbitrary crack configurations. It is shown that the resulting spaces contain the solution to the full problem, while their dimension is significantly reduced. However, to render the online construction of such spaces efficient for general crack configurations, the full inversion of the initial system’s stiffness matrix is necessary, a task that is computationally infeasible. To lift this limitation, hierarchical matrix representations are used, which significantly reduce the complexity of this operation by representing matrices in a data-sparse format. The resulting method achieves significant computational gains, without sacrificing the flexibility and accuracy of the full-order model. The performance of the approach is demonstrated through examples involving cohesive crack propagation.

EVALUATION OF PHYSICS-INFORMED NEURAL NETWORKS PERFORMANCE FOR AORTIC BLOOD FLOW SIMULATION UNDER DIFFERENT SEVERITY OF STENOSIS

Arman Aghaee[1] and Owais Khan*[1]

[1]*Toronto Metropolitan University*

ABSTRACT

Background:
Physics-informed neural networks (PINNs) have emerged as a powerful approach to encode governing PDEs and training data to inversely model complex engineering problems. Recent efforts have aimed to solve the Navier-Stokes equations with applications to vascular blood flow. However, key limitations inherent to neural networks, such as spectral bias, which tends to bias the training to low-frequency functions can notably reduce solution accuracy. Since cardiovascular flows can become transitional or quasi-turbulent, spectral bias can exacerbate the errors. To address this challenge, we have developed a PINNs architecture that uses a Fourier-based activation function, borrowed from computer vision literature, and investigated the accuracy of our Fourier-based PINNs architecture under a range of patient-specific blood flow conditions.

Methods:
CFD Simulations: Aortic geometry was obtained from the open-source repository (www.vascularmodel.com, patient ID: 01750000). The geometry was deformed to virtually induce a stenosis severity of 0 - 70% in increments of 5% (N=15 cases). High-resolution CFD simulations (mesh size = 7M elements, # timesteps=10,000) were performed. Inlet Reynolds number was 823 while local Reynolds number in the stenosis ranged from ~600 – 2000. Sensor points were randomly sampled at 1600 points.
PINNs Architecture: The solution to the velocity field was approximated using a fully connected neural network, which is a function of spatial coordinates, time and network parameters. Three loss function were used in the optimization process to further regularize the solution: i) losses from the Navier-Stokes equation; ii) losses from the partially-known boundary conditions; and iii) losses from the known sensor data. Adaptive coefficients were used to control the weighting of these loss function during the training process. Skip connections were used to further improve the accuracy and minimize vanishing gradients. Sinusoidal activation functions were used due to their ability to represent high-frequencies in the data. Swish and Tanh activation functions were also used for comparison.

Results and Conclusion:
L2-Norms ranged from 0.63 to 0.3 and absolute percent error ranged from 45% to 19% from lowest to high stenosis severity. Sinusoidal activation function had an accuracy that was 13% and 12% higher compared to swish and tanh for the highest stenosis severity (i.e., 70%). Our findings demonstrate that while under laminar blood flow conditions, PINNs errors may be within reasonable range of ~15%; however, in transitional or quasi-turbulent flow conditions, the errors

can increase drastically. Further work should focus on fundamental improvements in PINNs for modeling complex transitional blood flow conditions.

LEVEL SET TOPOLOGY OPTIMIZATION FOR THE DESIGN OF ELASTIC SHELL SOLIDS

Filippo Agnelli[1]*

[1]*McGill University*

ABSTRACT

The goal of the project is to develop a topology optimization framework for the design of elastic shell structures. Shells are three-dimensional solid structural elements whose thickness is slender compared to its other dimensions, which makes them highly desirable across several fields of engineering for their structural efficiency. Current simulation tools have become prevalent to assist their characterization, however they are still elusive in providing optimized geometric solutions that comply to the requirements and constraints imposed by the shell geometry. In this work, we combine the Reissner-Mindlin kinematics and the level set method to systematically capture the optimal hole placement within a background shell mid-surface. For a given set of load cases and constraints, we synthesize the best three-dimensional surface shape that minimizes a functional, either compliance and/or stress under a volume constraint. A sensitivity analysis, combining the Hadamard shape derivative and the topological gradient, is conducted in curvilinear coordinate system. For the stress measure, the p-norm function is employed to integrate stress fields into a global stress measure. To the reduce the sensitivity with respect to the starting shape in the algorithm, we make use of the reaction-diffusion approach to update the level set function. To this end, the optimization problem is regularized by introducing fictitious interface energy, which acts as a perimeter minimization constraint. With this method, the desired number and shape of the holes can be tailored adjusting the value of the diffusion coefficient.
The efficiency of the method is compared to an equivalent three-dimensional solid optimization problem, executed under similar conditions on structures of thin-walled geometry. We design several shell structures of increasing complexity, from continuous by part flat plates, to curved surfaces, manifolds and non-manifolds with creases. Each example requires 250 iterations maximum to converge, which take about 10 min on a machine with 12 CPU. In most examples, the last hole nucleation or vanishing occurs around iteration 100, the last iterations only contributing to minor improvements. The obtained geometries are highly regular and compliant with respect to cutting processes. In comparison, the exact same algorithm applied to three-dimensional solid elements takes several hours to accomplish the same number of iterations, yielding a similar outcome, with slightly improved performances, but with an organic aspect (Fig. 1). Finally, the level set description enables to rapidly extract the surface which can be converted into B-Rep and used subsequently in CAD and CAM software.

MOVING WINDOW CONCURRENT ATOMISTIC CONTINUUM APPROACH FOR MODELING SHOCK WAVE PROPAGATION IN MULTIPLE PRINCIPAL ELEMENT ALLOYS

Alexander Davis[1], Abigail Hunter[2], Saryu Fensin[2] and Vinamra Agrawal[1]*

[1]Auburn University
[2]Los Alamos National Laboratory

ABSTRACT

Spall fracture is one of the most common ways a material can fail under high-strain rate loading. Extensive experimental investigations have indicated that microstructural features such as grain boundaries play a crucial role in the nucleation of voids leading to spall fracture. In this work, we develop a novel moving window concurrent atomistic continuum (MW-CAC) model to study shock propagation in face-centered cubic single-component (Cu) materials and multicomponent (FeNiCr) alloys. The technique uses the concurrent atomistic continuum (CAC) method that uses the unified formulation obtained from the Atomic Field Theory.

We study a Riemann problem involving a planar shock in a 3D domain with constant states (strain, particle velocity, temperature). We use the atomic resolution at the shock wave and continuum resolution outside. We track the moving shock wave using two moving-window algorithms - the conveyor and coarse-refine methods. In the conveyor method, we add and remove planes of atoms at regular intervals to recenter the moving shock in the atomistic window. In the coarse-refine method, we refine (coarsen) the continuum elements ahead (behind) the shock to follow the moving shock wave and keep it centered in the atomistic window. Next, we use the A-atom approach to introduce average atoms for simulations involving multiple principal element alloys. We use the A-atoms in the continuum regions. We study shock propagation in Cu and FeNiCr alloys with two equations of state (EOS), the linear Hugoniot and the thermoelastic Eulerian equation. We study shock front thickness and planarity as it evolves. The MW-CAC approach demonstrates excellent speed-up compared to large-scale non-equilibrium molecular dynamics simulations

ASSESSMENT OF FLOW-INDUCED STRESSES IN SPIRAL WELD PIPES WITH BENDS

Shahab Ahmadizade[*1], Suyash Verma[1] and Arman Hemmati[1]*

[1]*University of Alberta*

ABSTRACT

This study focuses on the computational modeling of fluid-induced stresses and their effects on curved spiral-welded liquid pipelines. We employ two distinct open-source solvers with different computational approaches to address the fluid-structure interaction (FSI) problem. First, Solids4Foam is utilized for the complex FSI analysis, which is an internal component of OpenFOAM. The second solver is CalculiX, a separate open-source tool for finite element analysis (FEA), notable for its compatibility and integrative potential with OpenFOAM. Our parameter space follows the operating dataset of two major pipeline industry leaders, which includes the design and material information of their liquid pipelines. Our study specifically targets pipelines with varying bend angles and radii under regular and fatigue conditions. These scenarios are initially simulated using unsteady Reynolds-Averaged Navier-Stokes (RANS) models, incorporating the k-ω turbulence model in OpenFOAM. After the initial assessment of the flow dynamics and development of our first stress-prediction model, we upgrade our fluid modeling technique to Detached Delayed Eddy Simulations (DDES), which combines the high-accuracy Large Eddy Simulation (LES) formulations with k-ω RANS model.

For this conference, we will focus our attention on challenges and limitations of FSI analysis with available techniques, particularly solids4Foam. Solids4Foam is sensitive to how meshes conform when transferring data between fluid and solid domains. If meshes on the solid and fluid components are not properly aligned in size and conformity, Solids4Foam encountered challenges in adjusting the criteria for simulation convergence. The application of certain boundary conditions, particularly contact boundary conditions in the solid domain, presents complexities and may restrict the scope of the simulation. This limitation also complicated using varied materials within the solid domains, thereby further reducing simulations' flexibility. To address these limitations, we integrated preCICE and Calculix with OpenFoam. This strategy is designed to allow handling of more complex scenarios within the solid domain, thus offering a robust solution for fluid-structure interaction simulations. By utilizing these tools, we have improved both the accuracy and efficiency of our analysis, ultimately contributing to the enhancement of pipeline system design and structural integrity. This research represents a significant step forward in our understanding of fluid-induced stress prediction and assessment in pipelines. The ultimate objective of this work is development and deployment of a software package that utilizes reinforced learning, based on simulation and experimental data, to predict the formation and propagation of cracks induced by flow-induced stresses in pipelines at various operating conditions.

MULTIFIDELITY OPERATOR NETWORKS FOR CLOSURE MODELING IN MULTISCALE SYSTEMS

Shady Ahmed[*1] and Panos Stinis*[1]

[1]*Pacific Northwest National Laboratory*

ABSTRACT

Digital twin applications require a synergy between the physical system and its virtual counterpart. In a typical application, the computational model is queried multiple times during the operation of the system where quick responses are necessary to monitor, control, and optimize the performance of the physical asset. Traditional simulation techniques are often too computationally expensive that they fail to fulfill the tight turnaround time requirements. Therefore, computationally-lightweight models are essential components of digital twin frameworks.

The trade-off between accuracy and cost can be addressed by identifying the key features and coherent structures of the system and building reduced order models to capture the dynamics of these large-scale phenomena. However, for multiscale systems, these models usually suffer in long time predictions due to the rapid propagation of errors in the small scales to contaminate the simulation of large scales. Closure modeling refers to correcting reduced order models' predictions by accounting for the effect of the truncated scales on the resolved ones. We look at the closure problem from a multifidelity learning perspective. In particular, a combination of proper orthogonal decomposition and Galerkin methods is used as the low-fidelity dynamical model for the dominant modes. Meanwhile, deep operator networks are utilized to make up for the contribution of the small scales in a multifidelity setup. Numerical experiments are carried out using prototypical benchmarks representative of large-scale geophysical flows prevalent in digital twins of Earth systems. Results show that operator networks can learn correction terms across a wide range of initial conditions and parameter values with reliable predictions for long forecast lead times.

APPLICATION OF UNSTRUCTURED GRID-BASED CFD SIMULATIONS IN NAVAL AND SHIP HYDRODYNAMICS

*Hyung Taek Ahn**[1]

[1]*University of Ulsan*

ABSTRACT

The unstructured grid technique, pioneered by researchers such as Mavriplis, Nakahashi, Luo, Lohner, and Kallinderis[1] since the early 1990s, has primarily been employed in aeronautical applications. However, there is a growing trend to extend these technologies to the field of ship and naval hydrodynamics. This presentation will focus on the utilization of unstructured grid CFD simulation technologies in ship hydrodynamic applications[2]. Various challenges unique to ship hydrodynamics will be addressed, and potential solutions[3] will be discussed.

QUANTUM ANNEALING FOR PARTICLE MATCHING IN QUASI-CYCLIC DISCRETE-ELEMENT METHOD SIMULATIONS

Oliver Ahrend[*1] and Julia Kowalski*[1]

[1]*RWTH Aachen University*

ABSTRACT

There is an increasing interest in utilizing the potential of quantum computing for a wide range of compute-intense tasks across many academic and industrial disciplines. Different quantum computing technologies have been proposed that today are available in maturity levels ranging from the mere existence of a conceptual idea to ready-to-use technologies. So-called quantum annealers (QAs) are an example of the latter and exploit quantum fluctuations to solve special classes of discrete optimization problems. Today's QAs have many times more qubits than gate-based quantum computers, and can be used to study realistic problems. Here, we feature an engineering application, in which a particle matching algorithm arising in a quasi-cyclic discrete element method simulation is reformulated for a QA as a QUBO model. Implementation on a QA (D-Wave), however, requires us to select a large number of hyperparameters, such as annealing time, readout thermalization, programming thermalization. Based on the observation that typically the probability of sampling a correct solution is very low and large problems can not be solved reliably, a systematic sensitivity analysis would be desirable. So far, however, literature mostly provides information on the sensitivity in single parameters [1, 2, 3]. In this contribution we will address this lack of information. We first describe how a particle matching task can be reformulated for a QA, and show how a run is conducted. We then summarize the different types of hyperparameters present in the algorithm. Next, a sensitivity study is conducted to identify and analyze the correlation between solver parameters and parameter of the problem setting. We discuss our results and conclude on parameter selection strategies that guarantee a reliable solution.

DYNAMICS OF BUOYANT MISCIBLE INJECTION FLOWS IN A CONFINED MEDIUM

Soheil Akbari[1,2] and Seyed Mohammad Taghavi*[1]

[1]*Université Laval*
[2]*University of British Columbia*

ABSTRACT

In this study, we investigate buoyant miscible injection flows of a high-dense fluid into an inclined closed-end pipe filled with a low-dense fluid. We use mainly experiments, accompanied by complementary numerical simulations and semi-analytical methods, to analyze the influences of the flow and fluid parameters on the flow dynamics. The fluids are miscible, and the timescale of our experiments is adequately short so that the fluids do not mix remarkably. To generalize the results, the relevant dimensionless numbers of the flow are used, including the Froude number (Fr), the Reynolds number (Re), the buoyancy number (χ), the Archimedes number (Ar), the viscosity ratio (M), the Bingham number (B), the inclination angle (β), the aspect ratio (δ), the radius ratio (Rc), and the eccentricity (E). Results show that for the injection of a high viscous fluid, the separation of the heavy fluid front from the bulk of the fluid happens when Re and β are large [1]. For the injection of a viscoplastic fluid, a core fluid immersed in the in-place fluid is formed, for which there appear three different flow patterns, namely, the breakup, coiling, and bulging regimes [2,3]. In the breakup regime, as the injection continues and time grows, the injected viscoplastic fluid can no longer withstand the progressively-increasing buoyancy force, causing the yielding of the core fluid towards thinning and, ultimately, the core breaks up. In the bulging regime, the pressure and the interfacial shear stress applied by the upward flow of the in-place fluid on the core lead to yielding towards the bulging of the core. For the coiling regime, the core fluid remains unyielded and its diameter is unchanged until it distorts into a coiling structure. We develop a lubrication approximation model using the Herschel-Bulkley constitutive equation. Based on a rational prediction of the onset of yielding, we can classify the flow regimes versus an elegant combination of the dimensionless flow parameters, including B, χ, M, and δ.

3D PRINTED ARCHITECTED SHELL-BASED FERROELECTRIC METAMATERIALS

Jiahao Shi[1], Kang Ju[1], Haoyu Chen[1], Armin Mirabolghasemi[1], Saad Akhtar[1], Agus Sasmito[1] and Hamid Akbarzadeh[1]*

[1]McGill University

ABSTRACT

Ferroelectricity allows the generation of electrical power from mechanical oscillations and temperature fluctuations. Tailoring the underlying microarchitecture of ferroelectric materials imparts a promising route for enhancing their ferroelectric performance. In this study, we resort to shell-based architected materials to construct ferroelectric metamaterials with controllable multiphysical properties. A modified multiscale simulation, incorporating the poling process of architected piezoelectric materials, is developed to accurately determine their effective electromechanical properties. The interplay among relative density, shell topology, and ferroelectric figures of merit, metrices for assessing the performance of ferroelectric metamaterials as sensors and energy harvesters, is explored. A high-resolution 3D printing technique is adopted to fabricate the architected piezoelectric metamaterials; experimental measurements of their piezoelectric charge and dielectric constants corroborate their excellent sensing and energy harvesting functionalities in the next generation of lightweight intelligent infrastructures.

MODEL-BASED DESIGN APPROACH FINDING OPTIMAL LIQUID COOLING FLOW PATH FOR ELECTRIC VEHICLE BATTERY

Daisuke Aketo[*1] and Kenji Ono*[1]

[1]*Kyushu University*

ABSTRACT

In the early products of electric vehicles (EV), an air-cooling method was employed for the battery thermal management system (BTMS), however, because of more severe heat generation, many EV companies have adopted liquid cooling methods for more efficient cooling. BTMS shape is usually plate-like structure on box shaped batteries. In these BTMS, it is a critical determinant for thermal performance where are flow paths in their plates. If we can estimate these performances and design flow paths in early product development phase, it facilitates subsequent development process. For estimating such industrial thermal flow problems, Computational Fluid Dynamics (CFD) is assumed an important role. However, in early product development phase there are sometimes many shapes (results of trial-and-error), so it is difficult to simulate them all for CFD calculation cost. We study how to solve these issues based on Model based design and Machine learning. At first, for simplicity, we defined that these flow paths can be expressed in the form of graph data. These plates are discretized into elemental components as nodes with connections represented as edges. Next, we solve the equations of conservation of mass, pressure loss, and conservation of heat which are given by the relationships between nodes and edges. The coefficients of these equations are defined with each shape feature and adjusted to fit CFD results in advance, so this simulation methods results are like CFD ones. In this paper, we introduce the simulation and examples of shape parametric optimization to demonstrate the advantage of the proposed approach in terms of speed and simulation cost.

OPTIMIZING GRADIENT BACK-PROPAGATION FOR HYBRID NEURAL DIFFERENTIABLE SOLVERS

Deepak Akhare[1], Xiantao Fan[1], Tengfei Luo[1] and Jianxun Wang[1]*

[1]*University of Notre Dame*

ABSTRACT

Hybrid neural differentiable models represent a significant advancement in scientific machine learning, standing on the innovative concept of seamlessly integrating domain-specific knowledge with cutting-edge deep learning models, offering a novel solution to the limitations of both traditional numerical solvers and neural networks. Traditional models are effective for well-understood physical phenomena but struggle with complex systems, while neural networks excel in learning unknown/unresolved physics from data but often lack in interpretability and can have difficulties in generalizing to new situations. By combining these approaches, hybrid models aim to leverage the advantages of both, leading to improved predictive capabilities in modeling complex physical systems and potentially discovering new physics from sparse and indirect data.

The effectiveness of these hybrid models depends largely on the differentiability of the solvers they use. Differentiable programming addresses this need, allowing for the joint optimization of machine learning and numerical model components within a unified framework. This field has seen growing interest, with differentiable solvers and hybrid models showing potential in a variety of scientific applications. However, training these models can be challenging, particularly when dealing with dynamic data over long timeframes or when using iterative solvers, such as implicit or Poisson solvers. These situations can create extensive computational graphs for gradient calculations, leading to high memory requirements and concerns about the scalability of the models. This research will investigate methods for effectively training hybrid neural differentiable models, particularly in scenarios involving long-term model rollout or iterative implicit learning scenarios. The evaluation will center on the effectiveness of these methods in decreasing computational requirements, while also addressing the possible drawbacks associated with these techniques.

A CONSISTENT NON-LINEAR AND GEOMETRICAL REDUCED ORDER MODELING APPROACH WITH UNCERTAINTY QUANTIFICATION APPLIED TO THE CONVECTION DOMINATED INCOMPRESSIBLE NAVIER-STOKES EQUATIONS

Nissrine Akkari[1] and Fabien Casenave*[1]

[1]*Safran*

ABSTRACT

In this work, we propose a non-linear and geometrical Reduced Order Model ROM using a Gaussian Mixture Variational AutoEncoder (GMVAE) [1]. GMVAEs are proposed in the literature for unsupervised data clustering using Gaussian Mixture Models (GMMs).

In the offline stage, the GMVAE compresses the instantaneous velocity and pressure fields of the fluid flow of a variable geometry, along with the fields describing the masks of the geometries respectively for each unsteady solution at a given geometric configuration.

In the online stage, unlike the least-square minimization of the ROM residual [2], the zero-constraint of the residual enables uncertainty quantification by sampling from a specific statistical model from the learned mixture of statistical models. In fact, the geometrical reduced order model coefficients are obtained by solving the zero-constraint of the residual of the Navier-Stokes equations, which is based on the non-linear projection of the residual upon the latent space of the GMVAE using the encoder part of it. A consistent formulation of this reduced order model is guaranteed thanks to the encoding of a time discretization of the velocity term in the Navier-Stokes equations [3]. The geometrical reduced order solution at a given time instant and at a given geometry of the fluid flow is obtained thanks to the decoding of a sample of a statistical model from the mixture latent features. This statistical model is inferred by encoding the terms of the Chorin predictive and corrective scheme at the preceding time step and, the mask of the current geometry.

The proposed geometrical and unsteady non-linear reduced order model is applied to the convection dominated incompressible Navier-Stokes equations, in order to infer the unsteady and turbulent flow past a NACA2412 generation at an angle of attack equal to 30°, with a variable thickness and chord length.

MECHANICAL BEHAVIOUR OF TUBULAR TOPOLOGICAL INTERLOCKING ASSEMBLIES

Reymond Akpanya[*1] and Alice C. Niemeyer*[1]

[1]*RWTH Aachen University*

ABSTRACT

A topological interlocking assembly is an arrangement of several rigid blocks that are in contact with each other and are constrained by a fixed frame such that each subset of blocks is kinematically constrained and therefore cannot be removed from the whole assembly. The platonic solids are examples of convex blocks that allow such interlocking assemblies, see [1]. Exploiting topological interlocking enables the construction of large concrete structures without the usage of mortar as binding material. Over the years various blocks that give rise to topological interlocking assemblies by assembling copies of a given block, have been proposed. Dyskin et al. are notable pioneers in the field of topological interlocking [1]. In [2], the authors provide an recent overview of assemblies with interlocking properties.

In this presentation, we discuss an algebraic construction method that facilitates the design of various topological interlocking assemblies. More precisely, we construct blocks whose copies can be assembled to form tubular structures with interlocking properties. This is achieved by exploiting two dimensional crystallographic groups, i.e. the symmetries of periodic wall paper patterns. Here, we focus on the design of tubular topological interlocking assemblies that prevent certain simultaneous movements of the blocks in the assembly when the frame remains unfixed. The motions of interest are the simultaneous radially outwards movement of every block. Hence, we generate examples of tubular interlocking assemblies that prevent the described motions and compare their structural behaviour to the behaviour of interlocking assemblies that do not prevent these movements when the frame is not fixed. In particular, we achieve this comparison by conducting several finite element studies. Moreover, we address the challenge of manufacturing the proposed structures with carbon
reinforced concrete.

INCREMENTAL TENSOR DECOMPOSITIONS FOR BUILDING EFFICIENT DIGITAL TWINS

Doruk Aksoy[*1] and Alex Gorodetsky*[1]

[1]*University of Michigan*

ABSTRACT

With recent advancements in large-scale parallel computing, there is an increased interest in constructing high-fidelity digital twins of complex systems. Especially for systems that have limited physical experimentation possibilities, high-fidelity simulations may provide the main source of information for constructing digital twins for deployment into online operations. However, performing such simulations is computationally intensive and generates extreme amounts of data. The size of the generated simulation data makes it challenging to use the data in further analysis. As the spatial and temporal resolution of these simulations grow, even storing the data may become a serious bottleneck.

In this talk we address this problem through the use of low-rank tensor decompositions. Specifically, we will present incremental algorithms that provide computationally efficient ways of compressing generated data with accuracy guarantees. We demonstrate the efficacy of incremental tensor decompositions through tensor train and hierarchical Tucker formats. Our research presents two specific algorithms: The Tensor Train Incremental Core Expansion (TT-ICE)[1], an incremental tensor train decomposition algorithm that offers state of the art compression speed, and Hierarchical Incremental Tucker (HIT)[2], the first known algorithm in the literature to perform incremental updates to hierarchical Tucker format.

Beyond the advantage of space savings, our algorithms offer a reduced representation that facilitates downstream learning tasks such as Bayesian inference and deep learning[3]. Our results reveal computational savings concerning memory requirements and execution time for the incremental algorithms compared to their traditional one-shot counterparts. We validate our findings using datasets from parametric-PDE-driven simulations of a chaotic system and particle-in-cell simulations of an electric propulsion system. Those examples demonstrate the scope of our approach's applicability.

EXPLOITING RATE-DEPENDENT INSTABILITIES IN SOFT METAMATERIALS THROUGH SHAPE AND TOPOLOGY OPTIMIZATION

Ryan Alberdi[*1], Craig Hamel[1], Aabhas Singh[1], Kevin Long[1] and Adam Cook[1]*

[1]Sandia National Laboratories

ABSTRACT

Soft metamaterials can offer programmable responses to external stimuli, making them desirable for applications such as soft robotics, shock and vibration mitigation, and flexible electronics. In line with the metamaterial concept, the response of these materials is governed to a large extent by the geometric and topological makeup of their small-scale features. However, the link between structure and response is less intuitive for soft metamaterials due to their reliance upon highly nonlinear instabilities. This is further complicated by the effects of viscoelastic relaxation, which recent studies have shown to alter the emergence of instabilities in non-intuitive ways. To exploit this complex design space and advance the development of soft metamaterials, we propose a computational design framework based on shape and topology optimization. Our software stack employs a unique library for solving nonlinear solid mechanics problems that poses them in an energy minimization form to robustly handle instabilities while accounting for the path-dependence of viscoelastic phenomena. Moreover, a modular architecture allows for the use of both CAD-parameterized shape optimization and level-set topology optimization. We present examples demonstrating how this approach can be used to tailor the rate-dependent response of soft metamaterials exhibiting snap-through and buckling instabilities.

POLYPLAS: A PYTHON IMPLEMENTATION OF A TOPOLOGY OPTIMIZATION FRAMEWORK FOR PLASTICITY WITH UNSTRUCTURED POLYGONAL FINITE ELEMENTS

Emily Alcazar[1], Jonathan Russ[2] and Glaucio Paulino[1]*

[1]*Princeton University*
[2]*Johns Hopkins University*

ABSTRACT

We present PolyPlas, a Python program for a structural topology optimization framework considering von Mises plasticity with unstructured polygonal finite element meshes. The modular structure of this code is inspired by PolyTop, an educational code for compliance minimization for linear elastic material. Unlike the previous PolyTop program, PolyPlas is fully realized in Python for the purpose of open-source access to both academic and industry users alike. The nonlinear physics are modeled by the radial return mapping algorithm coupled with a displacement control subroutine. A discussion on volumetric locking effects in conjunction with the polygonal finite elements is also included herein. Finally, several numerical examples are presented to illustrate the capabilities and efficiency of PolyPlas in solving topology optimization problems considering von Mises plasticity.

MULTI-LEVEL NEURAL NETWORKS FOR ACCURATE SOLUTIONS OF INITIAL AND BOUNDARY-VALUE PROBLEMS

Ziad Aldirany[*1], Régis Cottereau[2], Marc Laforest[1] and Serge Prudhomme[1]*

[1]*Polytechnique Montréal*
[2]*Aix-Marseille Université*

ABSTRACT

In recent years, machine learning approaches, such as the physics-informed neural networks (PINNs)[1], the deep Ritz method[2], or the weak adversarial networks[3], have shown promising results for several classes of initial and boundary-value problems. However, their ability to surpass, particularly in terms of accuracy, classical discretization methods such as the finite element methods, remains a significant challenge. One of the main obstacles of deep learning approaches lies in their inability to consistently reduce the relative error in the computed solution. We present a novel approach, the multi-level neural networks, in order to reduce the solution error when using deep learning methods. The main idea consists in computing an initial approximation to the problem using a simple neural network and in estimating, in an iterative manner, a correction by solving the problem for the residual error with a new network of increasing complexity. This sequential reduction of the residual associated with the partial differential equation allows one to decrease the solution error, which, in some cases, can be reduced to machine precision. The underlying explanation is that the method is able to capture at each level smaller scales of the solution using a new network. Numerical examples in 1D and 2D dealing with linear and non-linear problems will be presented to demonstrate the effectiveness of the proposed approach.

A MODEL FOR STRAIN RATE DEPENDENT REVERSIBLE CYTOSKELETAL FAILURE IN CELLS EXPOSED TO SUPER-PHYSIOLOGICAL DEFORMATION RATES

Samuel Boland[1] *and Patrick Alford**[1]

[1]*University of Minnesota*

ABSTRACT

All cells are exposed to mechanical forces and deformations, and must be able to rapidly adapt to maintain their functional integrity. To better understand the relationship between applied loads and cellular mechanics, we have developed a method for directly measuring single-cell mechanical properties called cellular micro-biaxial stretching (CμBS), which uses traction force microscopy methods coupled with a device that applies precise deformation to the substrate on which the cells are seeded. We recently performed a series of experiments wherein we applied a repeated rapid stretch and hold deformation with varied stretch rate to micropatterned vascular smooth muscle cells. We found that, regardless of the rate at which the cells were stretched, all cells displayed stress-relaxation, typical of viscoelastic materials. But, increasing the stretch rate yielded decreased stresses, which directly conflicts with conventional viscoelastic models. In fact, cells exposed to super-physiological strain rates, mimicking trauma, displayed nearly no increase, and often a decrease, in stress following stretch. While these results suggest that some component of the cell is failing at high strain rates, repeated stretch experiments showed that in most cases the stress is recovered in subsequent stretches, so the observed decrease in stress is not due to plastic deformation. To explain this phenomenon, we have developed a model of stress fiber strain rate dependent reversible failure, in which actin-myosin binding kinetics are dependent on fiber stress and fiber stress is strain-rate dependent. Here, I will present this model and its implications for cellular mechano-adaptation.

A METHOD TO CONSTRUCT LOW RANK TENSOR NETWORK POLYNOMIAL REDUCED ORDER MODELS

Nicholas Alger[*1], Blake Christierson[1] and Omar Ghattas[1]*

[1]The University of Texas at Austin

ABSTRACT

We present an efficient method to fit low-rank multivariate polynomials to implicitly defined smooth mappings between high-dimensional spaces. By implicitly defined, we mean that evaluating the mapping requires solving a large non-linear system of equations. Such mappings arise as, e.g., parameter-to-output mappings in inverse problems governed by partial differential equations (PDEs). To overcome the curse of dimensionality, we represent arrays of polynomial coefficients in low-rank Tucker-tensor-train format. Tucker-tensor-trains are fit to data generated by evaluating the mapping and, crucially, symmetric actions of high order derivatives of the mapping. Derivative actions are computed using adjoint-based techniques. We use the method to approximate key mappings in several PDE-based inverse problems. The results show that (1) it is feasible to construct high order (e.g., 6th order) polynomial reduced order models, and (2) using high order polynomials and derivatives substantially increases accuracy.

FINITE ELEMENT MODELLING OF MATERIALLY UNIFORM DIELECTRIC ELASTOMERS

Mawafag F. Alhasadi[1], Ahmed Bayram*[2], Qiao Sun[3] and Salvatore Federico[1]*

[1]*University of Calgary*
[2]*Wood PLC, Calgary*
[3]*University of Calagry*

ABSTRACT

Non-magnetisable electroelastic materials are characterised by a strong coupling between elastic and electrostatic properties. Dielectric elastomers are electroelastic materials that can undergo very large deformations when subjected to electric fields, and have attracted much attention due to the vast range of applications as sensors and actuators. The foundations for the study of this class of materials have been laid by the seminal works of Toupin [2] and several others. In brief, the Helmholtz' free energy is a function of both the deformation and the electric polarisation, so that both contribute to the stress.
We are interested in the theory of uniform elastic dielectric. In the theory of material uniformity established by Noll [1], a body is uniform if all points are made of the same material. When this is the case, there is an "archetypal" point from which all points can be mapped by means of a tensor field called implant tensor. The theory can model a vast range of inhomogeneous materials, i.e., materials for which the material properties depend on the material point. The case of homogeneous bodies is retrieved when the implant tensor is constant, i.e., independent of the material point. For an electroelastic body, uniformity implies that the Helmholtz' free energy depends on the material point exclusively through the implant tensor.
In this study, we developed a finite element solver in Matlab, designed to handle electromechanical simulations and whose capabilities are demonstrated by simulating a layered-beam-type actuator. The beam has two layers made of the same dielectric elastomer, with the top layer sandwiched between two (ideally) infinitely compliant electrodes, between which a difference of potential is applied. In this way, only the top layer of the beam is activated and thus the beam bends when actuated.
The inhomogeneity simulated in our test is contorted aeolotropy: the implant tensor is a randomly generated orthogonal tensor depending on the material point. In this way, the implant represents a particular case of local distortion. Under an applied electric field, the inhomogeneous beam not only bends but also warps, in contrast to a perfectly homogeneous beam. The study of inhomogeneities is important to predict potentially undesirable warping of this type of actuators. We plan to apply this model to other actuator geometries and loading conditions.

HYPEROPTIMIZATION INSIGHT FOR TOPOLOGY OPTIMIZATION

Hazhir Aliahmadi[1], Ruben Perez*[2] and Greg van Anders*[1]

[1]*Queen's University*
[2]*Royal Military College*

ABSTRACT

The nonlinear relationship between the form and function of physical structures in our built environment raises challenges for design. Modern design methods, such as topology optimization, provide structural solutions but obscure the relationship between the form of the solution and the formulation of the underlying design problem. Here, we show how to extend classical molecular dynamics methods to provide novel forms of insight into the origin and organization of design features in problems typically studied via topology optimization. Our computational approach to morphogenesis problems extends topology optimization techniques by adapting physics-based approaches that underly recent, significant advances on related problems in materials design. The framework we present here for problems in morphogenesis surmounts known design problems including grayscale ambiguity, manufacturing inaccuracy, and artificially over-specified criteria. Our results give examples where coarse-grained molecular methodologies can be used to derive results for macroscopic design problems

A FRAMEWORK FOR CONTEXT-SPECIFIC CONSTITUTIVE MODEL CALIBRATION

Coleman Alleman[*1] and Celso Carranza*[1]

[1]*Sandia National Laboratories*

ABSTRACT

Virtually all modeling and simulation relies critically on the calibration of model parameters that describe the behavior of a physical system under different environmental conditions and loads. However, approaches to obtaining and validating optimal parameter values vary widely due to differences in available data, material physics, simulation codes, and user experience. There are many aspects to the problem of developing such an approach, but one that has received relatively little attention is transferability. It is common to think of a set of parameter values as optimal in the global sense that a model best fits given data with a this single set of values. The canonical example is calibration to minimize the sum of squared error between the model output and some set of observations. In this paradigm, the calibrated model itself is transferable from one context to the next. Contrary to the assumption that there exists a single, context-independent optimal model calibration, engineering practice clearly demonstrates that different model calibrations to the same data can be optimal for different end-use scenarios. With this in mind, we propose a calibration scheme that takes into account the end use, and can be repeatedly applied to the same input data to achieve model calibrations that are optimal for specific contexts. In this paradigm, it is the approach that is transferable between contexts, rather than the calibrated parameter values. We demonstrate the efficacy of this framework with simple but relevant problems in elasto-plasticity.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology \& Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

EXPLORING VASCULAR WALL FRACTURE THROUGH AN INTEGRATED EXPERIMENTAL AND NUMERICAL APPROACH

Marta Alloisio[*1], Fadi Aldakheel[2] and T. Christian Gasser[1]*

[1]*KTH Royal Institute of Technology*
[2]*Institut für Baumechanik und Numerische Mechanik*

ABSTRACT

Vascular tissue fractures play a crucial role in cardiovascular events like strokes, and aortic dissection, major causes of global death and disability. A better understanding of vascular tissue fracture, therefore, bears the potential to improve the treatment of vascular patients and optimise medical device designs. In addition to robust in-vitro experiments, the identification of fracture mechanical properties relies on robust and efficient numerical tools.
We present different Finite Element Method (FEM) approaches to model vascular tissue fracture focusing on the symmetry-constraint Compact Tension (symconCT) test, an in-vitro test protocol to study vessel wall fracture [1]. Our numerical models represent the fracture by (i) cohesive zones placed at finite element facets [1], (ii) cohesive zones embedded within the finite element following the Partition of Unity FEM (PUFEM) [2], and (iii) the phase-field approach [3].
Regardless of very good agreement with the recorded experimental data, the approach reported in (i) revealed an excessively large cohesive fracture length of 11.4 mm at which complete separation was observed. Important rate-dependent dissipation mechanisms in the fracture process zone might, therefore, have been overlooked, and the embedded formulation (ii) incorporated additional dissipation in the traction separation law. Towards avoiding challenges related to the dynamic introduction of the cohesive zone elements according to approach (ii), a phase-field model was implemented in FEAP (University of California at Berkely), comprising approach (iii).
The numerical efficiency and robustness of the investigated approaches are explored, and the plausibility of model predictions is discussed in relation to experimental observations of the symconCT test results. As the primary aim of our work was the comparison of different numerical methods, an overly simplified vessel wall description was used. Fundamental mechanisms associated with the inception and development of damage, leading to tissue failure, are not explicitly described. Irreversible tissue description that incorporates the time-dependent failure mechanisms across length scales might provide more realistic insight into vascular tissue failure.

MODELING THE TARGET ANTIGEN HETEROGENEITY IN IMMUNOTHERAPY WITH CAR-T CELLS

Regina C Almeida[*1], Emanuelle Arantes Paixão[1] and Orlando Warlem Sudré Júnior[1]*

[1]Laboratório Nacional de Computação Científica

ABSTRACT

Immunotherapy with chimeric antigen receptor T-cells (CAR T cells) is a recent cancer treatment approach, wherein T lymphocytes are extracted from the patient, genetically manipulated to recognize the specific antigen expressed by the patient's tumor cells, and expanded in culture. Upon reinfusion into the patient, these cells are capable of identifying and eliminating cancer cells expressing the targeted antigen. Despite the success of this adoptive therapy against various cancers, mainly those of the hematopoietic system, the durability of remission has been the subject of recent research. Studies have indicated that the immune pressure resulting from CAR T cell immunotherapy induces changes in antigen expression by cancer cells, such as antigen loss or reduction in expression. Eventually, antigen expression may drop below the level necessary for CAR T cells to recognize cancer cells, compromising the durability of the therapy response [1].
Building on a groundbreaking study [2], this study entails developing a series of mathematical models employing integral-partial differential equations to investigate the influence of antigen-mediated resistance mechanisms on therapy outcomes. Tumor cells are assumed to exhibit heterogeneity in terms of antigen expression density, represented as a continuous variable influencing the dynamics of CAR-T cell in vivo expansion and cytotoxicity, encompassing bystander effects. The investigation delves into the contribution of these mechanisms across various biological scenarios, including pre-existing antigen-negative cancer cells and mutations, contributing to a more profound comprehension of pivotal factors influencing resistance to CAR-T cell immunotherapy, as well as assessing the validity and predictability of the developed models in the presence of uncertainties.

TIME-STEPPING FOR NONLINEAR BIOLOGICAL TISSUES: IS FIRST ORDER ENOUGH?

Javier Almonacid[*1] and Nilima Nigam*[1]

[1]*Simon Fraser University*

ABSTRACT

Biological tissues are complex, heterogeneous materials. In the case of skeletal muscle, the quasi-incompressibility of the tissue brings computational challenges that, while known and understood for quasi-static simulations, are still open problems for fully dynamic simulations.

In this talk, we present some recent results regarding time-stepping schemes for finite-element formulations of hyperelasticity. In particular, we discuss the influence of the order in which the variables are discretized (Rothe's method vs. method of lines), as well as the performance of some traditional second-order schemes.

ADJOINT-BASED INVERSION FOR FRICTIONAL PARAMETERS IN EARTHQUAKE SIMULATIONS

Vidar Stiernström[1], Martin Almquist[1] and Eric M. Dunham[2]*

[1]Uppsala University
[2]Stanford University

ABSTRACT

Earthquake cycle and dynamic rupture simulations are promising tools to better understand earthquake nucleation and seismicity. The bulk of the solid Earth is modeled by appropriate partial differential equations of elasticity. Fault friction is modeled by rate-state friction laws, which involve nonlinear relations between fault tractions, slip velocity, and state variables that capture the dependence of frictional strength on the slip history. However, parameters of the friction law, as well as initial stresses, are generally unknown and difficult to constrain. Determining frictional parameters and initial stresses requires inverting seismic and/or geodetic data. The inversion is a PDE-constrained optimization problem where we seek parameter values that minimize the misfit between model output and data.

We propose a gradient-based optimization, where the gradient of the misfit is efficiently computed by solving the adjoint problem. We show that, for linear elasticity coupled to nonlinear rate-state friction, the adjoint problem consists of the same linear elasticity equations, but with linearized rate-state friction. The adjoint friction law and state equation include time-dependent coefficients that are functions of slip velocity and state from the forward problem. Only a special case of this method has been derived previously, for quasi-dynamic cycle models with a boundary element discretization of the linear elastic slip-stress change relation [Kano et al., 2013].

To discretize the elastic wave equation, we use summation-by-parts (SBP) finite differences. The fault interface conditions are imposed weakly, using simultaneous approximation terms (SAT), which are based on characteristic variables to avoid excessive stiffness from the friction law [Erickson et al., 2022]. We prove that this SBP-SAT discretization is dual-consistent, meaning that the adjoint of the discretized forward problem is a stable and consistent discretization of the adjoint problem. Additionally, the computed gradient is the exact gradient of the discrete misfit functional as well as a consistent approximation of the continuous gradient. The former is demonstrated by numerical simulations with a rough fault. Numerical inversions with synthetic data further show that the method is indeed capable of determining frictional parameters.

DESCRIPTION, VERIFICATION, AND VALIDATION OF A THERMO-FLUID SOLVER FOR LASER POWDER BED FUSION MELT POOL SCALE PREDICTIONS

ABSTRACT

The Laser Powder Bed Fusion (LPBF) process is an additive manufacturing technique which achieves consolidation of metal powder using a laser to selectively melt, layer-by-layer, parts of a powder bed. At the melt pool (MP) scale, driving forces include laser heating, solid-liquid phase change, evaporation, and surface tension. Evidence shows that reliable numerical predictions of MP evolution require thermo-fluid solvers modeling all the aforementioned terms [1]. These terms induce strong coupling between the governing equations, requiring additional considerations to ensure accurate resolution. However, few LPBF publications report a complete description of their frameworks: assumptions are not stated and the solution sensitivity to the space and time discretization is rarely assessed. This makes it difficult to reproduce the results and assess their adequacy.

This work provides a thorough description of the open-source thermo-fluid Finite Element (FE) solver Lethe, focusing on its application to MP scale simulations. It features verified and validated solvers required to solve the energy and incompressible Navier-Stokes (NS) equations. It also implements a Volume of Fluid (VOF) method for the evolution of the liquid-gas interface and adaptative mesh refinement to ensure sufficient discretization.

Lethe uses a monolithic approach for the NS equations resolution and implements the continuum surface method to model the fluxes at the liquid-gas interface. Required surface normal and curvature are computed from the VOF solution using L2 projections, thus reducing parasitic velocities. Phase change is resolved using the energy equation, considering implicitly the enthalpy change through the specific heat capacity and latent heat of fusion contributions. Viscous and/or Darcy penalization model the stasis in the solid and drag effects in the mushy zone. The laser heating is a Gaussian heat flux and the evaporation cooling is implicitly treated.

The solution’s sensitivity to space and time discretization is presented for static, rising, and thermocapillary droplet cases and capillary wave propagation benchmarks. Finally, results for LPBF cases are presented, focusing on the time evolution of the MP dimensions for the stationary and moving laser irradiation of bare plates presented in the experimental work of Cunningham et al. DATA-DRIVEN MULTISCALE MODELING

NR Aluru[1]*

[1]The University of Texas at Austin

ABSTRACT

The breakdown of classical constitutive theories for problems in mechanics (fluids, solids, thermal, etc.) at the nanoscale require the inclusion of electron correlations and atomic scale interactions. Furthermore, in many areas of mechanics, new physics arises at small scales that makes the use the continuum theories questionable. These, and many other issues, require the development of theories and computational approaches that seamlessly integrate physics from the quantum scale to the continuum scale to accurately resolve the length and time scales encountered in nanomechanics problems. This talk will focus on two aspects – first, we will discuss how deep learning can be used to bridge ab-initio to continuum scales. As a demonstration example, we will show how the structure of confined soft matter can be accurately resolved using deep learning-based multiscale theory. Second, we will demonstrate that deep learning methodologies can be used to model problems involving phenomena such as electron transfer processes, chemical reactions, and transport.

TOWARDS THE INVERSION OF GEOPHYSICAL DATA GENERATED WITH PARAMETRIC PDES THROUGH DEEP LEARNING

Julen Alvarez-Aramberri[1], Ángel Javier Omella[1] and Vincent Darrigrand[2]*

[1]University of the Basque Country (UPV-EHU)
[2]CNRS-IRIT

ABSTRACT

Deep learning (DL) techniques have become more powerful for simulating and inverting geophysical problems, enabling fast real-time solutions to invert problems by training Deep Neural Networks (DNNs) (see, for instance, [1,2]).

However, to produce reliable and robust results, DL methods need customized design choices specific to the problem being solved and the available data. Indeed, one of the main challenges is obtaining sufficient data that connects variations in the problem's model parameters with the solution of the forward problem, which is often stated as a Partial Differential Equation (PDE).

Thus, this work analyzes the impact of the quantity and quality of the data on DL inversions and also examines how the selection of the loss function might affect the results. For that, we generate synthetic measurements for problems with geophysical interest using a massive data generator based on a Goal-Oriented hp-adaptive Finite Element Method (FEM) [3]. Our initial findings suggest that this approach can provide valuable insights for solving inverse problems with DNN techniques that require data.

ABSTRACT

Predicting buckling loads in spherical shells is essential in a wide range of applications, from industrial tanks and pressure vessels to critical aerospace engineering components. Buckling is highly sensitive to defects or geometric variability, as characterized by the knockdown factor (reduction in buckling load for imperfect shells). For non-trivial shells this factor is an empirical value – the ratio between the measured buckling load and the prediction for a perfect shell [1]. However, the testing procedure is usually destructive and unsuitable for practical applications. Circumventing the experimental route became possible with the advent of finite element analyses, as these simulations can reliably predict the knockdown factor when the geometry is known in detail. Nevertheless, obtaining predictions for practical shells with multiple defects still involves significant computational resources [2].
We created Graph Neural Network (GNN) surrogate models to address this challenge by leveraging GNNs' ability to predict the buckling response efficiently. We explore the benefits of GNNs in reducing mesh dependency and handling arbitrary and complex domain shapes. We also characterize GNNs' limitations, particularly in dealing with large node numbers, proposing a practical strategy that properly balances between mesh refinement and the integration of far-field phenomena [3]. We demonstrate the advantages of the proposed strategy in the context of buckling of spherical shells, but we believe that the methodology is applicable in different contexts.

VALIDATING 3-AXIS MECHANICAL SHOCK ENVIRONMENTS WITH NONLINEAR DYNAMIC MODELS

Tyler Alvis[*1] and Mikhail Mesh*[1]

[1]*Sandia National Laboratories*

ABSTRACT

It is important to confirm components and systems will survive their intended environments through testing before the system is finalized. Additionally, it is more cost effective to perform component tests throughout the design process. These components are tested in the laboratory and are commonly tested uniaxially. However, it is possible that a uniaxial test requires a larger input force to reach the desired response than a 3-axis response would require. The larger force in the uniaxial test can cause damage to the component, even though the real input from the environment would not case the damage. Multi-axis testing is therefore desirable, though it is more complicated and time consuming for test engineers to design and calibrate the test fixtures to reach the desired loads. To improve the test design process, the test fixture can be modeled computationally to quickly iterate through designs. In extreme shock environments, it is important to capture the nonlinear behavior of the system. These nonlinear features include large displacements, nonlinear material behavior, contacts, preloads, and friction. Shock tests examined in this work are performed by launching an aluminum projectile from an air gun into a resonant plate fixture to impart the shock into the unit under test that is mounted on the plate. In the explicit dynamics analysis procedure initial velocity is applied to the projectile and collision of the projectile and plate is simulated. This process allows to avoid any simplifying assumptions, including approximations of the input force. It has been discovered that results are sensitive to the models used to represent nonlinear materials such as felt and rubber, that are utilized for tuning of the input forces. Special attention has been paid to tuning those models to achieve desired behavior, particularly with respect to damping characteristics. This presentation explores effects of those materials and other nonlinear characteristics as well as various other features of the model. Commonly depreciated aspects of the model, such as threaded inserts or the preload of bolts, are modeled to evaluate their necessity to the model. Simulation results are compared to the test data. Validating the modeling methods used will ensure trust for future test fixture designs.

NON-LINEAR DIMENSIONALITY REDUCTION METHODS IN NON-NEWTONIAN FLUID MECHANICS

Fabio Amaral[*1], Cassio Oishi[1] and Steven Brunton[2]*

[1]São Paulo State University
[2]University of Washington

ABSTRACT

Simulating complex fluid dynamics involves computational challenges, such as the numerical solution of full-order models associated with parametric nonlinear partial differential equations. In recent decades, the construction of reduced-order models based on machine learning techniques has emerged as an elegant alternative to mitigate the computational costs associated with solving high-dimensional problems. In this context, dimensionality reduction methods are crucial for managing with the reduced coordinates extracted from data.

Nonlinear dimensionality reduction methods offer advantages in comparison with traditional techniques adopted in fluid mechanics, like Proper Orthogonal Decomposition (POD). In general, these nonlinear strategies achieve effective reconstructions with minimal mode usage. Autoencoders (AE) stand out as a common nonlinear dimensional reduction method across various applications. Additionally, Kernel Principal Component Analysis (KPCA) serves as an alternative nonlinear method, extending the capabilities of POD through non-linear kernels. It is worth to notice that both linear and nonlinear methods have been widely applied in the context of Newtonian fluid flows [1].

By considering a class of non-Newtonian fluids, known as viscoelastic fluids, our study demonstrate that nonlinear methods capture dynamics in a way that reconstructions preserve essential characteristics, such as the mechanical energy of the problem. This is particularly significant for viscoelastic flows, where elastic energy is often overlooked in favor of kinetic energy during reconstructions. This aspect also highlights the importance of choosing the right metric when working with different types of flow. Furthermore, viscoelastic problems presents a set of new parameters for the fluid, leveraging the interest for parametric reductions, which the non-linear models also shows better results when compared with POD.

The selection of an appropriate method extends beyond accurate reconstructions; it significantly influences downstream applications, such as reduced order models. We illustrate how the careful selection of nonlinear methods can enhance reconstructions, facilitating the application of reduced order techniques like Sparse Identification of Nonlinear Dynamics (SINDy).

Our study contributes to the discussion of viscoelastic fluid flows by comparing linear and nonlinear dimensionality reduction methods. The use of nonlinear kernels may recover more information due to the nonlinear nature of the problem, shedding light on the nuances between linear and nonlinear approaches.

PHYSICS-GUIDED HEAT SOURCE FOR TRANSIENT LASER ABSORPTANCE PREDICTION IN METAL ADDITIVE MANUFACTURING

Abdullah Amin[*1], Robert Lowe[1], Nishat Sultana[2] and Wing Kam Liu[3]*

[1]*University of Dayton*
[2]*University of Cincinnati*
[3]*Northwestern University*

ABSTRACT

In the realm of Laser Powder Bed Fusion (LPBF) Additive Manufacturing (AM), properly quantifying laser energy absorption is a pivotal and requisite first step for accurately simulating the physics of laser-material interactions. Because, when higher laser energy is observed in other words, at higher Volumetric Energy Density (VED), a vapor depression zone (keyhole) form. This formation of keyholes significantly influences the energy absorption rate, the melt pool dynamics and, ultimately, the quality and properties of the as-manufactured part. The traditional approach for modeling and predicting laser energy absorption is purely physics-based and employs ray tracing to determine the laser ray paths. Although effective, this approach is computationally expensive and thus presents significant practical challenges when applied to part-scale analyses. Thus, to advance the state of the art in simulating the LPFB AM process, there is a need for novel modeling approaches that better balance high-fidelity capture of laser absorption with practical levels of computational expense. To address this compelling research opportunity, we have developed a “physics-guided laser heat source,” an innovative solution designed to approximate and replace the resource-intensive ray tracing method. This approach involves an in-house-developed C++ code that employs physical laws derived from synchrotron X-ray visualization (solved by the Finite Volume Method (FVM)) coupled with sphere radiometry measurements for a more accurate laser heating model. Predictions obtained from our new physics-guided heat source are compared to (a) a physics-based simulation using ray tracing in ANSYS and (b) experimental measurements under seven different test conditions on a powderless bare IN718 plate. Our results exhibit excellent agreement with both the experimental data and the physics-based model, achieved at an order of magnitude lower computational cost. This advanced yet more efficient computational modeling approach is poised to significantly enhance the simulation of multi-layer and multi-track scan paths in LPBF processes. Consequently, the developed method holds great promise for accurately simulating part-scale LPBF processes, including keyhole porosity and lack-of-fusion porosity.

ABSTRACT

Predicting flow in pore-scale porous media is pivotal across diverse scientific and industrial fields due to its impact on the intricate dynamics of microscopic fluid movements. For instance, in environmental engineering, the pore-scale flow prediction plays a crucial rule for devising effective pollution control and remediation techniques. The current study aims to develop a hybrid training dataset that incorporates turbulent numerical simulation results and experimental data to predict the transient flow behaviour and thermal performance of a metal foam heat exchanger. This prediction is accomplished through the application of a deep forward neural network-boundary condition (DFNN-BC) model. A novel approach is presented for predicting the passage of transient flow through pore-scale porous media (PSPM), covering a broad range of two input parameters namely, Reynolds number ($4{,}000 < Re_{inlet} < 20{,}000$) and pore per inch ($1 < PPI < 40$). The achievement of this objective necessitates precise metal foam geometry as a crucial prerequisite for the analysis. The extraction of the three-dimensional (3D) geometry of metal foam is carried out by employing a convolutional neural network (CNN) on a series of metal foam images. The Optimized CNN architecture consists of 14 layers with learnable weights, where a rectified linear unit (ReLU) activation function is utilised to introduce nonlinearity. Following the provision of the 3D geometry and the validation of the CNN approach, a high-fidelity and double turbulence model based on finite volume (FV) simulation is applied to a localised region of a heat exchanger that incorporates metal foam. The simulation employs the large eddy simulation (LES) method to capture transient flow through the metal foam, while the Reynolds average Navier-Stokes (RANS) model is employed to characterise the flow over the pore-scale porous media (PSPM) and within the free stream. To address the challenges posed by the intricate PSPM, the prediction method updates the boundary condition during each iteration of the loss function solution. Following the validation of the DFNN-BC emulated results using experimental data, the heat transfer coefficient and pressure drop of the metal foam heat exchanger for the entire domain are estimated.

FINITE ELEMENTS AND MATRIX STRUCTURAL ANALYSIS

Behrooz Hassani[1] *and Rama Amiri**[1]

[1]*Ferdowsi University of Mashhad*

ABSTRACT

This reflection centers on a memorable encounter with Professor Reddy in the late Professor Ernest Hinton's office at Swansea University, Wales, UK, in 1994, highlighting the profound impact of Reddy's seminal book on the finite element method. Beyond reminiscence, this article aims to address a pervasive issue in computational mechanics, particularly in material design and nanotechnology fields.

The prevalent terminology of solving truss or frame structures by the 'finite element method' (FEM) has become widespread, creating challenges in dispelling the misconception that structures comprised of prismatic members are and should be addressed using finite elements. The root of this issue lies in finite element textbooks that often fail to differentiate between the 'matrix analysis method (MAM)' and the FEM. Even notable works, such as Professor Reddy's excellent book on FEM, inadvertently conflate these two different techniques.

While both MAM and FEM share similarities in forming member equations in matrix form, assembling them, and solving the resultant system of equations, they differ in the following:
1- MAM is used for discrete structures, while FEM is devised for continuum problems.
2- Contrary to the MAM, in the FEM, the domain of the problem is artificially divided into elements, creating the FE mesh.
3- In analyzing skeletal structures, in MAM, the components of member stiffness matrices are obtained from force-displacement (including moment-rotations) relations. In FEM they are resulted from the assumed shape functions used for the approximation of general displacements, which are polynomials without inherent physical meaning.
4- MAM yields exact solutions, while FEM solutions are approximations. For instance, in an Euler-Bernoulli beam under uniform loading, the exact solution involves a fourth-degree polynomial, whereas FEM approximates it with piecewise cubic functions. This discrepancy is even more pronounced in internal forces and stresses. Another example, exemplified in textbooks, is the suggestion of the need for finite element nodes at locations of point loads on beams. In MAM, by obtaining the end member general displacements and forces the exact solution will be achieved, using statics and strength of materials,

Due to Professor Reddy's significant influence in the community, the author seeks his insight and invites him to write a short note on this issue, which has caused ambiguity in the field.

PHYSICS-BASED IMAGE REGISTRATION USING NEURAL ORDINARY DIFFERENTIAL EQUATIONS

Amirhossein Amiri Hezaveh[*1] and Adrian Buganza Tepole*[1]

[1]*Purdue University*

ABSTRACT

We present a machine-learning framework for registering medical images, where the satisfaction of equilibrium equations in the large deformation regime is the center of attention. In this regard, a multi-objective optimization problem consisting of: i) a predictor step that maximizes a metric of similarity between the registered and target images, ii) a corrector step that minimizes the total potential energy subjected to Dirichlet boundary conditions given by the predictor step.
The equilibrium equations are fulfilled in a weak sense in the corrector step, where a Dirichleth boundary value problem defines the physics problem, with the Dirichlet conditions coming from a predictor registration step. In this regard, analogous to the finite element method, we minimize the potential energy corresponding to the Dirichlet boundary conditions defined by the predictor deformation field. This type of solution procedure avoids us dealing with the calculation of the second-order derivatives existing in the strong format of the equilibrium equations. Additionally, since the fully connected neural networks are not inherently invertible transformations, we rather use neural ordinary differential equations (NODEs). This architecture has strong expressibility, while the invertibility is guaranteed when a small enough time-step is taken in the NODE discretization.
The structure of the presentation is as follows: firstly, we will overview the fundamentals of the large strain theory of elasticity as well as the basis of the finite element schemes that employ similar predictor-corrector schemes to solve the weak form of the governing equations. Subsequently, we describe the main steps of the new method, i.e., the predictor and corrector steps. Several numerical examples are then discussed to highlight the features of the new technique and to understand the registration and physics problems in depth. We extend the formulation from problems of nonlinear elasticity to account for growth and remodeling, which are essential phenomena in describing medical images of living systems. The framework for growth and remodeling is the kinematic split of the deformation gradient into growth and elastic deformations, with the growth component obeying rate equations based on mechanobiology knowledge, and the elastic component contributing to the elastic energy. Finally, we apply the new method to problems of interest: zebrafish wound healing analysis from confocal images, brain atrophy from MRI data, and skin growth from 3D photographs during tissue expansion procedures.

NON-HERMITIAN DEGENERACIES IN BAND STRUCTURE AND MODAL CHIRALITY OF IN-PLANE STRESS WAVES IN LAYERED MEDIA

Alireza Amirkhizi[*1] and Vahidreza Alizadeh*[1]

[1]*University of Massachusetts, Lowell*

ABSTRACT

We study the coupled in-plane wave propagation in layered media with and without linear loss. Using the transfer matrix method, the band structure as well as the modal behavior of such systems are determined. For lossless cases multiple examples of non-Hermitian degeneracies of the band structure (i.e. of the dynamic operator K/M endowed with Bloch-Floquet periodicity and parameterized by the frequency and wave vector component parallel to the layers) are shown with diverse characteristics. In such cases, two neighboring exceptional points bookend an interval with broken phase symmetry. The interval is generally a stop band but it is shown to appear both in double pass bands as well as double stop bands. The chirality of the broken phase modes will be presented and discussed. Scattering off finite layered systems will also be presented based on the calculation of the scattering matrix from the transfer matrix. Degeneracies of permutated scattering matrix are associated with single-sided non-reflectivity, broken phase symmetry, and potential for lasing, when gain media are utilized. Second order EP pairs are shown to appear when (balanced) gain reaches a threshold. Potential examples for higher order (>2) degeneracies are presented.

EFFICIENT WAVE MANIPULATION VIA OPTIMIZATION AND MACHINE LEARNING

Feruza Amirkulova[*1], Tristan Shah[1] and Stas Tiomkin[1]*

[1]San Jose State University

ABSTRACT

Efficient wave manipulation via optimization and machine learning
Feruza Amirkulova, Tristan Shah, and Stas Tiomkin
San Jose State University

In this talk, we will present our recent studies on the efficient design of acoustic metamaterials using traditional approaches such as gradient-based optimization methods as well as advanced machine learning techniques such as deep learning and representation learning combined with model predictive control [1, 2]. Specifically, broadband sound focusing, steering, localization, and Willis coupling are the focus of this talk. We will review recent advances and current challenges encountered during the application of gradient-based optimization [3], deep learning, model-free reinforcement learning [4], and generative modeling [5, 6] in an inverse design of acoustic metamaterials. We will summarize and group existing approaches in the inverse design of metamaterials and then discuss current algorithmic limitations and open challenges to preview possible future developments in metamaterial design. We will present numerical examples in both time and frequency domains for arbitrary 2D planar configurations of cylindrical scatterers including fluid, rigid, and elastic scatterers. Proposed frameworks are not limited to 2D planar cylindrical configurations; they can be extended to consider 3D scatterers as well as to study complex acoustic and elastodynamic wave phenomena in non-periodic and periodic media.

ABSTRACT

This contribution presents recent developments of a Fourier series-based methodology for the numerical analysis of parabolic and hyperbolic partial differential equations (PDEs) with complex boundary conditions. Such a framework is based on a discrete "extension" approach for the high-order trigonometric interpolation of a non-periodic function (i.e., mitigating the notorious Gibb's "ringing" effect), where the ultimate goal is to build high-performance, FFT-speed, dynamic PDE solvers on general (structured, curvilinear) geometries that can provide stable and efficient resolution while faithfully preserving the dispersion/diffusion characteristics of the underlying continuous operators.

In particular, the algorithms presented here extend the class of such methods (known as "Fourier continuation") to encompass variable-coefficient 3D systems, general (curved) 3D domains, 3D parallelization, Neumann-like (e.g., traction or convective flux) boundary conditions, nonlinear/nonstationary (ODE-governed) coupling (e.g., dynamic 0D-coupling), and applications to higher-order PDEs with multiple boundary conditions (e.g., Lagrangian mechanical formulations). The resulting solvers enjoy a number of desirable properties for scientific computation: accuracy by means of relatively coarse discretizations; little-to-no numerical dispersion or diffusion errors; mild (linear) CFL constraints on (explicit) time integration; and efficient parallelization for distributed-memory high-performance computing.

With an eye towards mutual validation of both simulation and experiment, the efficacy of the current state of these tools is demonstrated in the context of some of the collaborative scientific problems that have inspired them, including those in engineering (ultrasonic non-destructive testing and seismic wave propagation [1]), geophysics (seismogenic tsunamis [2]), and medicine (fluid-structure hemodynamics [3, 4], dye diffusion [5, 6]). Performance studies and comparisons to other solvers are additionally presented.

NEW STRAIGHTFORWARD BENCHMARK SOLUTIONS FOR BENDING AND FREE VIBRATION SOLUTIONS OF CLAMPED NANOCOMPOSITE RECTANGULAR THIN PLATE

Dongqi An[*1]*

[1]*Dalian University of Technology*

ABSTRACT

This study presents new straightforward benchmark solutions for bending and free vibration of clamped anisotropic nanocomposite rectangular thin plates by a double finite integral transform method. Being different from the previous studies that took pure trigonometric functions as the integral kernels, the exponential functions are adopted, and the unknowns to be determined are constituted after the integral transform, which overcomes the difficulty in solving the governing higher-order partial differential equations with odd derivatives with respect to both the in-plane coordinate variables, thus goes beyond the limit of conventional finite integral transforms that are only applicable to isotropic or orthotropic plates. The present study provides an easy-to-implement approach for similar complex problems, extending the scope of finite integral transforms with applications to plate problems. The validity of the method and accuracy of the new solutions that can serve as benchmarks are well confirmed by satisfactory comparison with the numerical solutions.

[1]*Seoul National University*

ABSTRACT

Atomic oxygen bombardment is a major threat of degradation of surface materials on reusable spacecraft that pass through the low earth orbit segment. Therefore, ultra-high temperature ceramics (UHTC) have received increasing attention as a potentially promising material to minimize the degradation caused by atomic oxygen impact of surfaces. However, experiments to measure the performance of surface materials in the LEO environment are very difficult and expensive, so it is necessary to build a computational simulation performance evaluation technology that can replace such experiments. As part of this computational analysis, molecular dynamics simulation is attracting attention because by understanding and analyzing material behavior at the atomic level, it is possible to understand the oxidation behavior of surface materials by simulating the collision of atomic oxygen, which is considered to be a major degradation factor of surface materials, and identifying the oxidation mechanism. For molecular dynamics simulation at the atomic level, it is necessary to use a potential that can simulate chemical reactions between atoms called a reactive force field, which can simulate the degradation process caused by atomic oxygen.

The biggest problem of reactive force fields is that there is no potential that simulates the interaction between UHTCs and oxygen, and developing one requires a large amount of quantum chemistry data and a variety of techniques to optimize it. This has the problem of being very costly in terms of time. In order to increase the accessibility of potential development and secure potentials that can simulate chemical reactions between various elements, this study utilized an open source (SIMPLE-NN) that can generate an interatomic machine learning potential. This code uses the (ASE) package, an atomic simulation environment package, TensorFlow, and supports an in-house code for the quasi-Newtonian method. It also features a weighting system based on a Gaussian density function and can develop potentials that are compatible with a molecular dynamics simulation environment called LAMMPS. In the pursuit of formulating a machine learning potential for the improved simulation of ablation on surface materials as candidates for the exterior of reusable spacecraft, a training dataset was meticulously chosen. An iterative learning strategy was then implemented to ascertain the alignment of machine-learned potential energy surface (PES) values with those energies calculated using Density Functional Theory (DFT).

UTILIZING SELF-SIMILARITY FOR SOLUTION VERIFICATION

Steven Anderson[*1]

[1]*Los Alamos National Laboratory*

ABSTRACT

While most problems in computational physics have no known analytic solutions, there are many problems (or classes or problems) which possess important mathematical symmetries. Self-similarity is a type of mathematical symmetry, which is characterized by the lack of characteristic length or time-scales when an appropriate transformation of variables. For example, the set of hydrodynamic Riemann problems are self-similar (in 1, 2, or 3 dimensions) under a simple transformation $\zeta=x/t$. This self-similarity may be utilized in analyzing numerical solutions, as the discrete solution of the original governing equations (in the laboratory frame) may be transformed to the self-similar frame. Of course, in the discrete system, the temporal and spatial discretization introduces inherent length and time scales (i.e., the grid scale). Thus, while the true continuum self-similar solution ought to be unchanging in time (the self-similarity removes any time dependence), the self-similar transformation of the discrete solution manifests effectively as a time-dependent resolution. That is, the self-similarly-transformed numerical solution appears very poorly resolve at early times, but appears to resolve in time. We apply numerical analysis using this self-similar approach to several common problems, including the triple-point 2D Riemann problem and the Sedov blast wave.

SHAPE-MORPHING NONLINEAR SOLUTIONS FOR MODEL ORDER REDUCTION

William Anderson[*1] and Mohammad Farazmand*[2]

[1]*Lawrence Livermore National Laboratory*
[2]*North Carolina State University*

ABSTRACT

We develop methods for fast and scalable computation of reduced-order nonlinear solutions (RONS). RONS is a framework for reduced-order modeling of time-dependent PDEs, where the reduced solution has nonlinear dependence on time-varying parameters. RONS provides a set of explicit ordinary differential equations (ODEs) to evolve the time-varying parameters. These ODEs evolve the parameters so that we minimize the instantaneous error between true dynamics of the PDE and dynamics of the reduced model. Additionally, using the RONS framework, conserved quantities of the governing PDE are easily enforced in the reduced solution. As the number of parameters in the reduced-order solution grows, formation and integration of the RONS equation becomes computationally expensive. To address these computational bottlenecks, we introduce three separate methods: symbolic RONS, collocation RONS, and regularized RONS. These new methods allow applications of RONS to problems which require many parameters in the reduced solution. To demonstrate the efficacy of RONS with these new approaches we consider several numerical examples including simulation of the Kuramoto-Sivashinsky equation and the Fokker-Planck equation in high dimensions. ENHANCING FRACTURE HEALING: INVESTIGATING THE ROLE OF EXTERNAL FACTORS, INCLUDING PARTIAL WEIGHT BEARING AND REHABILITATION, IN ESTABLISHING IDEAL BOUNDARY CONDITIONS

Annchristin Andres[*1], Michael Roland[1], Kerstin Wickert[1], Benedikt Braun[2], Tina Histing[2] and Stefan Diebels[1]*

[1]*Saarland University*
[2]*University Hospital Tuebingen*

ABSTRACT

Understanding the intricate interplay of factors influencing the healing process is paramount to optimizing fracture healing. This study addresses interfragmentary movement and focuses on the central role of partial weight bearing, muscle attachments, and rehabilitation exercises in generating perfect boundary conditions for ideal healing. Considering the dynamic nature of the healing phases - from initial connective tissue to fibrous cartilage to soft callus - we define the fracture stimulus thresholds for each phase depending on the fracture situation. As part of this methodology, healthy subjects (n=20) underwent various partial weight and rehabilitation scenarios. In addition, careful measurements were taken to actively record incorrectly adjusted walking aids and over- and under-weight bearing scenarios. To thoroughly investigate the nuanced effects of partial loading and rehabilitation exercises, state-of-the-art instruments include measurable insoles and hand force sensors from novelTM. These instruments actively facilitated the recording of forces during crutch walking, complemented by using EMG sensors by DelsysTM and XsensTM motion capturing system. The individual collected data are integrated into the AnyBodyTM musculoskeletal simulation system, which enables precise joint and muscle forces and moments computation. The collected monitoring data from five patients with tibia fractures now enable the fit customization for each patient. Digital twins of the respective bone-implant systems are generated based on post-operative clinical imaging, with simulations applying the customized boundary conditions. This customization involves identifying the optimal fracture stimulus and interfragmentary movement for every healing phase, every partial weight bearing, and every rehabilitation exercise typical for a tibia fracture. The subsequent integration and evaluation of this diverse data set through musculoskeletal simulations results in a comprehensive understanding of the factors contributing to perfect boundary conditions for fracture healing. Linking local stresses and strains in the fracture gap to the healing window, cf. [1] and [2] and analyzing the healing progress with an inhouse bone healing model based on [3] help to unravel the complexity of the healing process to ultimately develop strategies for optimal rehabilitation and create ideal conditions for fracture healing.

LARGE EDDY SIMULATION OF FLUID/STRUCTURE INTERACTION OF TWO IN-LINE CYLINDERS IN A TURBULENT FLOW

Pierre-Emmanuel Angeli[*1] and Maria Adela Puscas*[1]

[1]*CEA Paris-Saclay*

ABSTRACT

This work reports the numerical results obtained by the CEA with the in-house CFD software TrioCFD within the framework of an OECD/NEA benchmark focusing on the fluid/structure interaction issue. The experimental facility consists of two in-line cantilever cylinders placed in a thin channel and subjected to vibrations under the effect of a turbulent flow. Experimentally, the average and RMS velocity profiles upstream and behind the cylinders, as well as the time signals of pressure, velocity (in fluid) and acceleration (at the top of cylinders) are recorded. The numerical simulations are performed using the wall-resolved large eddy simulation approach. Two grid sizes are considered in order to estimate the mesh sensitivity. The simulations employ a two-way coupling strategy where the fluid and solid equations are solved separately with two distinct solvers, and the fluid/solid interface is tracked with the Arbitrary Lagrangian-Eulerian (ALE) method. More precisely, we employ an explicit Dirichlet/Neumann time marching algorithm working at each iteration as follows:
(i) resolution of the Navier-Stokes equations in ALE formulation with Dirichlet boundary condition at the fluid/solid interface, yielding the fluid forces and the displacement velocity of the mesh points,
(ii) resolution of the structure equations from the Euler-Bernoulli bending beam model with Neumann boundary conditions (imposed loads), yielding the beam velocity,
(iii) the velocity and normal stress continuity is ensured on the fluid/solid interface,
(iv) the beam velocity and fluid forces are exchanged.
The average and RMS velocity profiles computed downstream of the cylinders are found to be in correct agreement with the experimental measurements, even with the coarse mesh. The vortex shedding frequencies for both cylinders are well recovered. Thus provisional results are encouraging. However, at the time of the present abstract, the results of the simulations with the finest mesh are still pending. The average and RMS velocities, as well as the spectra of velocity, pressure, and cylinder acceleration at given points will be further compared to that recorded experimentally.

ACCELERATING ISOGEOMETRIC ANALYSIS WITH JAX: A HIGH-SPEED GPU-POWERED NUMERICAL PDE SOLVER

Cosmin Anitescu[*1] and Timon Rabczuk*[1]

[1]*Bauhaus Universität Weimar*

ABSTRACT

In this talk, we present a computational framework developed for solving partial differential equations (PDEs) using isogeometric analysis (IGA), leveraging the machine learning framework JAX. Our implementation combines the efficient high order basis of isogeometric analysis with the high-performance computing capabilities of modern GPUs. The solver is designed with a high-level Python interface, inspired by the user-friendly approach of FEniCS, allowing for straightforward formulation and solution of complex PDE problems.

Key features of our solver include its ability to operate at speeds surpassing existing implementations, thanks to GPU acceleration and just-in-time compilation. The solver supports complex multi-patch geometries and various solution strategies, including those based on the weak form (Galerkin method), or the strong form (collocation methods). This versatility ensures that users can select the most appropriate approach for their specific problem, optimizing both accuracy and computational efficiency.

We will demonstrate the solver's capabilities with benchmarks against traditional solvers, showcasing its speed and efficiency. The combination of JAX's automatic differentiation and GPU acceleration with the geometric flexibility of isogeometric analysis opens new avenues for the fast and accurate solution of structural dynamics problems across various scientific domains.

LIMITATIONS OF DISPLACEMENT BASED FINITE ELEMENT METHOD WITH REGARD TO SOLUTION OF PLANE DYNAMICAL PROBLEMS

Danish Ansari[*1], Saravanan Umakanthan[1] and Parag Ravindran[1]*

[1]*Indian Institute of Technology Madras*

ABSTRACT

This work discusses the limitations of displacement based finite element methods with regard to solution of particular types of plane stress dynamic problems. It can be shown analytically that for a finite plate subjected to uniaxial loading, the state of stress at different points in the plate remains uniaxial only if the boundary traction increases linearly with time. It is seen that the lateral strain becomes incompatible when uniaxial state of stress is assumed for the entire plate and the applied boundary traction is harmonic in time. The existing consensus is that the shear and lateral stress components are small in comparison to the applied uniaxial stress, and they can be ignored. To check this assumption, a thin rectangular plate made of a linear elastic material is subjected to uniaxial boundary traction on one end and an appropriate displacement restrain is applied at the opposite end. The traction is temporally varied in linear, sinusoidal and Haversine manner. The appropriate boundary value problem is solved using a commercial displacement based finite element software and a custom multi-field based formulation following the idea in Shankar et al. (2016). The results indicate that the magnitude of the shear stress and lateral stress though small in comparison with the applied uniaxial stress, are nearly 1000 times more than that estimated by the commercial finite element package for sinusoidal and Haversine variation. More importantly, the magnitude of these stresses do not depend on the temporal variation of the boundary traction in case of commercial software but it does in case of the multi-field formulation and analytical solution. This indicates that the results of dynamic analysis using displacement based finite element method should be used with caution.

IN SILICO MODELING OF INTRAMEMBRANOUS AND ENDOCHONDRAL OSSIFICATION USING FUZZY LOGIC

Pieter Ansoms[1], Jos Vander Sloten[1] and Liesbet Geris*[12]

[1]*KU Leuven*
[2]*University of Liège*

ABSTRACT

The most common type of fracture healing is secondary or indirect bone healing. In this type of healing, both intramembranous and endochondral ossification take place. The latter form of ossification is preceded by chondrogenesis and the mineralization of the formed cartilage matrix. Oxygen and nutrients are transported through the blood and reach specific areas of the fracture callus by the growth of new blood vessels (angiogenesis). The perfusion of blood is a key factor that allows both intramembranous and endochondral ossification to take place. Fuzzy logic (computational) models of fracture healing have been developed since 2000 by Ament and Hofer [1], and a significant contribution has been made by Simon et al. [2], incorporating the perfusion of blood into these models. However, the distinction between soft cartilage and mineralized cartilage, and hence, the mineralization of cartilage and the correct implementation of bone formation through a cartilage intermediate, are lacking. This research incorporates the aforementioned distinction and explores the (negative) interaction between cartilage and angiogenesis. In this model, a set of rules determines the growth of three tissues: soft cartilage, mineralized cartilage and woven bone, along with the perfusion of blood. These rules describe the following processes of fracture healing: angiogenesis, intramembranous ossification, chondrogenesis, cartilage mineralization, endochondral ossification and atrophy. Additionally, the hypoxic nature of cartilage is incorporated by a rule describing vascular resistance. To capture the mechanical loading of the tissues, a finite element analysis is performed and distortional and dilatational strains are extracted. The growth over time is captured by the iterative calculation of all input variables (cperfusion, cperfusion, adj., csoft cart., cmin. cart., cwov. bone, cwov. bone, adj., εdist. and εdila.) and output variables (Δperfusion, Δsoft cart., Δmin. cart. and Δwov. bone). Tissue composition and blood perfusion of surrounding elements are regarded as well for angiogenesis and ossification. An ovine experiment, performed by Claes and Heigele [3], was replicated in terms of geometry, applied axial load and external fixator.
Differences between more rigid/flexible fixation are a result of temporal and spatial differences in the formation of tissues, which are caused by the presence of higher strains in the fracture callus in the more flexible case.

NUMERICAL SIMULATION OF THE FOUR-EQUATION TWO-FLUID MODEL FOR ONE-DIMENSIONAL MULTIPHASE FLOW, USING THE FLUX-RECONSTRUCTION (FR) METHOD

Alessandro Antunes[*1], Anderson Nascimento[1], Cleuber Silva[1], Giselle Silva[2], Paulo Lyra[1] and Darlan Carvalho[1]*

[1]*Federal University of Pernambuco*
[2]*Petrobras*

ABSTRACT

In the oil industry, the so-called flow assurance depends on the knowledge of parameters such as speed, pressure and volumetric fractions of the fluids that flow within the production pipelines. Due to the high computational costs involved in simulating flow in oil pipelines, that can have more to 3.0 km length, one-dimensional models are used more frequently in real world applications. Commercial multiphase fluid flow simulators such as ALFAsim and LedaFlow typically uses first-order schemes for the discretization of the advective terms of the flow equations. It is well known that first-order schemes are robust but very inaccurate to the large amount of artificial numerical diffusion introduced. In this context, we propose the use of the very high-order (VHO) flux-reconstruction (FR) method to improve the accuracy and efficiency of the two-fluid model. In our context, the flux-reconstruction method was used to solve the mass conservation equation of the isentropic four-equation single-pressure two-fluid model. To validate the accuracy of our formulation, we present and discuss the numerical results for some benchmark problems. For these problems, our results are very promising and compare quite well with the results found in literature using other classical low and high order methods.

DIRECT NUMERICAL SIMULATIONS OF TURBULENT PULSATING FLOWS THROUGH CURVED PIPES

Gokul Anugrah[*1], Jonathan Wenk[1] and Christoph Brehm[2]*

[1]University of Kentucky
[2]University of Maryland

ABSTRACT

This study is driven by an investigation into aortic dissection, a cardiovascular disease. Direct numerical simulations using an immersed boundary method[1] are conducted to analyze the hemodynamics within a model of the aorta. Pulsating flows with various frequencies are examined for the aorta, conceptualized as a curved pipe with different radii of curvature. A pulsating flow, with different frequencies, is added to a steady base flow, serving as the inlet boundary condition. The average Reynolds number, based on the time-varying inlet flow, is set at 8000, while Womersley numbers of 22 and 32 are considered. Centrifugal effects cause the peak velocity to shift towards the outer part of the curved section. This phenomenon persists even after the flow exits the curved section, with the peak velocity continuing to be directed towards the outer part. Distinct variations in velocity flow fields and Reynolds stresses are noted for different radii of curvature, whereas doubling the frequency of pulsation yields a less pronounced effect. Dean vortices manifest throughout most of the curved section, with the breakdown of these vortices and the transition to fully turbulent flow occurring at different locations for pipes with varying radii of curvature.

Despite a consistent breakdown mechanism, larger curvature ratio pipes experience an earlier transition to turbulence. The average kinetic energy in a cross-section due to the pulsating component increases along the curved section, indicating heightened kinetic energy at the exit. The outer downstream part of the curved section, representing the descending aorta, exhibits a notably high time-averaged wall shear stress index. Additionally, time-averaged pressure attains a higher value at the outer part of the curved section, implying a positive pressure gradient in the radial direction. The implications of fluid dynamic quantities in the development and progression of aortic dissection are discussed.

A GENERALISED DEEP LEARNING MODEL FOR HOMOGENISATION OF MULTIPHYSICS PROPERTIES OF COMPOSITE MATERIALS

Rajesh Nakka[1], Attada Phanendra Kumar[1], Dineshkumar Harursampath[1] and Sathiskumar Anusuya Ponnusami[2]*

[1]Indian Institute of Science
[2]University of London

ABSTRACT

Multifunctional composite materials have gained significant attention in weight-sensitive applications such as the aerospace industry. The optimal design of such materials necessitates evaluation of their multi-physical properties in different loading environments. There exist experimental, analytical and numerical methods for homogenisation of multiphysical composite properties. The experimental approach is highly time-consuming and cost-intensive. Analytical methods can be used for simple cases, but these methods fail to capture the distribution and geometry details of the reinforcements. FEA-based homogenization can be employed to overcome these limitations. Though this approach gives accurate solutions, modelling of statistically equivalent representative volume element (RVE) and choosing appropriate multiphysics boundary conditions is a difficult task. An efficient composite design process requires a simple and faster method for evaluating composite properties. Hence, active research is focused on utilizing machine learning methods to build surrogate models that can predict the properties of interest with the same levels of accuracy as FEA-based homogenization.

Generally, surrogate models are designed to take micro-structure information (in the form of an RVE image, for example) as input and predict its properties [1]. The applicability of the final model depends on the details of the input data or training data, so one must strive to add as much micro-structure information as possible. Further, the existing models developed so far aimed to predict the properties of a single physics as well as a single material system. Having a unified model for predicting multi-physical properties for a wide range of material systems would be beneficial to understanding the response of the composite under various kinds of loads, thus speeding up the design of composites for multi-functional applications. In addition, quite often, surrogate models do not explicitly account for underlying mechanics. The present research aims to embed physics into the surrogate model, an example is the enforcement of homogenisation bounds as a constraint during the model training [2]. In the end, a single physics-respecting CNN-based surrogate model to predict different multi-physical (thermo-elastic, thermal conduction and piezo-electric) properties is presented.

EXAMPLES OF ANALYSIS METHODS FOR ULTRASONIC VIBRATION-ASSISTED MACHINING

Shigeru Aoki[*1]*

[1]*Tokyo Metropolitan College of Industrial Technology*

ABSTRACT

Ultrasonic vibration has been applied to many machining methods and reported to improve machining performance. As examples of machining with ultrasonic vibration, this paper deals with the reduction of welding residual stress, the improvement of machined surfaces in the drilling of laminated materials, and the improvement of machining efficiency in knurling. For each example, the advantages of applying ultrasonic vibration are demonstrated through experiments, and simple analysis methods are proposed to demonstrate the usefulness of ultrasonic vibration.

First, the reduction of residual stress is examined. An experiment was conducted in which welding was performed while ultrasonic vibration was applied. As a result, it was found that tensile residual stress was reduced. Next, since the yield stress near the bead immediately after welding is low, the residual stress was determined by simulation method using a model that takes plastic deformation into account. The results showed that tensile residual stress was reduced for welding while applying ultrasonic vibration. It was also predicted that the higher the amplitude of ultrasonic vibration, the higher the residual stress generated, and the lower the yield stress, the lower the residual stress.

Second, improvement of the machined surface in drilling holes in laminated materials was investigated. Experiments were conducted to drill holes in laminated materials while applying ultrasonic vibration at different drill rotation speeds and feed rates. As a result, it was found that the surface roughness of the machined surface was improved. Next, since the drill is expected to intermittently drill holes in the laminate material in this process, the impulse due to cutting resistance was calculated using a model that takes intermittent cutting into account. As a result, it was found that the surface roughness was improved when the force product without ultrasonic vibration was smaller than or equal to the force product with ultrasonic vibration.

Third, the improvement of machining efficiency in knurling was examined. An experiment was conducted in which knurling was performed while ultrasonic vibration was applied. As a result, it became clear that the indentation machined became deeper when ultrasonic vibration was used. Next, analysis using a mechanical model that takes into account the plastic deformation of the specimen revealed that the use of ultrasonic vibration deepens the indentation.

DEVELOPING DATA-DRIVEN DISLOCATION MOBILITY LAWS FOR BCC METALS

Nicole Aragon[1], David Montes de Oca Zapiain[1], Eric Rothchild[1] and Hojun Lim[1]*

[1]*Sandia National Laboratories*

ABSTRACT

Body-centered cubic metals, such as tantalum, exhibit complex deformation behavior with a significant strength-dependence on temperature and applied stress. To accurately model these materials, it is critical to incorporate accurate dislocation mobility, a fundamental property that determines several characteristics of the plastic deformation. Experimental measurement of dislocation mobility is exceptionally challenging, thus dislocation mobility is often described by a simple empirical model parameterized by atomistic simulations, such as molecular dynamics (MD). These models typically assume fixed model form and parameters are determined by limited dataset. In this work, we utilize genetic programming to perform symbolic regression to establish a phenomenological dislocation mobility law that can easily be incorporated into mesoscale dislocation dynamics models. The proposed model is trained on a comprehensive dataset of MD simulations that characterizes dislocation velocities as a function of stress and temperature. Finally, to leverage the analytical nature of the developed model, dislocation dynamics simulations using the proposed mobility law will be presented.

A DISCONTINUITY-ENRICHED FINITE ELEMENT METHOD FOR MODELING FRACTURE GROWTH IN BRITTLE MATERIALS

Alejandro Aragón[*1], Jujian Zhang[1] and Yuheg Yang[1]*

[1]*Delft University of Technology*

ABSTRACT

Enriched finite element methods such as the eXtended/Generalized Finite Element Method (XFEM/GFEM) have become popular for modeling problems with material discontinuities (e.g., composites and fracture). The main advantage as compared to the standard finite element method (FEM) remains the versatility in the choice of discretizations, since in XFEM/GFEM discontinuities are completely decoupled from the finite element mesh. However, XFEM/GFEM is no without issues, which include the need for stable formulations to bound the condition number of stiffness matrices and the shifting of enrichments to deal with nonzero essential boundary conditions. Modeling complex kinematics such as branching and merging of discrete cracks remains challenging and requires an intricate computer implementations. At worst, it is currently not possible in XFEM/GFEM to recover smooth reactive tractions from boundaries with prescribed nonzero displacements.

Here we introduce the Discontinuity-Enriched Finite Element Method (DE-FEM) [1,2,3] as an alternative procedure to XFEM/GFEM for modeling crack growth in brittle materials. While DE-FEM retains the mesh-geometry decoupling virtue of XFEM/GFEM, it addresses all of its drawbacks by placing enriched nodes directly along discontinuities. Most notably, this is done with a straightforward computer implementation that enables complex kinematics, namely the modeling of multiple crack growth with branching and merging. Numerical examples show the capability of DE-FEM in obtaining accurate stress intensity factors—with an interaction integral that considers the interplay among cracks and in capturing crack patterns similar to those observed in the literature.

DISCOVERY OF EQUATIONS IN HETEROGENEOUS MATERIAL MECHANICS THROUGH MACHINE LEARNING APPROACHES

Yuki Arai[*1]*

[1]*Kindai University*

ABSTRACT

In this presentation, we explore the complex mechanics of heterogeneous materials, such as fiber-reinforced composites, focusing specifically on the stress fields within these materials. Utilizing the AI-Feynman [1][2] algorithm, our aim is to uncover the intricate relationships between variables and to discover equations that sufficiently represent these dynamics.
Conventionally, stress evaluation of heterogeneous materials has been performed by numerical simulation on a per-case basis. This approach is expensive and resource intensive, especially for probabilistic evaluations.

AI-Feynman creates a dataset that follows the basic equations found in Feynman physics textbooks and identifies the physical equations from the data. In our research, applying the AI-Feynman algorithm to datasets generated from numerical simulations enables us to probe inherent non-linear interactions and dependencies, offering insights into the mechanics of complex heterogeneous materials.

In this presentation, we will introduce the details of the problem setting and the AI-Feynman algorithm. Additionally, we will discuss the results of the equations that have been discovered. In conclusion, the validity and effectiveness of this approach in the mechanics of heterogeneous materials will be discussed.

The significance of this study lies in broadening the application scope of machine learning in engineering. Utilizing AI-Feynman reveals critical variables and their interdependencies under complex stress conditions in materials like fiber-reinforced composites, providing new understandings and unprecedented insights, and potentially contributing to new theoretical comprehensions.

A GENERAL HIGHER-ORDER SHELL THEORY USING ORTHONORMAL MOVING FRAME FOR TRANSVERSELY ISOTROPIC HYPERELASTIC MATERIALS

Archana Arbind[1]*

[1]*Indian Institute of Technology Kharagpur*

ABSTRACT

This study presents a general higher-order shell theory to analyze the large deformation of tubular shell structures made of transversely isotropic hyperelastic materials. The salient feature of this shell is threefold: (i) this shell theory formulation has been done using an orthonormal moving frame (OMF) instead of the classical natural covariant frame, which makes the mathematical formulation relatively simpler even for very complex hyperelastic constitutive relation owing to the orthonormal nature of basis vectors; (ii) General-higher order nature of approximation through-thickness of the shell make it equipped to model the deformation of a thin shell as well as thick shell, and at the same time it also removes thickness stretch associated numerical locking, and (iii) the constitutive relations of transversely isotropic hyperelastic material, both stretch and invariant based, are considered eying application in the vascular mechanics. The displacement field of the line normal to the shell reference surface is approximated by general power series polynomials for single-layer shell structure. Subsequently, the kinematics of the shell for orthonormal basis has been derived. It has been shown by Arbind, Reddy, and Srinivasa in [1] that such a coordinate system makes it possible to represent kinematic quantities, e.g., determinant of the deformation gradient, far more efficiently than the in the classical tensorial representation with covariant basis. This study can be regarded as an extension of [1] for incompressible/compressible anisotropic softshells. Here, for a general shell surface geometry, the weak form finite element formulation of the shell theory is presented. Further, the theory has been applied to large deformation analysis of tubular structures, such as biological tubes, under internal pressure. For incompressible material, incompressibility constraint has been applied via the penalty method and the Lagrange multiplier method. For the post-buckling analysis, a nonlinear finite element formulation considering the arc-length method has also been presented. Various numerical examples are shown to verify and validate the formulation presented in this study.

Keywords: Higher-order shell theory, thin or thick shell structure, transversely isotropic hyperelastic materials, analysis of curved tubular shell.

A HIGHER ORDER FINITE VOLUME MULTILEVEL WENO SCHEME FOR MULTIPHASE FLOW IN POROUS MEDIA

Todd Arbogast[*1], Chieh-Sen Huang[2] and Chenyu Tian[1]*

[1]*The University of Texas at Austin*
[2]*National Sun Yat-sen University*

ABSTRACT

We present a multi-level weighted essentially non oscillatory (ML-WENO) reconstruction on general computational meshes for solving partial differential equations exhibiting advection and degenerate diffusion. The reconstruction combines stencil polynomial approximations of various degrees, including constants, defined on any set of stencils that need not be arranged hierarchically. The nonlinear weighting biases the reconstruction away from both inaccurate oscillatory polynomials of high degree (i.e., those crossing a shock or steep front) and smooth polynomials of low degree, thereby selecting the smooth polynomial(s) of maximal degree of approximation. We also give a general result for determining when a stencil polynomial approximation is accurate. The reconstruction leads to a very general finite volume scheme that can handle shocks or steep fronts in the solution. We apply our new ML-WENO scheme to problems in two-phase flow in porous media.

[3]University of Chicago
[4]The Pennsylvania State University

ABSTRACT

Recently, several deep learning-based models for weather forecasting have been demonstrated with skill approaching or even exceeding traditional numerical weather prediction (NWP). These models include Graphcast, Fourcastnet, FuXi, Pangu-weather, ClimaX, and the AIFS, each with vastly different training methods, machine learning architectures, and variables predicted. It is unknown whether these complex architectures are needed or what part of their training protocols are necessary to achieve their impressive results for medium-range weather forecasting.

Here we introduce Stormer, a simple transformer-based model that achieves state-of-the-art performance on weather forecasting with minimal changes to the standard transformer backbone. Using several ablations studies, we identify the key components of previous work as well as develop new methodology, including weather-specific embedding, randomized dynamics forecast, and pressure-weighted loss, to improve deep learning-based weather forecast models. At the core of Stormer is a randomized forecasting objective that trains the model to forecast the weather dynamics over varying time intervals. During inference, this allows us to produce multiple forecasts for a target lead time and combine them to obtain better forecast accuracy. Stormer performs competitively at short to medium-range forecasts and outperforms current methods beyond 7 days, while requiring orders-of-magnitude less training data and compute. We also investigate downstream applications for our newly developed model. Specifically, to perform data assimilation using real, in-situ observations of the atmosphere and for uncertainty quantification using a combined initial condition and model-based ensemble system.

GRADED ARRAYS OF RESONATORS AND MACHINE LEARNING FOR THE RECONSTRUCTION OF ELASTIC WAVE SIGNALS

Luca Iorio[1], Luca Rosafalco[1], Jacopo Maria De Ponti[1] and Raffaele Ardito[*1]*

[1]Politecnico di Milano

ABSTRACT

In the recent literature, it has been proven that graded arrays of resonators can significantly increase the displacement amplitude of the resonating components [1], with important applications in the field of energy harvesting via piezoelectric patches [2]. As a matter of fact, such metamaterials are highly efficient in the localization of elastic waves and in the amplification of local fields. Such a feature is harnessed in the transduction of elastic energy into electrical energy. On the other hand, the array of resonators, equipped with piezoelectric material, could be used as a sensor for elastic waves. The proposed device exploits the aforementioned amplification and the specific circuits connected to the piezoelectric patch, in order to reconstruct the temporal pattern of an elastic wave. To that purpose, we propose an elastic waveguide, in the form of a slender beam, equipped with an array of paired resonators, operating in close proximity to their first resonance frequency. In view of the rainbow effect, the elastic signal is physically separated into its frequency contents, with a selective excitation of the elements in the array. The piezoelectric patches on each pair of resonators are electrically connected in series, so that it is possible to halve the number of output channels and to double the generated current. The analysis of the signal retrieved from each pair of resonators is carried out by means of an encoder-decoder model, that is designed with the aim of reconstructing the input signal. The typical computational schemes of machine learning are adopted. The selective amplification enables the development of a wave analyzer with an increment of the signal-to-noise ratio. The proposed approach can be adopted to reduce the power consumption of the electronic device that are customarily adopted for signal interpretation. The research activity has been carried out with the support of the H2020 FET-proactive Metamaterial Enabled Vibration Energy Harvesting (MetaVEH) project under Grant Agreement No. 952039

MULTI-FIDELITY AND SURROGATE MODELING APPROACHES FOR UNCERTAINTY QUANTIFICATION IN ICE SHEET SIMULATIONS

Nicole Aretz[*1], Karen Willcox[2] and Max Gunzburger[2]*

[1]*Oden Institute of Computational Engineering and Science*
[2]*Oden Institute of Computational Engineering and Sciences*

ABSTRACT

This work uses multi-fidelity and surrogate modeling to achieve computationally tractable uncertainty quantification (UQ) for large-scale ice sheet simulations. UQ is of utmost importance to enable judicious policy decisions combating climate change. However, high-fidelity models are typically too expensive computationally to permit Monte Carlo sampling. To reduce the computational cost while achieving the same target accuracy, we use multi-fidelity estimators such as Multi-Fidelity Monte Carlo to shift the computational burden onto less expensive surrogate models derived from coarser discretizations and approximated physics. Albeit sufficient to achieve some improvement over Monte Carlo, with the large size and complex geometry of ice sheets like Greenland and Antarctica these surrogates are still expensive to evaluate. To fully exhaust the capabilities of multi-fidelity estimators in face of the intrinsic low-dimensionality of the high-fidelity solution manifold, we would employ projection-based reduced-order models (ROMs). These typically 1) achieve significant computational savings in the order of several magnitudes, 2) guarantee approximation accuracy through established error theory, and 3) remain interpretable through the governing physical equations of the high-fidelity model. However, constructing ROMs via projection requires access to the full-order operators — a significant shortcoming for large-scale ice sheet solvers with legacy codes. We circumvent this requirement with Operator Inference, and lean the intrusive ROM from available full-order data and the structure of the governing equations. Since Operator Inference is sensitive to regularization for high-order polynomial terms, as are present in the shallow ice equations, we employ a nested Operator Inference variant to further exploit the projective structure and lessen the data requirements. We present examples for multi-fidelity simulations of the ice mass loss in Greenland.

MIXED ISOGEOMETRIC METHODS FOR HODGE–LAPLACE PROBLEMS INDUCED BY SECOND-ORDER HILBERT COMPLEXES

Jeremias Arf[*1] and Bernd Simeon*[1]

[1]*RPTU Kaiserslautern-Landau*

ABSTRACT

Through the seminal works of Buffa et al., the fruitful integration of the two discretization paradigms of Isogeometric Analysis (IGA) and Finite Element Exterior Calculus (FEEC) was demonstrated already in 2011. The latter concept explores and provides design steps for the approximation of so-called abstract Hodge–Laplace problems, which, in turn, represent PDEs derived from Hilbert complexes. The introduction of isogeometric discrete differential forms in [1] laid the foundation for discretizing classical de Rham complexes in a structure-preserving manner using B-splines, meaning the discretization of Hodge–Laplace problems derived from de Rham sequences. Although the FEEC theory was developed for general closed Hilbert complexes, and while Hilbert sequences play a role in various physical applications, connecting IGA and FEEC often proves challenging or is sometimes not directly clear. This is especially true for Hilbert complexes that also encompass differential operators of higher orders.

We present two approaches to obtain well-posed discretizations of a whole class of Hodge–Laplace problems using IGA, while maintaining the inf-sup stability condition. We focus on mixed weak formulations of saddle-point structure and second-order Hilbert complexes. In particular, we go beyond the standard de Rham case and demonstrate that ideas from FEEC and IGA are useful for non-de Rham chains as well. A central tool for describing the underlying settings and for choosing the finite element spaces is the Bernstein–Gelfand–Gelfand (BGG) construction considered by Arnold and Hu in [2]. Our approach allows us to incorporate geometries with curved boundaries, which is not directly possible with classical FEEC approaches, and also provides suitable discretizations in arbitrary dimensions. We show error estimates for both approximation methods and explain their applicability in the field of linear elasticity theory. The theoretical discussions and estimates are further illustrated with various numerical examples performed utilizing the GeoPDEs package [3].

EFFICIENT SENSITIVITY ANALYSIS ON A SIMPLE LASER POWDER BED FUSION BUILT USING HYPAD-FEM

Juan-Sebastian Rincon-Tabares[1], Mauricio Aristizabal[1], Arturo Montoya[1], Harry Millwater[1] and David Restrepo[1]*

[1]The University of Texas at San Antonio

ABSTRACT

Metal Laser Powder Bed Fusion Additive Manufacturing (LPBF-AM) is revolutionizing the global manufacturing industry due to the design flexibility of the process that allows fast innovation and production of optimized complex-shaped components. However, the transformative potential of LPBF-AM remains unrealized due to the need for reproducibility and reliability. These pitfalls create uncertainty in the performance of the fabricated parts due to the unmeasured influence of LPBF-AM process parameters. Modeling and sensitivity analysis have become promising approaches to measuring parameters' influence and overcoming these issues. This study introduces a methodology to perform an efficient sensitivity analysis on a simple build of LPBF-AM. The methodology implements HYPercomplex-based Automatic Differentiation (HYPAD) within traditional FEM formulations (which is known as HYPAD-FEM) to deliver fast and accurate sensitivity solutions [1]. HYPAD-FEM can simultaneously obtain multiple first and high-order sensitivities to initial conditions, load conditions, thermal properties, powder bed properties, or shape with a single average sample [2,3]. Using this methodology, one can exploit the full fidelity of a model to obtain fast and accurate sensitivities from the whole simulation, which are usually limited by computational cost and subtraction errors. The methodology is verified using a model that consists of a laser sequentially melting Ti64 powder layers on top of a bedplate in a rectilinear track. The model can handle property variations due to temperature, phase change, solidification, and a mobile energy beam source. This research is essential for understanding the performance variations due to the process parameters governing the LPBF-AM and determining best practices for improvement. Also, this study provides a crucial step towards enhancing the reproducibility and reliability of LPBF-AM, offering valuable insights for process optimization and part qualification.

[2]*FIRE1*

ABSTRACT

Accurate assessment of a patient's volume status is crucial in clinical practice, given the significant impact of hypovolemia and hypervolemia on morbidity and mortality rates, especially in heart failure and critical illness [1]. The inferior vena cava (IVC), crucial for systemic venous return, serves as a potential indicator for fluid responsiveness and volume status evaluation, often assessed indirectly through external ultrasound methods. However, the complexity of ultrasonographic volumetric assessment of the IVC, influenced by challenges such as the respiratory cycle, limits its clinical adoption. Understanding the intricate interplay between the respiratory cycle, IVC geometry, and collapse is essential for accurate interpretation.

This study aims to investigate collapsible tube phenomena, focusing on an idealized geometry resembling the IVC. We develop a numerical simulation framework to accurately represent IVC physiology and examine alterations in collapse across three distinct volume statuses: euvolemia, hypervolemia, and hypovolemia.

The idealized IVC model construction and computational solid and fluid models were conducted using ANSYS Workbench 2021R2, employing Mechanical and Fluent as solvers for structural and fluid dynamics, respectively. The IVC wall behavior was simulated using an isotropic, incompressible, 3rd order Ogden hyperelastic material, with external abdominal pressures during expiration and inspiration modeled with a constant pressure distribution applied to the outer wall.

We present a qualitative comparison of model deformation across different volume statuses and respiratory phases, revealing significant deformation in hypovolemia during both inspiration and expiration, while hypervolemia results in vessel expansion due to negative transmural pressure. Notably, euvolemia demonstrates distinct differences in inspiratory and expiratory areas compared to hypovolemia and hypervolemia.

The computed Pressure-Area curves provide valuable insights, with euvolemia displaying significant changes between respiratory phases. The agreement between our results and literature findings validates the reliability of our simulations [2,3].

In conclusion, this study offers foundational insights into the biomechanics of IVC-like vessel collapse, paving the way for further research to refine computational models, enhance clinical applicability, and deepen our understanding of collapsibility dynamics in various physiological and pathological contexts. Additionally, we are currently working on performing the same study with more realistic simulations by

implementing patient-specific data, which will not only enrich our findings but also help validate the robustness of our results.

APPLICATION OF VARIATIONAL DATA ASSIMILATION TO HIGH-SPEED OUTFLOW BOUNDARY-VALUE PROBLEMS OF THE IDEAL MAGNETOHYDRODYNAMICS EQUATIONS

Jose Arnal[*1] and Clinton Groth[1]*

[1]*University of Toronto Institute for Aerospace Studies*

ABSTRACT

Over the last several decades, considerable effort has been devoted to the development of accurate and efficient simulation methods for a range of space-physics phenomena based on global magnetohydrodynamics (MHD) descriptions and the solution of the equations of ideal MHD. Some notable examples include [1, 2, 3]. Despite the sophistication of these techniques, their accuracy in practice is very often limited by uncertainties in model input parameters. These uncertainties can become particularly evident in the forecasting of transient space-weather events, where the specification of appropriate initial and boundary data can be a significant challenge. The application of data assimilation techniques in which observational measurements are incorporated to constrain model uncertainties offers a means of improving the predictions of global MHD models. To this end, this study presents the first application of a variational-based data assimilation strategy to boundary value problems for the three-dimensional ideal MHD equations, with a systematic treatment for the solenoidal constraint associated with the magnetic field. In the proposed approach, synthetic in-situ data for prototypical steady high-speed MHD outflows representative of the solar wind are considered and model-data mismatch is efficiently minimized via an optimization procedure that makes use of a discrete adjoint method in the evaluation of model parameter gradients. Details of the finite-volume solution method for the ideal MHD equations as well as the data assimilation algorithm for the inner boundary data of the MHD outflows will be provided. Additionally, a number of observing system simulation experiments will be presented, demonstrating the error-reduction capabilities of the proposed variational data assimilation framework.

MECHANICS INFORMED RECONFIGURATION AND MEMORY FORMATION IN SOFT MULTISTABLE STRUCTURES

Juan Osorio[1] and Andres Arrieta[*1]*

[1]Purdue University

ABSTRACT

Shape adaptation in materials and structures enables multifunctionality by leveraging different geometrical configurations. These multifunctionality and adaptability stem from the property, form, and function relationship in which any variation in one results in changes in the other. One avenue for exploiting this relationship leverages geometrical multistability, the property of a system to exhibit several stable states that depend solely on the architecture independently from the material constitution. One roadblock impeding the implementation of multistable structures into engineering systems is the difficulty of designing functional shapes associated with each of their stable states. A class of multistable behavior characterized by strong order-dependence to inputs (also referred to as non-abelian response), referred to as hierarchical multistable, offers opportunities for embodying reconfiguration and memory. Furthermore, the mechanics of such hierarchical multistable structures inform the possible shapes and memory capacity of such structures, thereby providing a route towards their rational design.
We leverage the underlying mechanics of hierarchically multistable structures to realize physical systems that combine shape reconfiguration with memory formation. We demonstrate the utility of embodying reconfiguration and memory formation for the rational design of soft robots that display the features of temporal finite state machines (FSM) that yield different output shapes depending on the recorded sequence. We show how embodying into the structural response this type of temporal FSM strategy offers a new route for controlling soft robots without sensors and closed-loop control. Exploiting the nonlinear mechanics of multistable structures to the designer's advantage allows for physically embodying memory and computation, thereby providing a blueprint for encoding sense-compute-actuate loops in purely mechanical systems that resemble functions characteristic of the peripheral neural system in organisms.

BIRDSHOT: A FRAMEWORK FOR THE ACCELERATED DISCOVERY AND OPTIMIZATION OF ALLOYS

Raymundo Arroyave[*1]

[1]*Texas A&M University*

ABSTRACT

In this talk, we present the Batch-wise Improvement in Reduced Design Space using a Holistic Optimization Technique (BIRDSHOT) framework and its application to the efficient discovery of Refractory High Entropy Alloys (RHEAs). BIRDSHOT incorporates the strengths of ICME and combinatorial methods, while addressing all their drawbacks, as it: (i) employs novel machine learning (ML) and data-driven search algorithms to identify efficiently the feasible regions amenable to optimization; (ii) exploits correlations to fuse simulations and experiments to obtain efficient ML models for predicting PSPP relations; (iii) uses Bayesian Optimization (BO) to make globally optimal iterative decisions regarding which region in the RHEA space to explore/exploit, leveraging existing models and data; (iv) is capable of carrying out multiple optimal parallel queries to the design space. In this work, we apply our BIRDSHOT framework to efficiently explore and exploit the RHEA space, with a focus on the accelerated discovery of refractory alloys as potential replacements of state-of-the-art Ni-based superalloys used in gas turbine engines (GTEs). Our work considers a large number of application-relevant objectives and constraints. The framework first reduces the design space through a combination of CALPHAD-based phase stability predictions, physics-based as well as machine-learning models to identify the feasible space amenable for further investigation. Using advanced design-of-experiment protocols, we select an initial alloy set to explore. These alloys are in turn synthesized, homogenized, and processed in order to characterize their mechanical properties (including limited experiments at elevated temperatures) as well as their oxidation resistance. “Digital twins” of the same alloys are investigated using DFT-based calculations. Theoretical criteria for ductility extracted from these calculations are used for further screening of the alloy space. Our framework is further enhanced by augmenting the thermodynamic database using a theory-only high-throughput CALPHAD approach in addition to traditional CALPHAD-based thermodynamic assessment of phase stability based on literature and data generated from our own experimental investigation. Initial data is then fed into an advanced multi-information source, multi-objective, multi-constraint batch-based Bayesian Optimization approach to carry out an iterative search for increasingly improved refractory alloys.

URBAN FLOOD MAPPING USING SPH METHOD AND PRECIPITATION DATA BASED ON LIDAR DATA

Mehrad Artkeli Farahani[*1], François Morency[1] and Sacha Leprêtre[2]*

[1]École de technologie supérieure (ETS)
[2]CAE Inc.

ABSTRACT

Urban floods are among the most dangerous and devastating natural hazards with extreme and undeniable consequences. With the recent creation of freely accessible, high-accuracy Light Detection and Ranging (LiDAR) data at 1-meter resolution, one approach to mitigate flood risk involves pinpointing inundated areas through detailed flood mapping. Incorporating the precipitation data can improve the realism and accuracy of flood simulation due to its ability to provide invaluable insights regarding the quantity and spatial distribution of rainfall. Urban flooding's intricate flow patterns, influenced by structures and obstacles, challenge traditional Eulerian models. Smoothed Particle Hydrodynamics (SPH), a meshfree approach, offers a possible solution as it mitigates grid generation and mesh distortion issues.

This study aims to identify inundated areas by producing flood mapping using the SPH method and LiDAR data. DualSPHysics, an open-source code developed based on the SPH method, is used to map the urban flood. However, SPH models are generally more computationally demanding than grid-based approaches. Therefore, this code is accelerated by high performance computing and modern graphic processing units (GPUs), and its Lagrangian nature facilitates the tracking of flood particles in the simulation.

For this research, 1 km² of LiDAR data from Montpellier City in France, which is highly prone to flooding, is selected. The city geometry serves as a fixed solid boundary condition, and the dynamic boundary treatment is used to simulate fluid particles. In the SPH method, dynamic particles are fixed on the boundaries. As a fluid particle approaches the solid boundary, the density and pressure of the dynamic particles escalate, leading to an augmentation in the magnitude of the repulsive force acting on the fluid particle. Therefore, the fluid particles are maintained within the domain. The interparticle distance in the SPH simulation is also considered 0.5 meters. By comparing the results, specifically the inundation extent and velocity, with another numerical simulation, the application of the SPH method demonstrates success in simulating floods. This comparison affirms the effectiveness of the SPH method in capturing water flow dynamics. Identifying the flooded areas using the available LiDAR data provides decision-makers with essential information to develop plans addressing urban flood challenges and minimizing their impact.

DATA-DRIVEN WALL SHEAR STRESS PREDICTION FROM CONCENTRATION USING A SURFACE TRANSPORT MODEL

Mahmoud Elhadidy[1], Roushan D'Souza[2] and Amirhossein Arzani[1]*

[1]The University of Utah
[2]University of Wisconsin-Milwaukee

ABSTRACT

Measuring wall shear stress (WSS) is critical for many fluid flow applications, especially in the biomedical and cardiovascular fields. Accurately estimating WSS in vascular flows necessitates detailed velocity field measurements near the vessel walls, which are challenging to obtain experimentally due to inherent noise and limitations in the near-wall resolution. Motivated by concentration measurements in in-vivo CT angiography as well as in-vitro experiments, we hypothesized that such concentration measurements could be used to obtain WSS vectors in a data-driven fashion. The advection-diffusion mass transport equation relates concentration to velocity and WSS could be obtained from near-wall velocity in an inverse modeling framework. However, rather than focusing on inferring 3D velocity fields from 3D concentration data, we employ a surface transport model derived in [1] where the 3D transport equation is projected on the wall and velocity in the advection term is replaced by WSS thanks to its simple relationship with near-wall velocity [2]. Physics-informed neural networks (PINN) are used to solve the inverse problem and infer the WSS vector field from the near-wall concentration data. In this study, we used multiphysics computational fluid dynamics (CFD) simulations (Navier-Stokes equation and advection-diffusion transport) to obtain synthetic concentration measurement data. Idealized stenosed geometries were used to test the model. As a proof-of-concept, we focused on an idealized stenosed channel geometry to simplify the projection of the equation onto the surface (remove the curvature terms). We demonstrate the success and limitations of this approach in estimating WSS topology and WSS magnitude. Our streamlined inverse modeling process involved solving just one reduced-order surface equation rather than solving the traditional set of equations (continuity, momentum, and mass transport) in 3D and is therefore computationally very efficient.

ABSTRACT

Incompressible fluid analysis using the ISPH, which is one of the particle simulation models, requires solving the pressure Poisson equations. The linear equation solver using the iterative method such as the conjugate gradient (CG) method takes up most of the time-consuming part in the ISPH calculations. In addition, the number of iterations in the linear equation solver may increase as the simulation model scales. This is a common problem not only in particle methods but also in the implicit time iteration methods of the other discretized computational models. It is known that in FDM, FEM, etc., high quality preconditioning such as geometric multigrid preconditioning can greatly improve the convergence property of iterative methods, but there are few applications of the latter in particle methods. In this study, we developed a framework of geometric multigrid preconditioner using background cells to accelerate the solution procedure of the pressure Poisson equation in the ISPH, and implemented it in GPU environments. We demonstrated the effectiveness of cell-based multigrid preconditioner for a simple dam-break problem and for the tsunami run-up problem to the Fukushima Daiichi Nuclear Power Plant with complicated geometries of structures. As a result, the proposed method marked 3.64 times speedup over the CG method without preconditioning for a simple dam-break problem with 10 million particles. The tsunami run-up simulation was performed for about 8.15 million particles. The simulation with the CG method without preconditioning took 45 hours, whereas the same simulation with the proposed method took only 23 hours. Through this numerical experiment, we show that the proposed method is also effective for practical complex flow problems.

BEAM-TO-COLUMN ADHESIVELY-BONDED CONNECTION: A MECHANICAL MODELIZATION

Francesco Ascione[*1]

[1]*University of Salerno*

ABSTRACT

This paper presents two simple analytical expressions to predict the strength and stiffness of an adhesive beam-to-column connection between glass pultruded profiles (GFRP) subjected to shear and bending loads (vertical load applied at the free end of the beam). The joint configuration is characterized by a tubular column made of a commercially available hollow profile with a square cross section and two U-profiles arranged in the form of a built-up beam. The mechanical behaviour of this type of connection is governed by shear and bending stresses acting on the beam, with the latter becoming torsional stresses inside the adhesive layers and responsible for the failure of the connection.

Regarding the strength prediction, a simple mechanical model based on the scheme of a single lap joint subjected to a traction force is presented. While, for the stiffness prediction, a simple formula for evaluating the adhesive layer deformability is proposed. With the latter, and by means of the Principle of the Virtual Power, the vertical displacement (corresponding to the vertical load applied) is evaluated and, consequently, the stiffness of the joint predicted.

A comparison with the experimental results available in current literature has made it possible to verify the effectiveness of the proposed formulations which involve relatively few geometrical and mechanical parameters.

SCALABLE DIFFERENTIABLE CFD LIBRARY FOR SCIENTIFIC MACHINE LEARNING

Mohammadmehdi Ataei[*1], Oliver Hennigh[2], Massimiliano Meneghin[1] and Hesam Salehipour[1]*

[1]Autodesk
[2]NVIDIA

ABSTRACT

The integration of High-Performance Computing (HPC) and Machine Learning (ML) in Computational Fluid Dynamics (CFD) faces hurdles due to the reliance on low-level programming languages for HPC solver development. These languages often lack native differentiability and streamlined support for ML, creating a disconnect that hinders the development of high-performance ML-integrated simulation frameworks. The XLB library [1], utilizing the Lattice Boltzmann Method (LBM), is engineered to overcome these barriers, offering a tool that unites computational efficiency with ML advancements.

By leveraging recent compiler technologies from the AI community (like JAX, Pallas, and Warp), XLB, written entirely in Python, implements a highly extensible CFD package based on the Lattice Boltzmann method that elegantly blends high performance with ML capabilities. From the HPC perspective, XLB is capable of scaling on distributed multi-GPU systems, and leveraging cutting-edge hardware features to enable efficient out-of-core computation in the Grace-Hopper Nvidia architecture.

XLB's LBM kernels are fully differentiable, allowing seamless integration with ML libraries such as JAX. This capability is exemplified by its practical applications in fluid mechanics, which include deep learning correctors to reduce simulation errors and leveraging ML techniques for advanced fluid flow control.

The library's design not only facilitates the convergence of HPC and ML in CFD but also does so with an emphasis on accessibility and performance.

XLB is publicly available at: https://github.com/Autodesk/XLB

NONLINEAR SOLID MECHANICS WITH THE SHIFTED BOUNDARY METHOD

Nabil Atallah[1] and Guglielmo Scovazzi*[2]

[1]*Lawrence Livermore National Laboratory*
[2]*Duke University*

ABSTRACT

We propose a new unfitted/immersed computational framework for nonlinear solid mechanics, which bypasses the complexities associated with the generation of CAD representations and subsequent body-fitted meshing. This approach allows to speedup the cycle of design and analysis in complex geometry and requires relatively simple computer graphics representations of the surface geometries to be simulated, such as the Standard Tessellation Language (STL format). Complex data structures and integration on cut elements are avoided by means of an approximate boundary representation and a modification (shifting) of the boundary conditions to maintainoptimal accuracy. An extensive set of computational experiments in two and three dimensions is included.
Performed under the auspices of the U.S. Department of Energy under Contract DE-AC52-07NA27344 (LLNL-ABS-857519).

A SIMULATION FRAMEWORK FOR THERMOPLASTIC COMPOSITE CONTINUOUS RESISTANCE WELDING OF STRUCTURAL AEROSPACE JOINTS

Stephen Atkinson[1], Reza Vaziri[1] and Anoush Poursartip[1]*

[1]*The University of British Columbia*

ABSTRACT

Thermoplastic composite welding is a promising manufacturing technique to join aerospace components as the need to design more structurally efficient aircraft increases [1]. Previously limited to coupon laboratory samples or small static (spot) welding applications, a new technique has been proposed for continuous operation to mitigate power and consolidation force demands [2]. Using a robotically controlled welding apparatus a local zone is heated, in this case with an electrically resistive implant, which then moves along the joint. A candidate example for the continuous welding process is an aircraft fuselage skin and stringer assembly.

In any bonding process, the interface properties of the joint between the two adherends is unobservable or would be invasive to inspect in real-time. Additionally, the potential for geometry, boundaries, or materials to change along the weld path complicates production assessment of joint strength. Computational analysis is therefore used to create a virtual twin of the weld to calculate an accurate prediction of thermal history and determine optimal input conditions for power, speed, and pressure. Using a process simulation framework to systematically define the welding parameters allows for coupled implementation of a multi-physics hierarchy to extend functionality of the digital twin to include electrical behaviour, melting of the thermoplastic matrix, and subsequent flow compaction and solidification. The culmination of this modelling capability leads to a prediction of bond consolidation and residual stress, which in turn will affect mechanical performance in service. The over-arching goal of this simulation framework is to gain confidence in the welding operation, reduce costs associated with production inspections or testing, and implement real-time control, whilst ensuring that the resulting joint satisfies the original performance requirements.

DESIGN OF TRANSIENT HEAT MANIPULATORS VIA ISOGEOMETRIC OPTIMISATION

Elena Atroshchenko[*1], Chintan Jansari[2] and Stephane Bordas[2]*

[1]*University of New South Wales*
[2]*University of Luxembourg*

ABSTRACT

Heat manipulators are devices in which arrangement of materials with significantly different thermal conductivities is carefully designed to create a certain effect: e.g. to concentrate heat flux in some area (heat concentrator) or create an illusion that the heat map resembles some target heat distribution (thermal cloak, thermal inverter, etc). In this work, we use level-set isogeometric topology optimisation to design such heat manipulators for transient heat flow. The NURBS basis functions are used to parameterise geometry, topology and unknown temperature. Control points in the topology parameterisation serve as design variables, and the optimisation is carried out with the Sequential Quadratic Programming algorithm. Isogeometric analysis is used to solve the state and adjoint boundary value problems.

Performance of the method is demonstrated on a several benchmark examples.

EVALUATING FLOW-ADDED DAMPING VIA LINEAR STABILITY ANALYSIS

Clement Audefroy[*1], Frederick Gosselin[1], Sebastien Houde[2] and Mathieu Olivier[2]*

[1]Polytechnique Montréal
[2]Université Laval

ABSTRACT

Hydroelectric turbine designers require knowledge of the damping coefficient of a turbine blade to assess its durability under cyclic loading. In the case of hydraulic turbine, the flow-added damping is dominant. Numerical evaluation of flow-added damping is challenging with current methods which involve complex and computationally expensive simulations that require moving meshes like one-way or two-way coupling fluid structure interaction simulations. We introduce a new, efficient, and fast approach for assessing the added damping coefficient of a cantilever plate. This method is based on a finite element formulation using the FreeFEM ++ solver. The weak formulation of the problem is implemented in the solver and the flow-added damping is then evaluated through linear stability analysis. The method is quick to setup as the mesh is fixed. The computation time is a few minutes compared to several hours for existing methods. This method will eventually allow us to consider complex geometries, to get closer to a realistic turbine design. Our ultimate objective is to use an existing CFD flow solution on a guide vane or a runner blade and perform the linear stability analysis about it.

BAND GAP EVOLUTION IN NONLINEAR DYNAMICS OF METAMATERIALS MADE STRUCTURES VIA GRADUALLY-CHANGING MECHANICAL PROPERTIES

Riccardo Augello[*1] and Erasmo Carrera*[1]

[1]*Politecnico di Torino*

ABSTRACT

Metamaterials stand out as they diverge from the properties found in nature, offering unparalleled control over the propagation of waves, both in electromagnetic and acoustic fields. In contrast to conventional materials, which are limited by natural properties and exhibit predictable behaviors, metamaterials provide the unique ability for designers to tailor-made responses to specific inputs. The band gap is crucial in determining how metamaterials interact with and control waves, offering exceptional opportunities for tailoring their behavior in a range of applications.

An essential part of designing the band gaps and structural behavior of metamaterials is the numerical simulation. Traditional methods usually depend on three-dimensional (3D) and two-dimensional (2D) simulations, which are often hindered by high computational expenses and significant nonlinear approximations, respectively. The solution presented in this study involves the application of the Carrera Unified Formulation (CUF) [1]. CUF brings two significant advancements ideal for metamaterials analysis: the capability to represent them efficiently using a singular one-dimensional (1D) beam model, and the incorporation of the complete Green-Lagrange strain tensor. The first innovation addresses the typical constraints of standard finite element methods, significantly reducing the computational cost associated with solid finite elements and surpassing the limitations of both 2D and 1D models. The second key feature effectively overcomes nonlinear assumptions, particularly in scenarios involving von K´arm´an nonlinearities, as for 2D elements. Moreover, the proposed approach allows for the implementation of any nonlinear assumption, to evaluate the accuracy and reliability of the different theories.

The research delves into the examination of thin-walled structures and metamaterials, placing a strong emphasis on the alteration of band gap characteristics as these materials undergo significant displacement and the influence of the chaning of mechanical properties. This study extends to include a comprehensive nonlinear analysis, integrating the complete Green-Lagrange strain equations, which is critical for accurately assessing the behavior of these materials. Practical examples are provided to illustrate the evolution and development of band gaps in these structures. A key aspect of this research is the comparison of results obtained from this comprehensive approach with those derived from von K´arm´an approximations. This comparative analysis underlines the enhanced accuracy and relevance of incorporating full Green-Lagrange strains in understanding the dynamic properties of thin-walled and metamaterial structures.

A PHYSIOLOGICALLY VALID, MULTI-PHYSICS MODEL OF THE LEFT ATRIUM TO ASSESS THE INFLUENCE OF FIBROSIS ON ATRIAL FUNCTION

Christoph Augustin[*1]*

[1]*Medical University of Graz*

ABSTRACT

Image-based cardiac electromechanical (EM) models are valuable for understanding cardiac function in both normal and pathological conditions, aiding in diagnosis and therapy planning. Overcoming methodological challenges is crucial for advancing these models. This includes improving computational efficiency and robustness for model personalization and prolonged simulations under diverse conditions. Additionally, achieving physiological completeness with therapy-relevant mechanisms enhances predictive capabilities.

In this talk we focus on left atrial EM and present a modeling framework that integrates a 3D EM model with the physiologically comprehensive 0D CircAdapt model for closed-loop circulation. We show that the model successfully replicates physiological behaviors, responding to alterations in loading conditions and contractility induced by experimental protocols.
We employ this model to simulate fibrotic remodeling in atrial tissue, capturing its impact on electrophysiology, active contraction, and passive elasticity and investigate hemodynamic changes that can lead to thrombosis in the atria.

The framework's mechanistic completeness and efficiency make advanced left atrial EM modeling applications feasible. It enables the exploration of parameter spaces over prolonged periods, crucial for personalized modeling. The model's reliability in predicting acute transient responses to interventions underscores its utility in clinical scenarios.

ENHANCING MUSIC GENERATIVE SYSTEM THROUGH OPTIMIZATION WITH AI AND MIR TECHNIQUES

Ko Ko Aung[*1], Masato Masuda[1], Ryuji Shioya[1] and Yasushi Nakabayashi[1]*

[1]Toyo University

ABSTRACT

With the ongoing evolution of AI techniques, these technologies are actively pursued, resulting in significant achievements across various fields, including music generation. However, the generation process is still undergoing development and faces challenges, particularly in the realm of music. Since music is intangible and aesthetic, research in this area has taken diverse approaches. One significant challenge lies in acquiring data for the training process. Sound, being complex data, is currently captured through spectrum and MIDI data. While MIDI data remains more popular in music generation, limitations persist in obtaining data from musical instruments with and without MIDI systems. To address this, the SoundFont system has been employed to gather data from all sounds for the training process. Nowadays, various AI models, including RNNs, GANs, CNNs, etc., are available. In this study, a type of RNN called LSTM was utilized, with different models investigated for the training process. The current system was further modified using MIR techniques, manipulating audio data by adding feature extraction, such as tempo, velocity, and duration adjustment. The current system's achievement lies in the ability of the Hierarchical LSTM model to generate music from any type of musical instrument. However, an apparent challenge in music generation is finding an optimal approach. Researchers typically use two methods: Subjective and Objective. Both methods are still in development. The current system investigates both approaches, with the subjective method requiring more time due to its reliance on human input through surveys and musician perceptions. In contrast, the objective approach is computational and mathematical. In this research, both methods were examined to assess aesthetic value and computational achievement while seeking an optimal way to generate music. Looking ahead, a new generative system will be created for not only Burmese traditional instruments, not currently involved in the MIDI system but also any traditional instruments. By enhancing music generative systems, numerous benefits can be derived, including the capability to generate all instruments, support for musicians' creativity, and improvement in the music industry.

MODELING THE IMPACT OF SURFACE TENSION ON LUNG MECHANICS: A CONTINUUM POROMECHANICAL APPROACH

Nibaldo Avilés-Rojas[*1] and Daniel E. Hurtado*[12]

[1]*Pontificia Universidad Católica de Chile*
[2]*Massachusetts Institute of Technology*

ABSTRACT

During respiration, lung mechanical response can be explained by the interaction of forces arising at the alveolar walls and the surface tension resulting from the air-liquid interface in the alveoli. This interfacial phenomenon plays a crucial role in respiratory function and has been linked to the hysteresis observed in quasi-static pressure-volume curves. Pulmonary surfactant, a complex mixture of proteins and lipids that is adsorbed, desorbed, and squeezed out from the air-liquid interface, is primarily responsible for the pulmonary hysteretic response, as it dynamically modulates surface tension values [1, 2]. This physicochemical activity of surfactant and the intrinsic porous nature of the lung parenchyma reveals the need to understand lung mechanics from a multiphysics perspective.

Poromechanical models present a unique opportunity to improve the modeling of respiratory mechanics, as they, by construction, couple ventilation with lung deformation. However, modeling the impact of alveolar surface tension on lung response has received less attention than alveolar wall elasticity, possibly due to its complex multi-scale behavior that depends on the physicochemical nature of surfactant activity. Indeed, previous attempts by poromechanics to address lung response only consider the elastic term related to lung tissue in their constitutive modeling framework, offering a fully poroelastic response [3].

In this work, we developed a continuum poromechanical model of lung mechanics suitable for incorporating the impact of surfactant dynamics and the resulting alveolar surface tension on organ response. Following a standard Coleman-Noll procedure, we derived a constitutive relation for lung stress, which includes a collapsing pressure resulting from the surfactant-dependent surface tension. Governing equations were solved using a non-linear finite element scheme on human lung geometries. To test our model, we derived quasi-static pressure-volume curves for air-filled and saline-filled lungs. Remarkably, our model can predict different inflation and deflation pressure-volume limbs, resulting in hysteretic loops. Furthermore, our simulations highlight the role of the surfactant alveolar activity in pulmonary compliance of P-V curves.

IDENTIFICATION OF HYPERELASTICITY IN HUMAN ARTERIES USING A MACHINE LEARNING BASED VIRTUAL FIELDS METHOD

Shuangshuang Meng[1], *Ali Akbar Karkhaneh Yousefi*[1] *and Stéphane Avril**[1]

[1]*École des Mines de Saint-Étienne*

ABSTRACT

Identification of constitutive properties of tissues is important in biomechanics, as they are needed to simulate some surgical treatments like percutaneous coronary intervention for instance. Due to advances of techniques like digital image correlation (DIC) in experimental mechanics, the virtual field method (VFM) has become a major approach to identify mechanical parameters, which rely upon the availability of full-field displacement data. However, it is limited to a prior-selected classical material model posing challenges, especially for biological materials [1]. Recently, machine learning has become a promising alternative as a nonparametric identification method. In this paper, an approach using a machine learning framework (NN-EUCLID) combined with the VFM is proposed. NN-EUCLID stands for Efficient Unsupervised Constitutive Law Identification and Discovery and is based on a specially designed Neural Network (NN) architecture [2]. The “Unsupervised” means training only requires measurable full-field displacement and reaction force data, whilst the lack of stress labels is compensated by leveraging a physics-motivated loss function. This framework has demonstrated its performance for hyperelasticity using 2D numerical data. Our study focuses on discovering the mechanical behavior of arterial walls in a bulge inflation test by extending the current 2D framework to 3D. To this aim, we combined the NN-EUCLID method with VFM. To be more precise, due to practical challenges in measuring a full-field strain map and distribution of reaction forces by DIC technique in experiments, we firstly adapted the original loss function based on VFM, thanks to its ability in material characterization using DIC on a small region of the inflated artery. Moreover, by designing the different virtual fields, we generated different combinations of tension/shear strain data for the training process, which strengthens the method's robustness with heterogeneous materials. Lastly, we implemented the trained model in Abaqus via a user-defined subroutine to validate our identified tissue properties. We showed that the identified model can accurately predict the mechanical response of the arterial wall in a different loading scenario like biaxial tension, demonstrating the potential of the combined VFM and NN-EUCLID method 3D tissue characterization.

DESIGN FOR MATERIAL PROPERTIES OF ADDITIVELY MANUFACTURED METALS USING TOPOLOGY OPTIMIZATION

Vibhas Mishra[1], Can Ayas[1] and Matthijs Langelaar[1]*

[1]Delft University of Technology

ABSTRACT

Geometrical design rules have been used extensively in topology optimization (TO) with the aim of ensuring the metal additive manufacturability of optimized designs. More recently, TO schemes that integrate the thermal and mechanical state of the part through simplified AM process simulation paved the way for reducing overheating, part distortion and residual stress buildup [1]. It is evident from these studies that the part design (geometrical features) to be realised by AM greatly influences the temperature transients and, hence, the microstructural features, which in turn control mechanical properties such as strength, ductility, and toughness.

In metal Additive Manufacturing (AM), the deposited material is subjected to a series of heating and cooling cycles. The locally occurring temperature peaks and subsequent cooling rates determine an important aspect of the microstructure: solid-state phase fractions and, ultimately, the local material properties. Since the geometry of the part determines the local thermal history during AM, this offers an opportunity to influence material properties through design.

For this purpose, a density-based TO framework is used for the design optimization. The thermal history of the compliance-minimized design is evaluated by a simplified wire arc additive manufacturing (WAAM) process model. The relation between the cooling time and the resultant yield strength is then obtained by an empirically established alloy-specific microstructural response [2]. Within the gradient-based optimising scheme, the sensitivities of the cooling time with respect to design variables were computed with the evaluation of the cooling time spent in the critical temperature range in a continuous and differentiable manner. Numerical examples illustrate the capability of our approach in adapting the design to achieve various strength values within a control volume for high strength low alloy steels, where resulting phase fractions significantly influence mechanical properties.

A GRADED METAMATERIAL-BASED CUSHION FOR BROADBAND NOISE MITIGATION OF IMPACT-DRIVEN OFFSHORE MONOPILES

Ana Carolina Azevedo Vasconcelos[*1], Dingena Schott[1] and Jovana Jovanova[1]*

[1]*Delft University of Technology*

ABSTRACT

The next generation of offshore wind farms will consist of larger wind turbines with higher power capacity. To withstand the upcoming wind turbines into the offshore environment, new foundations with larger sizes are also required. Monopiles are commonly used as wind farms foundations and are installed into the seabed through the blows of an impact hammer. During the pile driving process, the pile wall vibrates, which results in high underwater noise emission in frequency ranges that are harmful to marine life.

Several noise mitigation systems were developed to reduce the underwater noise, especially in frequency ranges around 1000 Hz. However, the increase of monopiles' diameter can also induce high noise emission in frequency ranges lower than 1000 Hz. For the existent noise mitigation systems, the attenuation of low frequency noise is not straightforward, which may require the combination of different systems to attain enough noise reduction.

To efficiently mitigate low frequency noise, acoustic/elastic metamaterials (A/E MMs) have been explored due to their unique properties for vibration control. Such properties rely mainly on the A/E MM microstructure, which are formed by resonant elements. The use of A/E MMs to mitigate the noise from the pile driving process was numerically introduced by [1], where a meta-interface formed by single resonators was designed. The meta-interface showed a noise reduction at a frequency range associated with the fifth vibration mode of the monopile, which was causing the highest noise level. In case the noise caused by other pile modes exceed the limit levels, new resonators should be designed.

This work proposes a new cushion formed by graded spiral resonators that will mitigate the energy coming from distinct monopile's vibration modes. Different from the resonators presented in [1], the spiral type has shown a better vibration attenuation performance in even lower frequency ranges, which can be more suitable for the upcoming monopile designs. In addition to that, a stress analysis is performed to verify the cushion's structural integrity. This is an important design step, since the cushion undergoes several impact hammer blows. Finally, the noise mitigation performance is verified, which shows a reduction of noise in frequency ranges where traditional mitigation systems are not completely efficient. The findings of this work open the doors to the development of new noise mitigation systems that are more indicated for the upcoming impact-driven offshore monopiles.

ASSESSING PERFORMANCE IN SHELL ANALYSIS: A COMPARATIVE STUDY OF ISOGEOMETRIC AND SPECTRAL ELEMENT METHODS

Nima Azizi[*1] and Wolfgang Dornisch*[1]

[1]*Brandenburg University of Technology*

ABSTRACT

In this contribution, we compare various shell formulations used in isogeometric analysis (IGA) and spectral element method (SEM) analysis of thin-walled structures. Additionally, we compare the results of a newly developed spectral element method based on NURBS-based geometry definition with the aforementioned methods. Different assumptions in the formulations and numerical integration methods are presented, and comparisons are made using well-known obstacle course examples and free-form shells. The performance assessment measures are not limited solely to deformation results but also include shear diagrams and the condition numbers of the stiffness matrix in each method. A discussion about the accuracy of the methods in estimating geometry and their impact on the precision of outcomes is also included. It will be demonstrated that neither the condition number nor the precision of the geometry definition provides sufficient information to predict the performance of the methods. Surprisingly, considering different aspects of shell analysis, the conventional isoparametric SEM exhibits very good performance.

Key Words: Spectral element method, Isogeometric analysis, Shell formulation

DATA-DRIVEN COMPUTATIONAL FRAMEWORK FOR SHELLS

Hamza Azzayani[1], Zengtao Kuang[2], Qun Huang[2], Norman Mathieu[1], Hamid Zahrouni[1] and Heng Hu[2]*

[1]*Université de Lorraine*
[2]*Wuhan University*

ABSTRACT

This work proposes a distance-minimizing data-driven framework for large deformation of composite shells. The basic idea is to minimize the distance between the constraint space and the material space of the stress-strain data [1], thus bypassing the need for material modeling. The material space can be derived from numerical simulations, e.g., using the homogenization method, or from experimental tests of real samples. The constraint space contains the equilibrium and compatibility equations derived based on the seven-parameter Büchter-Ramm shell [2] that is suitable for both thin and moderately thick shells. The minimization procedure consists of an iterative operation [3] between the two spaces to find the optimal solution ensuring the minimum distance functional. Some numerical examples of homogeneous and multi-layered shells are investigated to verify the efficiency of the proposed algorithm. An analysis of the data size and accuracy of the proposed model is also discussed.

USING NONLINEAR DOMAIN DECOMPOSITION METHOD AS A SMOOTHER IN NONLINEAR MULTIGRID

Mehdi Babamehdi[*12] and Matthias Bolten*[2]

[1]*Forschungszentrum Jülich*
[2]*University of Wuppertal*

ABSTRACT

Nonlinear Partial Differential Equations (PDEs) frequently arise in different fields of science, e.g. material science, fluid dynamics etc. Finite element discretization of such problems usually leads to large nonlinear systems, either due to the need of higher accuracy, having to deal with large physical sizes or both. Solution of such big discretized nonlinear problems needs fast, highly scalable, and parallelize solvers. Nonlinear multigrid is a well-known method for efficiently solving nonlinear boundary value problems. The full approximation scheme (FAS) solves nonlinear problems on fine and coarse grids. To smooth the nonlinear problem a nonlinear smoother must be utilized and since implementation is supposed to be in matrix-free form for an efficient finite element code, this form of implementation of the smoother should be plausible. For this purpose, Nonlinear Restricted Additive Schwarz Method (NRASM) seems to be a very interesting choice. The method converges with the same rate as linear iterations applied to the linearised equation. In addition, it is inherently parallel and proper to be implemented in matrix-free form. We combine FAS and a nonlinear restricted additive Schwarz method to obtain hybrid NRASM/FAS. The full approximation scheme is used to solve the nonlinear problem and the NRASM is used to smooth the nonlinear boundary value problem in local subdomains on each level of the multigrid method. Within the NRASM, we use the Jacobian-Free Newton Krylov method as the local solver on each subdomain. We consider different nonlinear equations in three dimensional space as test problems. Several parameters of the methods were investigated in this study to have a better understanding of influence of the parameters on the efficiency of the method, the behavior of the methods and its convergence rate.

AN EQUATION ERROR APPROACH FOR DIRECT INVERSION FROM FULL-FIELD WAVE DATA

Olalekan Babaniyi[1] and Mobina Ghorbaninejad*[1]

[1]*Rochester Institute of Technology*

ABSTRACT

We consider the problem of reconstructing the mechanical properties of soft tissue from full-field wave data. This is a problem of interest in the elastography field where the mechanical properties are used to noninvasively diagnose, and monitor the treatment of various diseases. Standard techniques used to solve this inverse problem either oversimplify the physics of the problem, resulting in poor reconstructions of the mechanical properties, or are too computational expensive to be done in real time. We present an equation error approach that can be used to efficiently solve the inverse problem. We discuss some of the mathematical properties of this variational formulation, and evaluate its performance on simulated data.

NUMERICAL STUDY OF THE IMPACT OF GROOVES ON REFRIGERANT FLOW BOILING IN MICROCHANNEL HEAT EXCHANGERS

Pragun Badhan[*1], Kiyonori Yokose[1] and Motohiko Fukuoka[1]*

[1]*Daikin Industries Ltd.*

ABSTRACT

Microchannel heat exchangers are increasingly being adopted due to their compact size and superior heat transfer performance in air conditioning systems. To promote the heat transfer in microchannels, grooves on the inner walls of microchannels are commonly employed, but detailed detailed design of the grooves is inhibited by the lack of visualization of their impact on the flow boiling characteristics inside the channel. In this study, a Volume-Of-Fluid method based CFD simulation of saturated refrigerant flow boiling in microchannels has been developed. Validation of the simulation has been conducted with experimental data for smooth walled rectangular microchannels with the refrigerant R32 for mass flux range of 25-100 kg/m2-s, typical of air conditioning systems. Subsequently, simulations were performed for grooved wall rectangular microchannels. The results show an increase of 57% in heat transfer coefficient between smooth and grooved wall microchannels. Analysis of the simulation results reveals that the grooves promote heat transfer by increasing the wet area of the wall around the slugs and the elongated bubbles formed as the refrigerant boils in the channel. Furthermore, effects of the different operating conditions including inlet mass flux and wall heat flux on the slug/elongated bubble flow regime shape and behavior along the grooves are discussed. This study aims at demonstrating the potential of numerical simulations for designing microchannels along with complicated structures like grooves.

ADVANCING LUNG FINITE ELEMENT MODELS THROUGH DIGITAL IMAGE CORRELATION TECHNIQUES

Arif Badrou[1], Crystal A. Mariano*[1], Matthew Shankel[1] and Mona Eskandari[1]*

[1]*University of California, Riverside*

ABSTRACT

Lung diseases, including chronic obstructive pulmonary disease (COPD), asthma, and most recently, COVID-19, pose a significant threat to global health, with over 4 million deaths worldwide and billions of dollars spent annually [1]. Computational models play a crucial role in advancing therapies and deepening our comprehension of lung physiology, yet pulmonary biomechanics research on this frontier remains notably absent; these endeavors are hindered by the lack of mechanical experiments needed to inform and validate models. Recently, we developed a custom-designed electromechanical breathing mimicry apparatus to replicate both artificial and diaphragm breathing [2]. This ventilation system enables testing ex-vivo lungs from various species such as rats, pigs, and even humans. The amalgamation of high spatial and temporal local meso-scale tissue strains and displacements collected continuously via digital image correlation (DIC) innovatively interfaced with global macro-scale pressure-volume lung loading facilitates a wealth of unprecedented data acquisition. Building on our established reduced-order modeling framework of a porcine lung specimen [3], the present study focuses on advancing this pipeline to create the first structurally-representative three-dimensional model of the breathing human lung. This inverse finite element model incorporates key features of the lungs, including the intricate structure and material properties of the airways, the pleura, and the parenchyma. Pressure is applied directly to the parenchymal tissue of terminal airways, employing a poroelastic formulation. Strains, pressure, and volumes obtained experimentally from the ventilation apparatus are utilized to calibrate the model. While the current human lung model employs generalized thoracic geometry, ongoing objectives focus on harnessing topological whole lobe morphology using 3D scanning techniques to enable patient-specific pipelines; thus far, this proof-of-concept has been promising when applied to our study of rat lungs. This work represents pioneering applications of experimental-to-computational lung research pipelines; the results underscore simulation efficiency and paves the way for developing more sophisticated models, which provide fresh insights into lung function, and contribute to the broader field of computational biomechanics.

WALL-MODELS OF TURBULENT FLOWS VIA SCIENTIFIC MULTI-AGENT REINFORCEMENT LEARNING

Jane Bae[*1], Di Zhou[1] and Petros Koumoutsakos[2]*

[1]*Caltech*
[2]*Harvard University*

ABSTRACT

The predictive capabilities of turbulent flow simulations, critical for aerodynamic design and weather prediction, hinge on the choice of turbulence models. The abundance of data from experiments and simulations and the advent of machine learning have provided a boost to turbulence modeling efforts. However, simulations of turbulent flows remain hindered by the inability of heuristics and supervised learning to model the near-wall dynamics. We address this challenge by introducing scientific multi-agent reinforcement learning (SciMARL) for the discovery of wall models for large-eddy simulations (LES). In SciMARL, discretization points act also as cooperating agents that learn to supply the LES closure model. The agents self-learn using limited data and generalize to higher Reynolds numbers in reproducing key flow quantities. We test the discovered wall model to canonical flat plate boundary layers, which shows good predictable capabilities outside the Reynolds numbers used to train the model.

FROM INITIAL PHASE SEPARATION TO SELF-ASSEMBLY IN BLOCK COPOLYMER THIN FILMS

Suwon Bae[1]*

[1]*Pusan National University*

ABSTRACT

Block Copolymers (BCPs) are a class of self-assembly materials. Due to chemical incompatibility between constituent blocks, while annealed, BCPs evolve from the as-cast state into lamellae, cylinders, and more depending on chain makeup. BCP chains experiences chemical incompatibility, segregate, and then gradually self-assemble into such morphologies. BCP chains in this process are not permanently stuck with a single morphological object, but likely travel around to get associated with different morphological objects. In order for BCP chains to do so, they have to jump over the matrix phase or overcome the energy barrier induced by microphase separation. Even at the equilibrium state, BCP chains are observed to keep hopping around and be engaged with multiple morphological objects, while the whole BCPs hold the overall equilibrium morphology.
Understanding of how BCP chains travel across the matrix phase to join another morphological object may give rise to enhanced long-range ordering; thus, we here study the trajectory of BCP chains when they hop and quantify the energy barrier they experience and should overcome. We use a molecular dynamics model we previously developed based on a Kremer-Grest model [1, 2, 3], where we explored a multidimensional parameter space associated with BCP ordering by adopting a machine leaning approach – an autonomous loop using a Gaussan Process control algorithm interatively selects high-value simulations to compute. With this established model, we build a BCP film on a substrate with periodic boundary conditions imposed along the plane and form vertical morphologies (cylinders and lamellae) because vertical morphologies make much easier for us to keep track of BCP chains. In the fully equilibrated morphologies, we carefully choose a single BCP chain that is part of a cylinder or a sheet of lamella. The selected BCP chain is displaced by a fraction of the repeat spacing each step with translation disabled and rotation allowed. Each displacement is followed by energy minimization and annealing, and this process is carried out until the selected BCP chain completely travel across the matrix phase. The thermodynamic integration is then preformed using the displacement and the force the molecule experiences every step to compute the free energy.

GAS EFFECTS ON HORIZONTAL RIBBON GROWTH OF SILICON

Nojan Bagheri-Sadeghi[*1] and Brian Helenbrook*[1]

[1]*Clarkson University*

ABSTRACT

Horizontal ribbon growth (HRG) of silicon wafers for solar cells is a promising method of growth from melt. HRG can significantly reduce the production cost and waste compared to Czochralski method where there are significant losses due to squaring and sawing of cylindrical ingots produced. Although, production of silicon sheets has been demonstrated using HRG, producing uniform and thin sheets has proven formidable. In HRG of silicon, the sheet floats on its melt due to its lower density and is pulled horizontally. The heat of fusion is removed by a cold impinging helium jet.

In this study, a three-phase computational model of HRG was developed including the moving solid-melt and melt-gas interfaces, solidification kinetics, and the physics of the triple-phase line (TPL) where the three phases meet. For spatial discretization, an hp-finite element method was utilized with fourth-degree basis functions on triangular elements, which was stabilized using a streamline upwind Petrov-Galerkin approach that allows the same order used for pressure and velocity. Furthermore, an arbitrary Lagrangian-Eulerian moving mesh and local mesh adaptation were employed.

Three-phase (solid, melt, and gas) and two-phase (solid and melt) models of horizontal ribbon growth were compared to identify the significance of different gas effects. The boundary conditions at the melt-gas and solid-gas interfaces for two-phase simulations were obtained from decoupled simulations of the gas phase. The results showed that the gas shear stress strongly changes the flow and temperature fields and the position of the triple-phase line. Also, the gas pressure distribution determined the vertical position of the triple-phase line. In the absence of growth angle effects, the results of the two-phase simulation with convective heat transfer coefficient, shear stress, and pressure specified closely matched that of the three-phase model. Even with non-zero growth angle effects, the two-phase model with all the boundary conditions applied agreed well with three-phase simulation results despite increased deviations at higher pull speeds. Finally, the results indicated that gas-induced velocities are significant compared to the Marangoni and buoyancy velocities, which could lead to flow instabilities and the variations in solid shape as observed in HRG experiments.

NEURAL ADDITIVE METHOD ACCELERATED DISCOVERY OF MATERIAL SYMMETRIES FOR HYPERELASTIC MATERIALS

Bahador Bahmani[*1] and WaiChing Sun*[1]

[1]*Columbia University*

ABSTRACT

Biological and human-made systems, including biological tissues and metamaterials for soft robots, often leverage specific forms of anisotropy to achieve optimal performance with minimal costs. The varieties of anisotropy can be captured through structural tensors or eigenprojection. This talk presents an approach in which we leverage the expressivity of the neural network to capture the precise behaviors of anisotropic hyperelastic materials while introducing feature space suitable for symbolic regression to enhance the trade-off among the predictive and descriptive accuracies, the interpretability, and the simplicity of the learned model. In this divide-and-conquer method, we start by acquiring a separable representation of the polyconvex hyperelastic energy functional using univariate neural networks. A key advantage of this step is its scalability concerning the number of strain invariants input into the energy functional, which can often exceed five for certain materials. In the subsequent phase, we employ genetic programming to perform symbolic regression on each of the learned univariate neural networks. This process transforms the neural network models into concise symbolic equations. Compared to the generic symbolic regression modeling effort, the success rate of training of this paradigm is higher, as demonstrated in the numerical experiments. Compared to the neural network models, the learned symbolic models often express the mathematical expression more economically than the neural network parametrization. This efficiency leads to the elimination of arithmetic operations and makes the computations more efficient without excessive pruning and fine-tuning.

COMPUTATIONAL MECHANICS ENHANCED BY PHYSICS AND DEEP LEARNING

Jinshuai Bai[*1], Xi-Qiao Feng[2] and YuanTong Gu[1]*

[1]*Queensland University of Technology*
[2]*Tsinghua University*

ABSTRACT

Computational modelling is one of the most important ways to study challenging mechanics problems. During modelling, numerical techniques are leveraged to approximate solutions of physics partial differential equations (PDEs), such as equilibrium equations and conservation of momentum. In recent years, deep learning has emerged as a promising tool for solving PDEs [1-3]. Therefore, the deep learning-based computational mechanics field has gained increasing attention. In this work, a computational framework enriched by physics and deep learning is proposed for nonlinear solid mechanics problems. In the proposed framework, the displacement is constructed by neural networks with radial basis function, while the solving process is done by minimizing the energy functional of mechanics systems. Numerical examples, including the 2D Cook's membrane and the 3D twisting rubber cases, are conducted to show its remarkable performance and stability. It has been demonstrated that the proposed framework is locking-free and compatible with parallel computing schemes. Consequently, the proposed framework provides an effective way for nonlinear solid mechanics with great potential.

DEVELOPMENT OF AN ELASTIC DEFORMATION ATLAS OF CEREBRAL MAJOR ARTERIES VIA STATISTIC APPROACH

Yan Chen[1], Yang Bai[1] and Marie Oshima[1]*

[1]The University of Tokyo

ABSTRACT

Medical literature suggests that the potential cause of aneurysmal pathology may be attributed to the interaction between the biomechanical characteristics of arterial walls and hemodynamic factors, including wall shear stress and pressure. Research indicates that in cases where vascular structures exhibit specific characteristics or patterns, there is a likelihood of corresponding patterns of aberrant blood flow, and such scenarios may elevate the risk of arterial vascular diseases[1].

Nowadays, statistical methodologies are gaining prominence in vascular morphology research. Data-driven studies, leveraging extensive blood flow simulations, seek to elucidate the pathogenesis of vascular diseases through a systematic analysis of the relationship between blood flow patterns and vascular variability. In this study, we employed unsupervised learning techniques to develop a Deformation Atlas for Cerebral Major Artery (CMA), utilizing a publicly available dataset of cerebral vasculature. This atlas is presented in a spatial coordinate format, depicting the distribution and range of variation in shapes of non-diseased CMA.
We applied Principal component analysis (PCA) for curves[2] to identify essential components that contribute to geometric variability and calculated their probability distributions. This analysis focused on how these distributions affect the vascular geometric parameters, contribute to the vascular classification, and influence blood flow patterns.

To mitigate the impact of nuisance parameters in shape data, such as minor misalignments and re-parameterizations, we employed Elastic Shape Models (ESM) which provides a Riemannian framework that is invariant to affine transformations and re-parameterizations of contours[3]. This enables the handling of data derived from different sampling methodologies and various discretization approaches in spatial coordinates, ensuring consistent analysis across diverse cases. We demonstrated the application of EMS in processing centerlines derived from medical images of varying resolutions (test data). We computed the probability density of these test datasets, which facilitated the categorization of the centerlines based on their shapes. This method illustrated how these centerlines were deformed from a baseline shape, providing insights into the morphological variations observable in the medical imagery.

VARIATIONAL MULTISCALE MOMENT METHODS FOR THE BOLTZMANN EQUATION

Frimpong Baidoo[*1], Irene Gamba[1], Luis Caffarelli[1], Thomas J.R. Hughes[1] and Michael Abdelmalik[2]*

[1]The University of Texas at Austin
[2]Eindhoven University of Technology

ABSTRACT

The Boltzmann transport equation yields conservation equations for mass, momentum and energy from its first five moments. These equations require closure relations for the deviatoric stress and heat flux so as to balance the number of unknowns with the number of equations. The most storied closure method is the Chapman-Enskog expansion[1] which yields a sequence of closures in orders of Knudsen number: Euler's and Navier-Stokes-Fourier equations at zeroth and first order, Burnett equations at second order and so on. Unfortunately, the Burnett equations are known to be unstable[2].

In this presentation, we propose a new framework for deriving closure relations based on the Variational Multiscale (VMS) method[3], which was originally created to derive stabilized Galerkin formulations to advective PDEs. Our VMS closure process subsumes the Chapman-Enskog expansion while opening the door to novel closures. It also provides a criterion based off the entropy production inequality of the Boltzmann equation for assessing the quality of a given closure.

Focusing on the linearized Boltzmann equation, we will describe the VMS framework and use it to introduce an entropy stable extension to the Navier-Stokes-Fourier equations. We will then present results on the application of these equations to the stationary heat transfer problem and the Poisseuille channel problem. In both setups, we obtain solutions that are accurate far beyond the early transition regime of rarefied gas flow that they are designed for.

DATA-DRIVEN DISCOVERY OF QUANTITIES OF INTEREST AND THEIR GOVERNING EQUATIONS IN COMPLEX SYSTEMS

Joseph Bakarji[*1], Nathan Kutz[2] and Steven Brunton[2]*

[1]*American University of Beirut*
[2]*University of Washington*

ABSTRACT

We tackle two common challenges in discovering interpretable physics from data of complex systems: 1) the identification of physics-informed quantities of interest and 2) the discovery of interpretable dynamics from incomplete measurements. We propose two approaches that constrain deep learning optimizers to identify physically-meaningful variables. This aims to merge the highly effective yet opaque feature learning of deep networks with the straightforward interpretability of physical laws. I will demonstrate the use of deep delay double-encoders to recover full-state variables and their governing differential equations from partial measurements, with applications to chaotic systems and uncertainty quantification.

THEORETICAL AND COMPUTATIONAL MODELLING OF CELL-CELL ADHESION IN 3D

Pradeep Kumar Bal[*1] and Marino Arroyo*[1]

[1]*Universitat Politècnica de Catalunya*

ABSTRACT

Cell-cell adhesion and decohesion are important in biology, to keep cellular tissues together and, in addition, to allow disengagement of cells during remodeling. Due to the fluid nature of the surface of the animal cells, the molecular bonds that keep cells together are laterally mobile. It limits the application of classical theories of adhesion and interfacial fracture in this context. These molecular bonds form clusters, attach to the cytoskeleton through mechanosensitive adapter protein molecules, and undergo turnover by endocytosis. Cells can tune various properties of these molecular bonds including diffusivity, stiffness, and force sensitivity. We lack a fundamental understanding of how mechanics, chemistry, and biological regulation integrate to support the adaptable function of cell-cell adhesion, and how effective mechanical properties of adhesions such as strength and toughness depend on the molecular properties of bonds. We develop a mathematical and computational model for cell-cell adhesion, based upon Onsager's principle, coupling active gel models of actomyosin cortex (which take into account shape changes, myosin activity, viscous dissipation, and the turnover of the cortex) to the adhesion dynamics of mobile binders (which take into account bond formation and dissociation kinetics, force sensitivity, and bond mobility) that would allow us to understand how the actin cortex and the adhesion complexes work together to give rise to adaptable junctions. For computational analysis in full three-dimensional generality, we consider an ALE parametrization based on an offset to represent the fluid deformable cell surface and use the Local Monge Parametrizations (LMP) method to approximate tensor fields on general surfaces given by a collection of local parametrizations using a FEM setup based on subdivision surfaces. Our work provides a conceptual background to guide new experiments that probe cell-cell adhesion and decohesion. We show how the interplay of mechanics and chemistry at adhesion patches leads to a wide range of behaviors that cells can use to stabilize cell-cell junctions during physiological stretch or to selectively detach during morphogenesis.

MECHANICS OF NETWORK GLASSES: GENERATION, DEFORMATION, ELEMENTARY EVENTS AND THEIR PREDICTION

Franz Bamer[*1], Somar Shekh Alshabab[1], Zhao Wu[1], Baghiashri Bachhav[1], Bernd Markert[1] and Michael Falk[2]*

[1]*RWTH Aachen University*
[2]*Johns Hopkins University*

ABSTRACT

A fundamental understanding of the mechanics of glasses remains an ongoing challenge in research, and is highly relevant to society and industry. This contribution focuses on the mechanics of glasses with topological structures of covalent bonds, leading to rings, i.e., nanovoids, of various shapes and sizes. A typical example of such material is silica glass, consisting of the most abundant elements on this planet.

The first part of this contribution presents two novel strategies to generate network glasses: the melting-quenching technique and a dual Monte Carlo bond-switching algorithm. While the first approach may be seen as the rather classical strategy to numerically generate glasses on the nanoscale, the second approach is a non-classical method that consists of a sequence of topological flip transformations in an initially hexagonal lattice.

The second part of this contribution focuses on mimicking the mechanical response behavior of such disordered materials on a molecular level. To do so, we use an overdamped, athermal description, which is particularly beneficial in disentangling the complex deformation mechanics of glasses. We also comprehensively discuss the theory of the mechanics of disordered materials. This method allows one to disentangle elementary fracture events in the network materials and study the anomalous yielding behavior of silica glass, which can be linked to the appearance or disappearance of nanovoids. Furthermore, this method allows one to study the problems of prediction and reversibility.

The third part of this contribution builds on the assumption that zones prone to experiencing nanovoids during deformation are predefined in the material and can be identified in the material prior to any deformation approach. Thus, we apply a local scanning method that can generate prediction fields, presenting spots prone to rearrangements. It is shown that these spots do indeed reveal a high correlation with the actual localized fracture events in the material due to mechanical deformation.

MODEL ENRICHMENTS IN REDUCED ABLATION MODELS FOR HYPERSONIC FLIGHT SIMULATION

Rileigh Bandy[1,2], Rebecca Morrison[2] and Teresa Portone[1]*

[1]*Sandia National Laboratories*
[2]*University of Colorado Boulder*

ABSTRACT

During hypersonic flight, air reacts with a planetary entry vehicle's thermal protection system (TPS), creating reaction products that deplete the TPS. Reliable assessment of TPS performance depends on accurate ablation models. New finite-rate gas-surface chemistry models are advancing state-of-the-art in TPS ablation modeling, but model reductions that neglect chemical species may be necessary in some cases for computational tractability. This work develops a theory-informed stochastic enrichment operator to improve the predictive capability and quantify uncertainties in such reduced models while maintaining computational tractability. We focus on a high-fidelity air-carbon finite-rate model [1] in which a low-fidelity model only tracks a subset of chemical species in the high-fidelity model. Discrepancies in predicted carbon monoxide production result. We propose an enrichment operator, embedded in the low-fidelity model, to quantify the effect of neglected species. The enriched model is calibrated with Bayesian inference and validated with posterior predictive assessments. Numerical results show the enrichment operator improves the low-fidelity model's predictions without significantly increasing computational cost.

A GENERALIZED FRACTURE MECHANICS-BASED MODELING METHOD FOR PREDICTING BEHAVIORS OF SHORT AND LONG FATIGUE CRACK PROPAGATION

Dongjun Bang[*1] and Ayhan Ince*[1]

[1]*Concordia University*

ABSTRACT

Failures due to high cycle fatigue (HCF) are characterized by the progression of short cracks across different length scales. This progression includes initial crack formation (nucleation), the growth of short cracks, and the subsequent extension into longer cracks. The sequential development of cracks across scales ultimately leads to fatigue failure. Given that most structural components exhibit predominantly short cracks within the HCF range, the behavior of long cracks holds lesser significance. Attempts have been made to bridge the mechanics of short and long crack propagation by exploring concepts such as crack closure [1] and a two-parameter mechanical driving force incorporating the influence of crack tip plasticity [2]. Despite some successes, existing fatigue crack growth models have lacked a comprehensive mechanical approach to adequately capture the intricate behavior of short cracks, thus limiting their practical applications. In light of recent studies conducted by the author's group on crack propagation modeling [3-4], a new generalized crack growth model has been proposed. This model aims to predict the behavior of both short and long cracks by considering two driving force parameters, Kmax and ΔK, affected by cyclic plastic deformation (i.e. residual stress fields), along with corresponding crack growth thresholds, ΔKth and Kmax,th influenced by the crack length in the short crack regime. This approach enables a unified modeling of fatigue crack behavior across short and long crack regimes. Fatigue crack growth datasets of titanium and aluminum alloys e.g. Ti-6Al-4V titanium and 7075-T6, 2024-T3 aluminum alloys were employed to validate the accuracy of the proposed model. Predicted results demonstrate a strong agreement with experimental crack growth data for these materials, affirming the efficacy of the proposed model.

VERIFICATION OF THE HIGH-ORDER VLASOV CODE LOKI IN THE RELATIVISTIC REGIME.

Jeffrey Banks[*1] and Jennifer Gorman*[1]

[1]*Rensselaer Polytechnic Institute*

ABSTRACT

Kinetic simulation of plasmas using grid-based codes is inherently costly due to the high-dimensional setting of the problem. The kinetic code LOKI implements finite difference algorithms in a variety of configurations up to 3D-3P. High-order accurate algorithms (4th and 6th order) are used as a way to mitigate the high cost of simulation by reducing the requisite number of grid points required for a given level of accuracy. This talk discusses various verification strategies that have been employed in LOKI in the relativistic setting for both Vlasov-Maxwell and Vlasov-Poisson. Manufactured solutions are used to verify the expected convergence behavior of the numerical methods in settings near to their operational use. Exact solutions for physically relevant problems, such as Landau damping, are further used to probe code performance.

ACCELERATING DYNAMIC FLUID SOLVERS IN FLUID-STRUCTURE INTERACTION SIMULATIONS

Isaac Bannerman[*1], Shaowu Pan[1] and Lucy Zhang[1]*

[1]*Rensselaer Polytechnic Institute*

ABSTRACT

The computational complexity inherent in fluid-structure interaction (FSI) simulations requires the development of efficient methods for solving both fluid and solid dynamics. This is especially crucial in minimizing the computational cost associated with fluid flow, given that it typically constitutes the most resource-intensive aspect. This need has driven the building of Reduced order models (ROMs) capable of predicting both steady-state and dynamic fluid flow. Currently, there exists frameworks where deep learning-based ROMs are used to accelerate steady-state solvers. Quite recently, a successful endeavor has utilized neural operators to expedite the solution of steady-state Partial Differential Equations (PDEs). Extending such framework to dynamic problems is demanding; it requires the management of the coupling between the ROM and the numerical solver at each time step, which poses a challenge. Moreover, one must carefully decide the input length, output length and how frequently the numerical solver should be called to prevent error accumulation while using the ROM prediction. Also, approaches such as those involving differentiable hybrid neural models rely on automatic differentiation (AD), limiting integration with non-AD-supported Computational Fluid Dynamics (CFD) or FSI platforms. In this study, we present a novel approach for accelerating the dynamic fluid solver by building a framework that allows the flexibility of using the ROM prediction as an initial guess of the fluid solver at any chosen time-step. Careful consideration of the prediction length and frequency of usage of the ROM output as initial guess prevents error accumulation while expediting solver convergence. Moreover, we develop a purely data-driven deep learning-based ROM, eliminating the need for the numerical solver to support AD. The capability of the method is verified by testing it on various dynamic fluid benchmark cases where the ROM prediction is used to accelerate fluid flow cases at Reynolds numbers (both interpolative and extrapolative) not encountered during the training of the ROM. For all cases, the methodology significantly speeds up the CFD solver while preserving the dynamical behavior of the flow and satisfying the conservation laws. The results obtained show the potential of applying the methodology to much complex cases as well as other computational fields that involve similar dynamics or the solution of time dependent PDEs.

[1]Dalian University of Technology
[2]Dalian Xinzhong Group Co., Ltd.
[3]Peninsula Alloy Inc

ABSTRACT

High entropy alloys (HEAs) especially CoCrFeMnNi HEAs have drawn more and more attention due to their excellent combination performance. However, the mechanical properties of archetypal CoCrFeMnNi HEAs still remain to be improved due to the single-phase FCC crystal structure. Although many efforts have been made on strengthening methods by grain refinement [1] or nitriding [2], the improvement of the mechanical properties is still unsatisfactory. To improve the mechanical properties of CoCrFeMnNi HEAs and broaden their application fields, we proposed that adding functionalized graphene in CoCrFeMnNi HEAs and investigated nanoscale mechanical properties and the strengthening mechanism using molecular dynamics (MD) simulation in this paper. The mechanical properties of pristine single-layer graphene nanoplatelets (GNPs) and double-side nickel-coated GNP (Ni-GNP-Ni) reinforced CoCrFeMnNi composites (Ni-GNP-Ni/CoCrFeMnNi) are studied under uniaxial tension by molecular dynamics (MD) simulations. Meanwhile, their tensile properties are also compared with those of double-side nickel-coated GNP with vacancy defects (Ni-defected GNP-Ni) and double-side nickel-coated multilayer GNPs (Ni-nGNPs-Ni) reinforced CoCrFeMnNi-based nanolayered composites. The simulated results show that the mechanical properties of Ni-GNP-Ni /CoCrFeMnNi composites are improved significantly by the addition of Ni coated GNPs. With increasing of the layers or volume fractions of GNPs in Ni-nGNPs-Ni, the elastic modulus, tensile strength and fracture strain of the composites are all increased significantly, but there exist a critical layer thickness between two graphene layers for Hall–Petch and inverse Hall–Petch relations of nanolayered composites. It is concluded that the main strengthening mechanisms for Ni-GNP-Ni/CoCrFeMnNi composites are strong interface bonding, effective load transfer from the CoCrFeMnNi matrix to the Ni-GNP-Ni and dislocation/twin strengthening by analysis of the evolution of atomic structure.

NUMERICAL INVESTIGATION ON FLUID-FLEXIBLE-STRUCTURE INTERACTION BASED ON SPH METHOD

Tingting Bao[*1], Jun Hu[1], Can Huang[2] and Yong Yu[1]*

[1]*Beijing Institute of Technology*

ABSTRACT

The fluid-flexible-structure interaction (FFSI) is characterized by the large deformation, the thin structure and the complex of the flow field. Accurately simulating FFSI poses three challenges, which are the reproduce of thin structure, the capture of moving interface, and the numerical stability of multi-physics field coupling, respectively. In this study, the FFSI is simulated by the smoothed particle hydrodynamics (SPH) because of its nature advantage in dealing with the moving interface. The shell model with single-layer particles[1] is introduced into SPH to simulate the thin flexible structure. The truncation error caused by single-layer boundary is modified by the normal flux approach[2]. κ-ε turbulence model[3] is introduced into SPH to enhance the numerical stability and capture complex flow details. In addition, other techniques or models that ensure efficiency and stability of the calculation are used in this study, including PST (particle shifting technique), δ-SPH method, and GPU (graphics processing unit). The flows around the single filament are simulated to verify the accuracy and stability of current FFSI algorithm based on the SPH method. Several important parameters that affect the motion characteristics of filaments are discussed to reveal the flow mechanism.

THE IMPACT OF ADVECTIVE DISPERSION ON THE DISPLACEMENT FLOW OF TWO HERSCHEL-BULKLEY FLUIDS IN A CONFINED GEOMETRY: EXTENDING THE D2DGA MODEL FOR NON-NEWTONIAN FLUIDS

Fatemeh Bararpour[1] and Ian Frigaard*[1]

[1]*The University of British Columbia*

ABSTRACT

Complete removal of drilling muds and sealing the space between formation and steel casing with cement slurries are the key elements in successful construction of water, geothermal, oil, and waste storage wells. This process is called primary cementing and the foremost purpose of this process is to eliminate gas leakages, which occur when the cement layers become inefficient in sealing the gap space. The primary cementing operation includes the invasion of a viscoplastic fluid at a high Peclet number (Pe≥10^5) into an eccentric annulus filled initially with another viscoplastic fluid, where the displacing fluid penetrates ahead in the center of the channel. Since the gap distance is smaller than the other length scales, the two-dimensional gap-averaged (2DGA) model is commonly applied to analyze the displacement process [1]. While the 2DGA model is effective in understanding the qualitative behaviours of fluids in confined geometries, it becomes incapable of monitoring the influence of the advective dispersion on the displacement process due to a homogeneous concentration profile considered across the gap [1]. Fortunately, there is another approach, the dispersive two-dimensional gap-averaged model (D2DGA), which is a promising model to capture advective dispersion effects [2]. This model is generated for two Newtonian fluids by modifying the two-dimensional gap averaged (2DGA) model. The key difference between the D2DGA and the 2DGA approaches comes from a 2-layer flow assumption considered for the distributions of fluids across the gap distance. To adapt the D2DGA model for two Herschel-Bulkley fluids, we consider the Augmented Lagrangian method to obtain a weak solution of the governing equations but keeping the same 2-layer flow assumption as the D2DGA model. Although the presence of a plug region in viscoplastic fluids leads to a more uniform front compared with Newtonian fluids, a comparison between the 2DGA model with the D2DGA model for two Herschel-Buckley fluids highlights the ability of the D2DGA model to track the advective dispersion.

A HIGH-ORDER FLUX RECONSTRUCTION APPROACH FOR HYPERBOLIC ELASTICITY

Abhishek Barat[*1], Brian Vermeire[1], Mojtaba Kheiri[1] and Ashok Kaushal[1]*

[1]*Concordia University*

ABSTRACT

A wide range of loading conditions in solid mechanics are either unsteady or transient, such as cyclical loading or vibration of turbomachinery components, stress concentrations in impulsively loaded homogeneous or heterogeneous materials, and free vibration of complex structures, amongst many others. These require accurate, efficient, and stable space-time discretization of the governing unsteady elasticity equations. While, classical approaches, such as the Finite Element Method (FEM), are widely-used for steady state or spectral vibration analysis, they are less suitable for more general or transient unsteady problems due to the structure of their large globally-coupled mass matrices.

In the current work we adapt the Flux Reconstruction (FR) approach, widely used in fluid mechanics, for the arbitrarily high-order accurate solution of hyperbolic elasticity problems. Similar to classical FEM, FR uses a polynomial representation of the solution in the computational domain. However, unlike FEM, the polynomials in the FR approach have compact support, meaning they are contained entirely within their respective elements. This allows FR to support discontinuous solutions at the interfaces between elements, which in turn reduces their mass matrices to a block diagonal structure, trivial to invert. Importantly this also enables them to maintain arbitrarily high-order accuracy for problems with discontinuous physics, such as step changes in material properties.

Specific focus will be given to development of the aforementioned numerical framework, upwind-based stabilization techniques, verification, validation, demonstration of the benefits of higher-order polynomial representations, and a comparison of different implicit and explicit time stepping approaches. It is expected that the proposed approach will greatly accelerate the solution of hyperbolic elasticity problems, which will be demonstrated via a range of practical example problems.

A SELF-CONSISTENT, HAMILTONIAN MODEL OF THE PONDEROMOTIVE FORCE AND ITS STRUCTURE PRESERVING DISCRETIZATION

William Barham[*1], Philip Morrison[1], Yaman Güçlü[2] and Eric Sonnendrücker[2]*

[1]*The University of Texas at Austin*
[2]*The Max Planck Institute for Plasma Physics*

ABSTRACT

A large number of interactions between matter and the electromagnetic field may be adequately captured by approximate models which reduce the interaction to a nonlinear polarization of the medium. In many ways, this concept is the heart of nonlinear optics, but also bears relevance in plasma physics in which asymptotic approximations often induce field dependent polarization and magnetization of the electromagnetic fields. A well-known laser-plasma interaction model gives rise to a nonlinear polarization of the electromagnetic medium. In the presence of an inhomogeneous oscillatory electric field, charged particles experience a net force, averaged over the oscillatory timescale, known as the ponderomotive force. Starting from the two-fluid equations, we derive a Hamiltonian model in which the nonlinear ponderomotive force self-consistently couples Maxwell's equations to an acoustic wave-type equation. We call the system of equations so derived the ponderomotive Maxwell system. One finds a simple Poisson bracket for the ponderomotive Maxwell system: it is a direct sum of the Poisson brackets for Maxwell and acoustic wave equations, as well as a coupling bracket.

Because the Poisson bracket is field-free, i.e. the Poisson bivector lacks field dependence, a structure preserving discretization is easily accomplished using finite element exterior calculus (FEEC). We explore the behavior of discretizations based on not only a traditional spectral element FEEC approach, but also a discontinuous broken-FEEC approach. Temporal discretization is accomplished using Hamiltonian splitting. Using both conforming and broken-FEEC methods with both low and high order discretizations in space and time, we simulate the ponderomotive Maxwell system in order to better understand the properties of this new approach to discretizing Maxwell's equations in nonlinear media. In all cases, we find good conservation of energy to the order of the splitting method used, and conservation Casimir invariants (e.g. Gauss's laws) to machine precision. To our knowledge this is the first time-domain solver for Maxwell's equations in nonlinear media which conserves energy and Gauss's laws, accommodates high order discretizations in both space and time, and which may use local, discontinuous basis functions to localize nonlinear solves (allowing for parallel implementation). Moreover, the methods used to discretize the ponderomotive Maxwell system shows promise to generalize well to a broad class of nonlinear wave models. Hence, the favorable qualities found in this solver for the ponderomotive Maxwell system might be used to study a much broader class of models in nonlinear optics and plasma physics.

ROBUST AND SCALABLE SOLVERS IN NONLINEAR POROELASTICITY

Nicolás Barnafi[*1]

[1]*Pontificia Universidad Católica de Chile*

ABSTRACT

Nonlinear poroelasticity models the flow of a fluid through a complex connected structure within a solid, where the solid is undergoing possibly large deformations. One natural application of this, which is our main target, is that of soft tissue. The porous structure of soft tissue is given mainly by blood circulation, which is in charge of providing oxygen to the tissue itself. The large deformation is instead given in many cases by the natural function of some organs, such as the heart and the lungs, but which is also relevant in other contexts such as brain concussions and muscle activity. The system of equations that characterizes this type of materials presents elements from two very different frameworks: nonlinear elasticity and generalized porous media equations, both extremely challenging topics.

In this talk, we will focus on two topics. The first one is robust discretization techniques for such a system of equations, with focus on a difficulty that we have named the "primal inconsistency", which is related to the presence of higher order derivatives in the primal formulation of the model that yield an inconsistent finite element approximation. The second topic will be the development of scalable algorithms for the solution of these equations, which we will base on an extension of the well-known fixed-stress solver for the Newton iterations of a nonlinear solution procedure. We will validate our claims with several numerical tests.

MATERIAL AND SHAPE OPTIMIZATION FOR THE ACTIVE RESPONSE OF LIQUID CRYSTAL ELASTOMERS

Jorge-Luis Barrera[*1], Caitlyn Krikorian[1], Elaine Lee[1], Kenneth Swartz[1] and Daniel Tortorelli[1]*

[1]*Lawrence Livermore National Laboratory*

ABSTRACT

Liquid crystal elastomers (LCEs) are responsive materials that can undergo large reversible deformations upon exposure to external stimuli, such as changes in temperature. These materials have drawn increasing interest in a wide range of applications, including soft robotics and sensors. While experimental measurements can provide valuable insights into their behavior, computational analysis is essential to exploit their full potential. Accurate simulation is not, however, the end goal; rather it is the means to their optimal design. Such design optimization problems are best solved with nonlinear programming algorithms that require gradients, i.e., sensitivities, of functions with respect to the design parameters, to efficiently traverse the design space. In this work, we design LCE structures using state-of-the-arts shape and material optimization, wherein the material optimization component pertains designing the alignment of the liquid crystals in the elastomeric matrix. To achieve this, a nonlinear LCE model implemented in a scalable and flexible finite element-based open-source framework, namely Serac, performs the analyses. The graph-based Livermore Design Optimization code, LiDO, is used to link the design parameterizations, finite element analysis, and optimization solver, and automate the sensitivity analysis. LCE design problems that optimize both the material orientation and shape to either reach a target deformation or maximize energy absorption are solved.

ABSTRACT

The meniscus, characterised by high through-thickness graded porosity, can be seen as a natural hydraulic damper. Energy dissipation experimental tests and macroscopic simulation (FE) on both native architectures (obtained by high resolution micro computed tomography) and artificially generated 3D printed architectures (based on CFD simulations of native tissue architectures) show an increase of energy dissipation by a factor of 100 with respect to common automotive hydraulic dampers (per unit volume of material).
Here we shed light on the mechanisms of energy dissipation at the pore scale by running Fluid Structure Interaction (FSI) simulations in highly deformable fully saturated soft tissues. We couple mesh-based methods for solid deformation and meshless CFD methods for fluid flow. Our investigation introduces a novel methodology that integrates FSI with advanced imaging techniques, providing unprecedented insight into the fluid dynamics of this complex tissue under physiological loading conditions.

ABSTRACT

The behavior of large-scale structures is strongly affected by their interaction with their foundation and supporting soil. This vouches for the importance of taking this effect into account when designing these structures. This paper explores the effect of foundation and soil flexibility in the design of structures via topology optimization. We consider the case of discrete contact, in which the structure is supported by pile groups, which are then responsible for transferring the borne load to their surrounding soil, as well as the case of continuous contact, in which the structure is in direct contact with the soil surface. The discrete contact case is modeled using classical finite elements to model the structure, together with the impedance matrix method to model the pile group. Direct continuity and equilibrium conditions at the interface between the structure and the pile group are establish to describe the coupling. Topology optimization is obtained using the Bi-directional Evolutionary Structural Optimization (BESO) method under various boundary conditions, with the goal of minimizing the compliance of the piled structure under a prescribed volume restriction. The continuous contact case is modeled via a coupling of the Indirect Boundary Element Method (IBEM) to model soil response and the Finite Element Method (FEM) to model the supported structure. Topology optimization is obtained using the Topology Optimization of Binary Structures (TOBS) method, to minimize structural compliance under volume constraints. Both analyses consider the case of a tall tower under vertical and horizontal loads, and the case of bridges under external loads. The results from both studies show that soil and foundation flexibility strongly affect the achievable optimization goal and cause the optimization algorithm to find significantly different optimal topologies, when compared to a first approximation considering rigid support for the structures.

GRAPH NEURAL NETWORKS FOR INTERPRETABLE MESH-BASED SURROGATE MODELING WITH ERROR TAGGING

Shivam Barwey[*1] and Romit Maulik*[21]

[1]*Argonne National Laboratory*
[2]*The Pennsylvania State University*

ABSTRACT

This work introduces an interpretable fine-tuning strategy for mesh-based modeling in the graph neural network (GNN) framework with application to fluid dynamics forecasting. Given a pre-trained baseline surrogate model, the end result is a fine-tuned model that identifies structures in physical space (corresponding to sub-graphs) intrinsically linked to the forecasting task, while retaining baseline predictive capability. These structures are adaptively produced in the forward pass and serve as explainable links between the baseline model architecture, the optimization goal, and known problem-specific physics. Additionally, through a regularization procedure, fine-tuned GNNs can also be used to identify, during inference, graph nodes that correspond to a majority of the anticipated forecasting error, adding a novel interpretable error-tagging capability to baseline models [1]. Ultimately, the objective is to show how augmenting pre-trained baseline GNNs with trainable adaptive pooling modules results in an interpretable fine-tuning framework for mesh-based predictive modeling. The core elements and contributions of this work are as follows:

(1) Multiscale message passing: Graph neural networks leverage multiscale message passing layers as backbones to model the evolution of an unstructured turbulent fluid flow [2].
(2) Interpretable fine-tuning: A trainable graph pooling layer -- which relies on a learnable node subsampling procedure -- is attached to the baseline GNN, creating an augmented GNN architecture with enhanced interpretability properties. Fine-tuning is then accomplished by freezing the parameters of the baseline GNN and ensuring the parameters in the newly introduced module are freely trainable.
(3) Error tagging: A regularization term, representing a mean-squared error budget, is added to the objective function during the fine-tuning process. The minimization of this term ensures that the fine-tuned GNN tags, during inference, a subset of the graph nodes that are expected to contribute most significantly to the GNN forecasting error, providing an novel avenue for a-posteriori error tagging for mesh-based models.

Demonstrations are performed using unstructured fluid flow data sourced from a backward-facing step configuration at high Reynolds numbers.

PHYSICS-INFORMED DIFFUSION MODELS: INTRODUCING PHYSICS INTO DATA-DRIVEN PROBABILISTIC MODELS

Jan-Hendrik Bastek[*1], Steve WaiChing Sun[2] and Dennis Kochmann[1]*

[1]*ETH Zurich*
[2]*Columbia University*

ABSTRACT

Denoising diffusion models, a popular class of generative models, have demonstrated exceptional capabilities in matching intricate probability distributions [1]. Their utility has extended beyond the realm of generating authentic-looking images and videos and now also plays an important role in the natural and engineering sciences, particularly in solving inverse design problems, such as designing metamaterials with nonlinear characteristics [2].

Centuries of research have led to a deep understanding of the equations governing such systems. Nevertheless, such generative models are typically still trained to solely match a data distribution, where the data is generated via a forward simulator such as the finite element method. While these data points naturally obey the physics, the model itself has no direct knowledge of the underlying equations.

We introduce a novel framework that integrates physical laws into the probabilistic setup of denoising diffusion models in a consistent manner. This enhances the model's capability to generate more realistic samples by not only adhering to the data distribution but also by respecting the underlying physics. We discuss extensions of this method to incorporate inequality constraints and optimization goals. Our various numerical studies showcase the benefits of incorporating this additional knowledge in training such models.

LOADING DEVICES AND NON-CLASSICAL THERMOMECHANICAL BOUNDARY CONDITIONS

Romesh Batra[*1]*

[1]*Virginia Tech*

ABSTRACT

To study thermomechanical deformations of a body B we regard the collection of other bodies contacting B as a loading device L. Here we consider only an intimate loading device defined as one that is perfectly bonded to the boundary ∂B of B and express the action of L on B at points of ∂B as boundary conditions. For simplicity, we first separately study the mechanical and the thermal problems. For the mechanical (thermal) problem, these are expressed as surface tractions (heat flux) at a point of ∂B in terms of displacements (temperature) and their in-surface gradients at points of ∂B. Note that neither surface tractions nor the heat flux, respectively, involve derivatives of displacements and the temperature along the normal to ∂B. For an intimate loading device surface tractions, the heat flux, the displacements and the temperature are continuous across ∂B enabling one to express surface tractions (heat flux) as functional of displacements (temperature) and their in-surface gradients. The leading term for the mechanical and the thermal problem is, respectively, the familiar equation for the Winkler foundation and the Robin boundary condition. Thus, the problem of analyzing the interaction between B and L is reduced to that of delineating deformations of B. The challenging task of showing that this procedure provides deformations of interior points of B close in some sense to those deduced by analyzing the two-body problem is left for a future study.
Boundary-value problems involving non-classical boundary conditions proposed here have not been studied. It is not clear what space of functions to use for the trial solutions since derivatives appearing in the boundary conditions may be higher than those in equations governing deformations at interior points of B. These boundary conditions involve a length scale that may alleviate the dependence of a numerical solution by the finite element method.

EFFECT OF MOISTURE ON PROCESS INDUCED DEFORMATION IN CARBON FIBER COMPOSITES

Martin Battilana[*1] and Anoush Poursartip*[1]

[1]*University of British Columbia*

ABSTRACT

Process induced deformation describes the phenomenon where the dimensions of a manufactured composite part are different from the tooling dimension. One of the key uncertainties in the models that predict process induced deformation is the effect of moisture absorption. The overall behavior of moisture transport in composites is commonly approximated by Fick's law of diffusion despite the absorbed moisture in a composite having both physical (reversible) and chemical (non-reversible) effects on the matrix [1]. Moisture swelling of the matrix will directly affect the composite residual strain and stress state, even absent plasticization, or other degradation effects. Since the full saturation of a part usually requires months to years in a moisturizing environment, the approach typically taken for design purposes is to assume a worst-case moisture content (a fully saturated part), as this is considered to be a conservative approach [2].

This presentation explores the effect of both symmetric and asymmetric moisture gradients on process induced deformation. A Fickian diffusion model was developed in ABAQUS to predict the concentration profiles as a function of time for various L-shape samples. A thermal analogy was then used for the 3D stress analysis in ABAQUS as the equations for thermal strain (1), ε_T, and moisture strain (2), ε_M, are identical:

$$\varepsilon_T = \alpha \Delta T \quad (1)$$
$$\varepsilon_M = \beta \Delta c \quad (2)$$

For the thermal strain, α is the coefficient of thermal expansion and ΔT is the temperature gradient. For the moisture strain, β is the coefficient of moisture expansion, and Δc is the concentration gradient. Inputting concentration profiles as temperature profiles and replacing the thermal expansion coefficient with the moisture expansion coefficient allows for the calculation of deformed part geometries which can be compared to experimental results. During the experiments, it was found that transient moisture gradients with asymmetric concentration profiles caused significantly more spring-in than the fully saturated steady state conditions, implying that the worse-case scenario for the moisture swelling effect is not the fully saturated part. The developed models not only show agreement with the experimental results, but also provide insight into the contribution from in-plane and through-thickness effects.

PHYSICS INFORMED MACHINE LEARNING-BASED COMPUTATIONAL FRAMEWORK TO ANALYSE NONLINEAR AND HETEROGENOUS VARIATIONS OF PLANT-BASED FOOD DRYING

Chanaka Prabuddha Batuwatta Gamage[*1], Charith Rathnayaka[2], YuanTong Gu[1] and Chanaka Prabuddha[1]*

[1]*Queensland University of Technology*
[2]*University of the Sunshine Coast*

ABSTRACT

Computational modelling plays a critical role in investigating the drying kinetics of plant-based foods to achieve energy-efficient drying and produce high-quality dried food products. However, traditional computational methods, such as mesh-based Finite Element Analysis (FEA) and mesh-free particle-based methods, face inherent challenges. Mesh-based FEA encounters significant difficulties when modelling multiphase interactions and the large deformation of materials. On the other hand, mesh-free methods are not very effective in simulating attributes like time-domain variations, and there is a shortage of model developments designed to capture heat and mass transfer variations within the context of food drying. None of the traditional computational approaches have demonstrated the ability to incorporate the inconsistency of material properties in the spatiotemporal domain and heterogeneous conditions when simulating the microscale physical models of plant-based food materials during drying [1]. This study introduces a novel Physics-Informed Machine Learning (PIML) framework to overcome some of the challenges faced by traditional modelling frameworks. The flexibility of this novel framework, coupled with a mesh-free approach, provides various advantages in the context of food drying. It can extract information from both data and physics [1], strengthening the prediction capabilities if one side is weak. If the PIML model is trained with only physics, without labelled data, it can be used to solve physics models [2]. PINN's mesh-free nature and gradient-descent optimization features provide more flexibility to solve nonlinear variations. Furthermore, interface calculations are much easier, allowing for domain decomposition to introduce heterogeneous boundary conditions and property variations easily, making the model more realistic [3].

SPACE-TIME FINITE ELEMENT GEOMETRIC MULTIGRID SOLVER FOR FULLY DYNAMIC POROELASTICITY

Markus Bause[*1] and Mathias Anelmann*[1]

[1]*Helmut Schmidt University Hamburg*

ABSTRACT

Constructing higher order numerical methods to coupled systems of partial differential equations, maintaining stability and inheriting most of the rich structure of the continuous problem, becomes increasingly difficult. Space-time finite element methods (STFEMs) allow the natural construction of higher order approaches even to complex systems. STFEMs offer the potential to achieve accurate predictions on computationally feasible grids with a minimum of numerical costs. The iterative solution of the arising algebraic systems requires advanced and tailored techniques. Geometric Multigrid (GMG) Methods are known as the most efficient iterative methods for the solution of large linear systems emerging from the discretization of partial differential equations [M. Anselmann, M. Bause, A geometric multigrid method for space-time finite element discretizations of the Navier–Stokes equations and its application to 3d flow simulation, ACM Trans. Math. Softw., 49 (2023), Article No.: 5, pp. 1-25].

We present and analyze higher order STFEMs for three- and multi-field simulation of poroelastic wave propagation studied, for instance, in computational subsurface or biomedical engineering or seismology and modeled by a coupled hyperbolic-parabolic system [M. Anselmann, M. Bause, N. Margenberg, P. Shamko, An energy-efficient GMRES-Multigrid solver for space-time finite element computation of dynamic poro- and thermoelasticity, Comput. Mech., submitted (2023), pp. 1-30; arXiv:2303.06742]. In the multi-field approach [M. Bause, S. Franz, Structure preserving discontinuous Galerkin approximation of a hyperbolic-parabolic system, Electron. Trans. Numer. Anal., submitted (2023), pp. 1–24; arXiv:2311.01264], the equations are rewritten as a first-order in space and time system such that Picard’s abstract solution theory for evolutionary problems becomes applicable. Families of continuous and discontinuous Galerkin FEMs in space and time are investigated and evaluated. To solve the algebraic systems with complex block structure, GMG preconditioning with local Vanka-type smoothers of GMRES iterations is suggested. The numerical and parallel performance of the approaches are benchmarked for challenging three-dimensional test problems.

TAYLOR-SERIES EXPANSION FOR MESHFREE METHODS IN COMPUTATIONAL SOLID MECHANICS

Yuri Bazilevs[*1]*

[1]*Brown University*

ABSTRACT

Numerical quadrature based on Taylor-series expansion approaches was introduced in the mid-80s for FEM to develop a parameter-free approach for hourglass control. It laid dormant for a while, and, much later, in the mid 2010s, it resurfaced in the context of RKPM to develop a so-called Natural Stabilization approach, which is arguably the most important recent breakthrough in RKPM that brought the necessary added robustness for a wide range of nonlinear solid mechanics applications. In this talk, I will present a general framework of Taylor-expansion-based methods in computational solid mechanics and its broad applicability to meshfree methods and beyond. I will demonstrate: i. How to develop Taylor-series-expansion-based formulations that are accurate and stable for nearly incompressible deformations; ii. How to stabilize correspondence-based Peridynamics without resorting to costly bond-associated approaches; and iii. How to develop general-purpose large-deformation meshfree thin shells.

DEVELOPMENTS IN THE USE OF THE BONDED PARTICLE MODEL TO STUDY ORE FRACTURE

Temitope Oladele[1], Dion Weatherley[2] and Lawrence Bbosa[3]*

[1]The University of Winnipeg
[2]The University of Queensland
[3]Mintek

ABSTRACT

In mineral processing, ore breakage is an essential first step for which the objective is to increase the exposed surface area of the valuable mineral, thereby increasing the likelihood of liberation in subsequent separation stages. This process is well known to be energy-intensive, and increasing scrutiny around sustainable practices has heightened the need to examine the efficiency of current practices. Factors such as pre-existing cracks and mineralogical structure are known to affect ore breakage mechanisms. However, isolating and investigating individual factors under experimental conditions is challenging and typically impractical.

Numerical techniques such as the Bonded Particle Model-Discrete Element Method (BPM-DEM) have been developed as a means of investigating in isolation, the effects of different factors on ore breakage behaviour under closely controlled breakage conditions using synthetic rock specimens. In this work, a model is developed to relate microstructural model parameters to the macroscopic mechanical properties that are typically obtained from standard geotechnical breakage experiments. The robustness of the model is evaluated by considering the sensitivity of fracture measures to the variation of model resolution, size-dependency and macroscopic mechanical properties (Young’s modulus and uniaxial compressive strength) of the numerical specimens.

It demonstrated that the macroscopic measures of fracture are in agreement with existing theoretical knowledge, in that the fracture starts with the initiation of stress at the point of contact, initiation of cracks following the accumulation of strain energy exceeding the particle strength, and the progression of cracks through the particle leading to failure. It is further shown that under different configurations, failure occurs with a variable degree of breakage, highlighting the opportunity of using this computational approach to study specific cases toward identifying efficient modes of breakage.

TOWARD DISCRETIZATION-CONSISTENT CLOSURE SCHEMES FOR LARGE EDDY SIMULATION USING REINFORCEMENT LEARNING

Andrea Beck[*1] and Marius Kurz*[1]

[1]*University of Stuttgart*

ABSTRACT

With a few exceptions, Large Eddy Simulation (LES) methods intended for practical engineering applications are based on an implicit scale separation filter, sometimes also referred to as a grid or discretization filter. For this approach, the induced filter kernel, and thus the closure terms, are determined by the properties of the grid and the discretization operator, leading to additional computational subgrid contributions to the closure terms that are generally unknown in a priori analysis [1].

Our talk will present a novel method for developing discretization-consistent closure schemes for implicitly filtered LES. In this approach, the task of adapting the coefficients of LES closure models is framed as a Markov decision process and solved in an a posteriori manner with Reinforcement Learning (RL) [2]. This optimization framework is applied to both explicit and implicit closure models. The explicit model is based on an element-local eddy viscosity model. The optimized model is found to adapt its induced viscosity within discontinuous Galerkin (DG) methods to homogenize the dissipation within an element. For the implicit modeling, RL is applied to identify an optimal blending strategy for a hybrid DG and Finite Volume (FV) scheme. The resulting optimized discretization yields more accurate results in LES than either the pure DG or FV method and renders itself as a viable modeling ansatz that could initiate a novel class of high-order schemes for compressible turbulence by combining turbulence modeling with shock capturing in a single framework. All newly derived models achieve accurate results that either match or outperform traditional models for different discretizations and resolutions. Overall, the results demonstrate that the proposed RL optimization can provide discretization-consistent closures that could reduce the uncertainty in implicitly filtered LES [3].

CALCULATION OF THE FORCED RESPONSE OF A PARTICLE-DAMPED STRUCTURE BASED ON MECHANICAL IMPEDANCE OBTAINED FROM MEASUREMENTS

Jonas Becker[*1] and Gleb Kleyman*[1]

[1]*Leibniz University Hannover*

ABSTRACT

Mechanical structures optimized for their total weight in particular are often susceptible to vibrations due to low structural damping. In order to dampen vibrations over a broad frequency band, particle dampers are a low cost and effective solution. Energy dissipation is achieved by friction and impacts of the particles inside the cavity. Depending on the excitation level, the behavior of the damper can be described using the solid, fluid or gaseous domain.

Although particle dampers are excellent for reducing vibrations, they are not widely used due to their complex design process. One of the reasons for this is the large number of design parameters. The current state of research involves time-discrete simulation of the individual particles, whereby the calculation time quickly reaches an unacceptable limit as the number of particles increases.
In this work, an alternative approach is proposed to simplify and accelerate the design process. The properties of a given particle container are determined experimentally in form of its mechanical impedance, independent of the system to be damped. As in electrical engineering, the impedance is a complex variable whose phase angle in this case results from the difference angle between the displacement and the force. To determine the mechanical impedance, the damper is excited with a defined displacement amplitude and frequency and the resulting force is measured. An equivalent mass and equivalent damping are calculated from the data obtained and the results are stored in a lookup table.

A beam structure is used to demonstrate the proposed approach. Harmonic balance is applied which is a state of the art method for steady state vibration analysis of nonlinear systems. As the impedance is defined already in the frequency domain, it can be directly used in a harmonic balance framework to obtain the nonlinear forced response function.

The major advantage of this approach is that as soon as the mechanical impedance of the particle damper is known, its effect on the system to be damped can be calculated with low computational effort. This allows for parameter studies to quickly find the optimum position of the damper on the structure or variations of it, as the damper remains independent of the structure itself.

SEMI-ANALYTICAL FAILURE PREDICTION OF ADHESIVE JOINTS BY FINITE FRACTURE MECHANICS

Thomas Methfessel[1], *Cherine El Yaakoubi-Mesbah*[1] *and Wilfried Becker**[1]

[1]*TU Darmstadt*

ABSTRACT

In many cases adhesive bonding is a very advantageous way to join load-carrying components, in particular when these components are relatively thin. A typical field of application is lightweight construction, where typically two relatively thin sheet-like adherends are joined through an intermediate adhesive layer. This joining technique has the advantage that no screws or rivets are necessary and that the load transfer is distributed over a larger overlapping area. The actual load transfer behavior, however, is somewhat demanding. Due to the given overlap geometry and the generally dissimilar stiffness properties of the adherends and the adhesive, local stress concentrations occur at the edges of the joints, which may trigger the onset of debonding cracks and subsequent failure and in this way determines the effective strength of the given adhesive joints.
The current contribution suggests a semi-analytical structural model for an adhesive joint with a closed-form higher-order description of the adhesive layer and the potential occurrence of a debonding crack. This enables a highly efficient failure prediction by the concept of Finite Fracture Mechanics [1], employing a coupled failure criterion that consists of a stress and an energy subcriterion. The comparison with accompanying finite element calculations and experimental findings reveals the high predictive quality of this approach.

PHYSICS-CONSTRAINED GAUSSIAN PROCESS VARIATIONAL AUTOENCODER

Thomas Beckers[*1]*

[1]*Vanderbilt University*

ABSTRACT

Understanding the dynamics of an observed object and being able to predict its future states is paramount for controlling autonomous systems or robots that interact with their environment. However, learning dynamics from real-world observations is challenging. Variational autoencoders (VAEs) have been one of the most popular approaches to the unsupervised learning of complex distributions. Their effectiveness has been proven in several examples, such as learning handwritten digits and faces, among others. In recent years, VAEs have been extended to process sequential data, such as video clips, by introducing a temporal constraint on the dynamics of the latent space. Thus, using image sequences of a complex system as input data, the encoder may be used to learn a reduced model of an object's dynamics in the video without ground truth data (unsupervised learning). Even though the object's dynamics is typically based on first principles, this prior knowledge is often ignored in the existing literature.

In this presentation, we present our work on a physics-enhanced variational autoencoder that places a physics-constrained Gaussian process prior on the latent dynamics to improve the efficiency of the variational autoencoder and to ensure physically correct dynamics in the latent space. Instead of directly learning the times series in the latent space, the GP models the unknown latent forces acting on the object, as the underpinning structure of the dynamics of the object might be well known. The physical prior knowledge expressed as linear dynamical system is here reflected by the Green's function and included in the covariance function of the Gaussian process. This novel approach improves the data efficiency of the autoencoder and guarantees a physically correct trajectory of the reduced-order model in the latent space with respect to the known object dynamics. The benefits of the proposed approach are highlighted in a simulation.

SOLVER-FREE REDUCED ORDER HOMOGENIZATION FOR NONLINEAR PERIODIC HETEROGENEOUS MEDIA

Andrew Beel[*1] and Jacob Fish*[1]

[1]*Columbia University*

ABSTRACT

Computational homogenization methods, particularly reduced-order methods, are crucial tools for reliable prediction of composite material behavior. Building on the recently developed fine-scale solver-free classical computational homogenization (solver-free CCH) [1], we propose a fine-scale solver-free reduced order homogenization approach (solver-free ROH) that avoids solving the fine-scale equilibrium equations and approximates the phase-average eigenstrains by sampling the fine-scale eigenstrain at a small number of points. The solver-free ROH pre-computes history-dependent eigenstrain influence tensors, identifies suitable sampling points within the unit cell, and chooses sampling point contribution factors based on training data from a small set of CCH simulations. During the online stage of the computation, these pre-computed quantities are used to compute unit cell phase-average strains, eigenstrains, and stresses, which are homogenized to give the corresponding coarse-scale quantities. In this presentation, the proposed solver-free ROH is formulated and verified in the context of small deformation in nonlinear periodic heterogeneous media. First, in the formulation, we review the solver-free CCH procedure for computing eigenstrain influence tensors, devise a sampling point approximation of the phase eigenstrains, and walk through the online stage unit cell computation. Next, we verify the solver-free ROH using loading cases outside the training data set. Finally, we use the proposed method to simulate a multilayer composite plate in three-point bending and open hole tension, demonstrating the method's efficiency and accuracy relative to the CCH [2].

PHYSICS-INFORMED SPECTRAL LEARNING TO SIMULATE FLUID FLOW BASED ON DISCRETE HODGE–HELMHOLTZ DECOMPOSITION

*Pouria Behnoudfar**[1] and Luis Espath*[2]

[1]*Mineral Resources, CSIRO*
[2]*University of Nottingham*

ABSTRACT

We introduce a Physics-informed Spectral Learning (PiSL) for solving the discrete Hodge–Helmholtz decomposition from limited data through a discrete L2 projection. This computational framework seamlessly integrates supervised and unsupervised learning techniques.

The PiSL framework demonstrates spectral (exponential) convergence, showcasing its efficacy in adaptively constructing a sparse set of Fourier basis functions and their corresponding coefficients. This adaptability is achieved by iteratively addressing a sequence of minimization problems, wherein the set of basis functions is incrementally expanded in a greedy fashion. Notably, the imposition of divergence- and curl-free constraints simplifies into a finite set of linear algebraic equations within the Fourier structure.

The performance of our proposed PiSL method is illustrated through several examples, highlighting its capability to efficiently address the discrete Hodge–Helmholtz decomposition from sparse data to predict fluid flow.

MODELING CELLULAR PHENOMENA AND THEIR IMPACT ON THE ORGAN-SCALE PHYSIOLOGY

*Marek Behr**[1]

[1]*RWTH Aachen University*

ABSTRACT

Computational modeling and analysis play an important role in bioengineering, particularly in the planning of therapies such as drug-eluting stent placement, and in the design of biomedical devices such as implantable blood pumps. Digital representation of blood flow and associated physiological phenomena has the potential to shorten the design cycle and give the designers important insights into causes of blood damage and suboptimal performance. Nevertheless it is clear that a full bottom up modeling across all scales, starting with molecular one, is not always a practical approach. Depending on the objective of the analysis, one needs to choose the appropriate level of abstraction. In many cases in bioengineering, this involves representing cellular phenomena in the blood stream at the homogenized continuum scale.

We give several examples of recent developments, involving drug propagation and vessel wall growth in case of arterial stents, and red-blood-cell damage and platelet aggregation in case of blood pumps. In order to obtain quantitative blood damage prediction, cumulative tensor-based measures of strain experienced by individual blood cells have been developed; red blood cells under shear are modeled as deforming droplets, and their deformation tracked in an averaged sense.

FINITE ELEMENT SIMULATION OF COMPLEX FLUIDS AND APPLICATIONS IN MANUFACTURING

Marek Behr[1], Blanca Ferrer Fabón[1] and Felipe González[1]*

[1]*RWTH Aachen University*

ABSTRACT

Many flows of engineering interest involve fluids which are governed by complex constitutive relations. For viscoelastic fluids in particular, the advective nature of the constitutive equation presents a significant numerical challenge. Moreover, the intrinsic coupling of three or more distinct field variables means that multiple compatibility conditions of the inf-sup type must be either satisfied or circumvented. Stabilized formulations of Variational Multi-Scale (VMS) type can provide robustness and accuracy at high Weissenberg numbers. They also allow arbitrary combinations of basis functions, including equal-order interpolations for all fields.

Development of these numerical methods is motivated by challenging applications in production technology, including injection molding and additive manufacturing. We will discuss efforts to reduce costly running-in trials for melt-based processes. Flow of polymer melt as it fills a cavity, or exits the printing nozzle, is often highly influenced by the microstructure of the material and by thermal effects.

Even if modeling and simulation of such production processes still involve many open questions, the computational analysis is advanced enough so that the transition to numerical design can be contemplated. We discuss some typical objective functions, process parametrization approaches, and show sample outcomes of automatic design.

EXPLORING IN-PLANE ELASTIC PROPERTIES AND ENERGY ABSORPTION OF THE BIO-INSPIRED GLASS SPONGE STRUCTURES

Hassan Beigi Rizi[*1], Harold Auradou[1] and Lamine Hattali[1]*

[1]*Université Paris-Saclay, CNRS, FAST*

ABSTRACT

The biological systems have evolved a diverse variety of robust skeletal architectures that can be used as lightweight structures to meet environmental requirements. However, the utilization of bio-inspired structures for energy absorption applications remains less common compared to conventional structures due to the novelty of the bionic approach in this field and limited fabrication capabilities. In this study, first we explored experimentally the in-plane elastic mechanical properties of lattice derived from Euplectella Aspergillum Glass Sponges (EA-sponge). Then, the lattice structure was designed by approximating the architecture of EA-sponge using a fused filament fabrication (FFF) process with thermoplastic Polylactic acid (PLA) filaments. The quasi-static compression test was conducted to study the energy absorption behavior of EA-sponges and compare its geometry to three other 2D square-base lattices with diagonal reinforcement and non-diagonal reinforcement. The results are discussed the effect of the geometrical t/d strut ratio, relative density and diagonal reinforcement or not on the maximization of the energy absorption.

SIMULATING THERMALLY INDUCED STRESSES AND THE RESPONSES TO SUBSEQUENT IMPULSIVE LOADING

Stephen Beissel[*1]*

[1]*Southwest Research Institute*

ABSTRACT

Many industries rely on simulations with explicit time integration to resolve the wave motion in solids due to the impulsive loads of impacts or explosions. But oftentimes the performance of the impulsively loaded solid is affected by pre-existing stresses due to prior thermal loading. The development of these thermal stresses is governed by the coupled thermo-mechanical equations. But because thermal conduction is much slower than wave motion, and the periods of thermal-stress development are many orders of magnitude longer than those for which explicit schemes are suitable, simulating the development of thermal stresses is typically done with the unconditionally stable time steps of implicit integration schemes. Simulating both loading events therefore requires transferring the computation from implicit to explicit schemes. Some codes offer both scheme types, and they enable the transfer without exporting the solution from one code and importing it into another. However, finite-element simulations involve many algorithms, and some of them – such as the element formulations and contact algorithms – depend on whether the integration scheme is implicit or explicit. The transfer from one scheme to another is therefore not a straightforward procedure, even within a single code.

This presentation introduces an alternate approach to simulating thermal stresses and subsequent impulsive loading on the same domain, and compares it to the sequential use of implicit and explicit schemes. This approach exploits the observation that the critical stable time step of explicit integration of the energy balance is several orders of magnitude greater than the critical stable time step of explicit integration of the equations of motion, given typical combinations of thermal conductivity, density and bulk modulus. This discrepancy allows scaling of the thermal conductivity to the artificially high value at which the two critical stable time steps are equal. With this scaling, the two explicit schemes simulate thermal-stress development at optimal computational efficiency for explicit integration. The fidelity of this approach depends on several considerations, including the damping of artificial dynamic effects resulting from conductivity scaling. Although this approach requires significantly more time steps than implicit integration, the explicit solution on each step is trivial. The primary benefit of this approach is avoiding the need to employ two different integration schemes, and therefore the need to transfer the computation from an implicit scheme to an explicit one. The implicit and explicit approaches to simulating thermal stresses are compared through sample computations and metrics of their computational efficiencies.

AN INTEGRATED COMPUTATIONAL FLUID DYNAMICS (CFD) - IMAGE ANALYSIS (CFD-IA) TO STUDY THE FLUID FLOW REGIMES INSIDE THE HUMAN MENISCAL TISSUE

Daniel Bell[*1], Jack Waghorne[1] and Olga Barrera[12]*

[1]*Oxford Brookes University*
[2]*University of Oxford*

ABSTRACT

The meniscus, a porous soft tissue renowned for its load-bearing capabilities and energy absorption properties, remains the subject of profound interest in biomechanics. Through high-resolution micro-computed tomography (μCT) scans, we delve into the intricate mechanisms underlying energy dissipation, implementing a novel methodology merging Computational Fluid Dynamics (CFD) with imaging techniques. Our examination highlights the meniscus's architectural resemblance to a sandwich structure, featuring a rigid outer layer and a pliant internal layer composed of collagen channels. These channels, intricately oriented to guide fluid flow, facilitate deformation and energy dissipation, suggesting a potential for optimised damping systems. Our investigation scrutinises the relationship between architectural characteristics and fluid flow dynamics, a pivotal pursuit for researchers endeavouring to identify biomimetic solutions for tissue replacement. Employing high-resolution 3D μCT scans, we analyse fluid flow patterns within the meniscal architecture across a spectrum of inlet velocities spanning from 0.1 mm/s to 1.6 m/s. Our findings unveil statistical correlations between architectural parameters (e.g., tortuosity, connectivity, porosity, and pore size) and fluid flow dynamics (e.g., number distribution, permeability). Some channels exhibit exceptional Reynold’s number values, reaching 1400 at an inlet velocity of 1.6 m/s, with a discernible transition from Darcy's regime to a non-Darcian regime occurring around an inlet velocity of 0.02 m/s. Furthermore, we identify location-dependent permeability variations ranging from 20 to 32 Darcy. Regression modelling shows relations between fluid velocity and tortuosity at elevated inlet velocities, while channel diameter emerges as a significant factor at lower inlet velocities. Moreover, as inlet velocities escalate, deviations from preferential flow directions increase, resulting in a notable reduction in the concentration parameter by an average of 0.4. This pioneering research offers invaluable insights into the fluid flow dynamics within the meniscus and its intimate interplay with structural attributes. By elucidating these intricate relationships, our findings pave the way for the development of biomimetic solutions tailored for tissue replacement leading to new innovation in biomechanics and regenerative medicine.

APPLICATION OF TOPOLOGY OPTIMIZATION METHODS TO SPATIAL PACKAGING OF INTERCONNECTED SYSTEMS WITH THERMAL STRESS CONSTRAINTS

Waheed Bello[*1], Corey Parrott[2] and Kai James[1]*

[1]*Georgia Institute of Technology*
[2]*University of Illinois Urbana Champaign*

ABSTRACT

Key Words: Spatial Packaging of Interconnected Systems with Physics Interactions, Neural Networks, Multi-Layer Perceptron, Electrothermal System, Finite Element Method

In the current industrial landscape, engineering systems often involve the packaging and routing of the various components. The design of these systems relies heavily on the expertise of engineers. Automated methods have been developed to solve the packing and routing problems independently. Jessee et al. have introduced a framework for 2D Spatial Packaging of Interconnected Systems with Physics Interactions (SPI2) which simultaneously solves the packing and routing problem while considering the implications of the physics interactions within the system [1]. The physics model involved the uncoupled thermofluid analysis of heat generating components connected via fluid-based cooling pipes. This study extends the SPI2 framework to include structural considerations, exploring the effects of thermal expansion of the cooling pipes on the optimal layout. The device locations, pipe widths, and connection points remain as the design parameters for representing the system. A finite element model is developed to analyze the elastic response of the pipes and the design sensitivities are derived using an adjoint analytical method. Support spring elements are introduced to model the fixed boundaries at each component preventing pipe expansion into the components. The design is subject to a constraint on the thermal stresses caused by the repeated cycles of heating and cooling in the pipes. This methods' capability is demonstrated by optimizing three thermal-fluid-structural systems, with results compared to designs obtained from the baseline SPI2 model. The study also explores the application of a Multi-Layer Perceptron for the real-time surrogate modelling of the SPI2 framework [2]. The Multi-Layer Perceptron mechanism learns the spatial topology of the system, mapping the initial input parameters to a system layout with optimized physics-based performance.

[1]EDF R&D
[2]Sorbonne University
[3]Sandia National Laboratories

ABSTRACT

The recent development of data-driven approaches has increased interest in developing robust and efficient algorithms to exploit data in engineering design and modelling in CFD. A common set of oberved data d can be some function of a system output, or some desired (targeted) data. A frequent question then arises: what should be the model input that gives as output the targeted or observed data. Solving such inverse problems using a high-fidelity CFD model is very expensive in computational time and storage. This cost is even more important if the CFD model is subject to uncertainties. We are often interested in a model output, defined as a quantity of interest (QoI) whose value, while in presence of uncertainties, will no longer be a scalar but a functional depended on the uncertain parameters. Besides the cost of high-fidelity CFD problems in presence of numerical uncertainties, the model must accurately describe highly nonlinear flow dynamics (like shock waves, etc).

The inverse problem we consider here takes a given model and an observed (targeted) output probability density function (pdf) on QoI, and builds a new model input pdf which is consistent with both the model and the data in the sense that the push-forward of this pdf through the model matches the given observed pdf. We present in this work a non-intrusive adaptive stochastic collocation method [3] coupled with a data-consistent inference framework of [1,2] to efficiently solve stochastic inverse problems in CFD. This adaptive surrogate model is built using a stochastic error estimator as refinement indicator in simplex elements. The efficiency of the proposed method is evaluated on analytical test cases and two CFD configurations. The proposed method is shown to be able to reconstruct both an observed pdf on the data and key components of a data-generating distribution in the uncertain parameter space.

VERIFICATION WITH ASYMPTOTIC SOLUTIONS: A NOVEL APPROACH FOR RADIATIVE TRANSFER PROBLEMS

William Bennett[*1] and Ryan G. McClarren[1]*

[1]*University of Notre Dame*

ABSTRACT

This work proposes to add a new dimension to the method of asymptotic analysis as verification. Conventional employments of this method compare a solution of higher order equations to the appropriate asymptotic limiting solution. The mathematical mechanism of asymptotics can however be invoked to determine the order that the higher order system ought to converge to the lower and verify that a simulation converges at the expected rate, providing greater coverage over the whole parameter space between the two solutions that requires only a solution to the asymptotic equations. In the context of radiation transport, the convergence relationship at the origin from transport to diffusion is found in terms of mean free time, t for infinite medium Green's solution problems to be $O(t^{-3/2})$ for planar geometry and $O(t^{-5/2})$ for spherical. Also, functions are found to represent the error away from the origin as a function of a self similar parameter. Finally, an initial layer correction term for anisotropic initial conditions is derived to bookend the analysis at early and late times. These results are combined into an powerful tool that yields extensive verification analysis with only a single solution of the radiative transfer simulation code.

DESIGNING A TRUE WAVE-FOCUSING ACOUSTIC BLACK HOLE THROUGH TOPOLOGY OPTIMIZATION

Martin Berggren[*1], Abbas Mousavi[1], Linus Hägg[1] and Eddie Wadbro[2]*

[1]Umeå University
[2]Karlstad University

ABSTRACT

The acoustic black hole is a device designed so that the wave propagation velocity is gradually reduced, ideally down to zero, at the same time as the amplitude is progressively increased. Thus, in the ideal case, the wave will never reach the end of the device, which has motivated the name ‘black hole’ for it. Such a device can be used to damp incoming waves, for weak signal sensing, and for wave focusing. For transverse elastic waves in beams and plates, such devices have been developed and extensively investigated during the last 20 years. However, the corresponding effect for acoustic waves in fluids has been much less studied. Unfortunately, the few types of layouts that have been suggested in the literature turn out to essentially lack the wave-focusing effect, despite their often-good damping properties. Here we demonstrate that density-based topology optimization can be used to design the interior of a wave guide that exhibits strong broad-band wave focusing. A complicating factor is that viscothermal effects turn out to be significant in this type of device and need to be considered in the optimization. Direct modeling through the linearized, compressible Navier–Stokes equations would be extremely computationally demanding for topology optimization. We therefore model these effects by a generalized impedance boundary condition at solid walls together with the Helmholtz equation in the bulk volume. This boundary condition is potentially present at each element interface in the computational mesh and the corresponding boundary condition is scaled by the square of the jump of the design variable across the interface. Thus, in the limit of zero–one-valued design variables, the viscothermal impedance boundary condition will only be imposed at solid–air interfaces. Using this strategy, we were able to design through topology optimization a truly wave-focusing waveguide device with length 255 mm and radius 115 mm that shows strong wave focusing towards a region at the end of the device in the 400–1000 Hz frequency band. In contrast, the standard type of design for a waveguide acoustic black hole, first suggested by Mironov and Pislyakov (Acoust Phys+ 48(3):347–352, 2002), is a very efficient damping device but fails to provide any wave focusing at all.

A MULTI-FIDELITY MODEL FOR LARGE-SCALE WAVE ENERGY EXTRACTORS

Michel Bergmann[*1] and Beatrice Battisti*[2]

[1]*Inria, Institut de Mathématiques de Bordeaux*
[2]*Politecnico di Torino, Inria*

ABSTRACT

The primary objective of this study is to efficiently forecast the motion of a floating rigid structure, which embodies a wave energy converter designed to harness the energy of sea waves. We introduce a multi-fidelity model based on domain decomposition. A high-fidelity solver is spatially coupled with a Reduced Order Model (ROM) utilizing Proper Orthogonal Decomposition (POD). The whole (large) computational domain is partitioned into a small computational domain, where the high-fidelity model operates, and the POD basis functions are precomputed for the remaining area along with an overlapping zone.

The high-fidelity model is used in a small computational domain located in the vicinity of the body where the flow exhibits complex nonlinear phenomena (like wave overtopping) that are difficult to model with a linear POD subspace. The utilization of the POD model extends beyond this region for two key reasons. Firstly, we enforce boundary conditions on the small high-fidelity domain using a physical POD subspace rather than resorting to artificial boundary conditions. Secondly, the global POD modes play a dual role by propagating informations across the entire computational domain.

We propose a projection-free reduced-order model where POD temporal coefficients are derived by minimizing the differences between the high-fidelity solution and the POD ansatz in the overlapping zone between high-fidelity and POD domains. Simultaneously, the POD model is tasked with consistently propagating the incoming wave, necessitating the POD ansatz to match some measurements obtained from inflow sensors, such as water elevation. The temporal coefficients of the POD ansatz are thus determined by simultaneously minimizing both quantities.

In this study, POD computation involves snapshots for both velocity and Volume of Fluid (VOF) fields, with the latter numerically representing the air-water interface position. The same temporal coefficients are applied to both velocity and VOF. Typically, sensors give only VOF information, and boundary conditions are enforced for both velocity and VOF.

The dynamics of the floating body are simulated within this framework, resulting in precise predictions of the body's motion for both in-sample scenarios (replicating the same flow configuration as used to compute the POD basis) and out-of-sample scenarios (predicting a flow configuration not included in the POD basis). Subsequently, this model is envisioned for application in numerical simulations of wave energy converter farms, which entail assembling several patches akin to the singular structure presented in this study.

ABSTRACT

Computational Fluid Dynamics (CFD) tools provide users with accurate simulations. Their main drawback is the computational cost, specially when complex phenomena are modelled. For this reason, machine learning approaches have been taken, reducing computational cost while keeping good accuracy.

One application that could benefit from these approaches are predictive digital twins. When a user wants to estimate the flow behaviour under real operation conditions, sensors are used. Usually, sensors provide very accurate measurements, but as they are placed only in certain points of the domain, the obtained measurements are sparse.

We propose a Deep Learning approach to obtain a high-resolution estimation of the flow around an obstacle when only low-resolution data of the most relevant fields of the flow (pressure and velocity) is available. For this work, a database of unsteady flows around a cylinder has been generated using the OpenFoam software. Then, after a post-processing step, the database is obtained in both low-resolution and high-resolution. The analysed domain is discretized using the levelset, so the data is obtained as a grid. This structure of the data allows us to make use of Convolutional Neural Networks (CNN).

The proposed method is trained in two steps. First, an Adversarial Autoencoder (AAE) is trained to learn a low dimensional codification of the pressure and velocity fields (P, Ux, Uy) from the low-resolution data. The decoder is trained to generate the pressure and velocity fields in low and high-resolution, which means it can recover the high-resolution information of the flow taking the low-resolution measurements as input. Then, a second network is trained to predict the development of the flow. The network is a Structure Preserving Neural Network (SPNN) [1], which calculates and integrates the evolution of the flow in the low dimensional space. The SPNN ensures that the prediction is thermodynamically consistent, improving the robustness and generalization of the neural network. The thermodynamic consistence is achieved by the GENERIC (General Equation for Non-Equilibrium Reversible-Irreversible Coupling) [2] formalism. Finally, the decoder of the AAE is applied to recover the high-resolution flow fields from the low dimensional space.

[3]The University of Texas at Dallas

ABSTRACT

This work aims at estimating the aeroelastic response of the blades of a standalone NREL-15 MW wind turbine [1]. To this aim, we will use a high-fidelity fluid-structure interaction solver based on a two-way coupling between a computational fluid dynamics (CFD) solver and a computational structural dynamics (CSD) solver [2], which has already been validated for lower-scale wind turbines. We will compare numerical results with those obtained from the engineering-based solver OpenFAST, developed by the National Renewable Energy Laboratory (NREL). The CFD solver adopts a Large Eddy Simulation (LES) approach, which resolves large scales and models the small subgrid scales through the Smagorinsky model. Rotor blades are modeled using the actuator line model, whereas the tower and nacelle are modeled using the immersed boundary method [3]. The CSD solver models the blades as cantilever beams using a modal approach under the assumption of linearity. A preliminary validation of the structural eigenfrequencies for the new wind turbine has been carried out, providing good agreement with the results available in the literature. The CFD-CSD results are compared with those obtained by the OpenFAST solver, which instead models the aerodynamic effect using the Blade Element Momentum (BEM) theory. This solver allows the user to employ two alternative models for the structural behavior of the blades, ElastoDyn and BeamDyn, using linear modal dynamics and geometrically exact beam theory, respectively. In the first set of simulations, a laminar, sheared wind profile defined by a power law is imposed at the inlet points of the computational domain. Results show that the tower shadowing effect evaluated by the CFD solver produces a considerable degradation in the turbine performance, while this effect is not captured by OpenFAST. A good agreement is found for the mean out-of-plane deflection along the blade, which represents the most influential deformation, despite notable differences in the in-plane deflections. The nature of these discrepancies could be attributed to the limited validity of the linear assumptions in the structural solver in the context of large-scale wind turbines and the non-negligible differences in the fluid modeling of the wake. Further details and analysis will be provided in the extended abstract.

PHYSICS-INFORMED NEURAL NETWORK-BASED MODELING OF THE ELASTIC RECONFIGURATION OF A PLATE UNDER FLUID FLOW

Lucas Berthet[*1], Bruno Blais[1] and Frederick Gosselin[1]*

[1]*Polytechnique Montréal*

ABSTRACT

This work focuses on the modeling with Physics-Informed Neural Networks (PINNs) of the reconfiguration of a flexible plate subjected to a perpendicular two-dimensional (2D) fluid flow. A PINN is a hybrid data-driven and physics-based model, wherein the neural network acts as a solver harnessing physical laws through additional loss functions. They are universal function approximators and meshless, by using backpropagation to compute derivatives from Partial Differential Equations (PDEs). PINNs have been applied to Vortex-Induced Vibrations (VIV) of rigid bodies, where the Fluid-Structure Interaction (FSI) remains stationary owing to the structural reference frame. However, this application does not extend to deformable multidomain interfaces. The latter are challenging for PINNs since their motion induces a relative displacement of collocation points, resulting in the simultaneous presence of all states within the training domain. Herewith, this work features a plate reconfiguring in a 2D fluid flow to showcase the representation of deformable FSI with PINNs. Indeed, plate reconfiguration is a nonlinear problem that exhibits VIV and flutter instability. Two PINN-based models are proposed for the static and dynamic reconfigurations. Both couple two PINNs to represent the structure and fluid respectively. The structural PINN integrates boundary conditions and PDEs of a fixed-free Euler-Bernoulli beam, on which only the pressure drag is applied. The fluid PINN is based on the incompressible Navier-Stokes equations with boundary conditions to represent a 2D infinite flow. The structural PINN provides forces to the fluid PINN, while the latter supplies pressure to the former. The fluid and the plate have respective sets of collocation points, where the PDEs and conditions are softly constrained. When deformation of the plate occurs, the associated points move, and the intersected fluid ones are masked with weights. The structural and fluid PINNs are trained simultaneously using a common loss that combines both formulations. Temporal terms in the PDEs and initial conditions are integrated into the framework to account for dynamic reconfiguration. A sequential training of both PINNs per time step is conducted to enforce causality. The models are verified with numerical results from a finite element model and validated with experimental data from a wind tunnel. In further work, these models will be extended to high-speed flows by applying a potential flow description and approximating the plate pressure drop. Yielding meshless and data-integration properties, PINNs offer flexible forward and inverse solvers to support conventional FSI numerical models.

IMPLEMENTING AND EXPERIMENTALLY VALIDATING PENALTY CONTACT IN COSSERAT ROD MODELS TO EFFECTIVELY MODEL CONTACT SCENARIOS IN THE FIELD SOFT MATERIAL ROBOTICS

Rebecca Berthold[*1] and Matthias Wangenheim*[1]

[1]*Leibniz University Hannover*

ABSTRACT

Authors: R. Berthold (1), M. Wangenheim (1)
(1) Institute of Dynamics and Vibration Research, Leibniz University Hannover, An der Universität 1, 30823 Garbsen, Germany
berthold@ids.uni-hannover.de

Soft robotics is an aspiring field of research that aims to enhance and diversify the field of classical robotics by incorporating flexible structures and soft materials. Through their low structural stiffness and the related softness, these robots are advantageous when operating in unknown environments, interacting with objects with various topology or enabling save human-robot interaction. Despite this prominent advantage, the closely associated contact behavior of soft robots has hardly been researched to date.

In order to close this gap, the presented work aims to establish mechanical contact modeling in the field of soft robotics and make them accessible to researchers. In a previous publication the necessity to consider contact modeling has been demonstrated [1].

In a next step a contact modeling is presented for cosserat rod models. Due to their low computational cost and simplicity while still modeling the robots sufficiently these rod models are well established in the filed of soft robots and beyond. Basing the presented work on a toolbox [2], that is frequently used in the field of soft robotics, the contact model will be more accessibly and adaptable for other researchers that work in the same research area.

In this work a penalty contact is implemented in a cosserat rod model, presented in the toolbox, to model contact normal forces. These forces then act as an external force on the beam and can deform the beam due to contact. In addition, tangential forces are implemented to account for frictional contact. Both, frictional and non-frictional contact is validated by means of experiments. It is compared and presented how frictional and non-frictional contact influence and effect various contact scenarios. Therefore, multiple contact examples are presented. The work shows that contact between the robot and its environment not only does not have to be avoided. On the contrary contact can also be deliberately used to increase the stability of soft structures and thus, for example, reach a desired point or increase a load-bearing capacity.

THE VIRTUAL ELEMENT METHOD ON APPROXIMATE DOMAINS: A NEW STRATEGY FOR HIGHER ORDER DISCRETIZATION OF PDES WITH CURVED BOUNDARY

Silvia Bertoluzza[*1], Monica Montardini[2], Micol Pennacchio[3] and Daniele Prada[3]*

[1]*IMATI-CNR Pavia*
[2]*Università degli Studi di Pavia*
[3]*Consiglio Nazionale delle Ricerche*

ABSTRACT

The virtual element method is an extension to polytopal tessellations of the finite element method. Since its introduction in the early 2010's the method has quickly gained the attention of the scientific community, thanks to its versatility, its robustness (in particular with respect to the shape of the elements), and its potential for high accuracy (the discretization can be designed to be of arbitrarily high order). We propose its combination with a shifted boundary approach, to handle problems on domains with curved boundaries, approximated by polygonal/polyhedral domains, with emphasis on the ones obtained as the union of squared/cubic elements out of uniform structured meshes. In order to ensure efficiency we devise a novel static condensation strategy acting on the edges of the decomposition, that allows to avoid the proliferation of degrees of freedom for polygonal/polyhedral elements with a large number of small edges/faces. We show, both theoretically and numerically, that resorting, possibly only in the proximity of the boundary, to the use of the virtual element method allows to satisfy, for any order, the assumptions required for the stability of shifted boundary type methods, thus allowing to fully exploit the potential of higher order discretizations in the presence of curved boundary.

REDUCED ORDER MODELS OF PARTICLE-LADEN FREE SURFACE FLOW

*Andrea Bertozzi**[1]

[1]*University of California, Los Angeles*

ABSTRACT

Particle-laden free surface flow arises in many applications from spiral separators to Bostwick consistometers in the food industry. I will review lubrication theory for particle-laden flow on an incline for viscous fluids for monodisperse and bidensity flows in which the dynamics is dominated by a balance between hindered settling of particles and shear-induced migration through the layer. I will present a new model for bidisperse particle-laden flows and will discuss the behavior of the flows in multiple regimes including the case where particles preferentially settle to the substrate and where the particles stay entrained in the flow and concentrate at the leading edge of the flow. The reduced order models take the form of systems of conservation laws which exhibit singular shocks in the high volume fraction limit.

COMPUTATIONAL ERROR ESTIMATION FOR THE MATERIAL POINT METHOD USING ERROR TRANSPORT

Martin Berzins[*1]*

[1]*University of Utah*

ABSTRACT

The Material Point Method (MPM) is widely used for challenging applications in engineering and animation but lags behind some other methods in terms of error analysis and computable error estimates. The complexity and non-linearity of the equations solved by the method and its reliance both on a mesh and on moving particles makes error estimation challenging. It is also the case that there is considerable variation in the order of accuracy of the different methods in the presence of grid crossing and large deformations. Furthermore, the overall time dependent nature of MPM also complicates matters as both space and time errors and their evolution must be considered thus leading to the use of explicit error transport equations. The preliminary use of an error estimator based on this transport approach has yielded promising results in the 1D case, [1] including for cases in which there is a massive amount of grid crossing leading to a loss of accuracy for conventional MPM methods.

The extension of the error estimation approach to two space higher dimensions is considered and together with additional algorithmic and theoretical results, shown to give promising results in preliminary computational experiments. The main approach adopted extends [2] to estimate the underlying error in the mappings that define the acceleration at nodes and in the mappings from nodes to particles. Some preliminary analysis is also undertaken to show how these errors at each step influences the overall error and how errors in stresses have an impact on the acceleration error and may reduce its accuracy. Finally this idea and these results are illustrated by undertaking computation experiments on standard test problems such as the vibrating ring problem used by Brannon and colleagues [3]. Finally, the difficulties faced in extending this approach to challenging real world problems are considered.

GRADIENT-FREE NEURAL TOPOLOGY OPTIMIZATION

Miguel Bessa[*1] and Gawel Kus*[1]

[1]*Brown University*

ABSTRACT

Gradient-free optimizers allow for tackling problems regardless of the objective smoothness or differentiability, but they require many more iterations to converge when compared to gradient-based algorithms. This has made them unviable for topology optimization due to the high computational cost per iteration of these problems. We propose a pre-trained neural reparameterization strategy that leads to an order of magnitude decrease in iteration count when optimizing the designs in latent space. We demonstrate this via extensive computational experiments in- and out-of-distribution with the training data. Although gradient-based topology optimization is still more efficient for differentiable problems, such as compliance optimization of structures, we believe this work will open a new path for considering problems when gradient information is not readily available (e.g. fracture).

[2]*EDF Lab Paris-Saclay*
[3]*EDF Lab Les Renardières*
[4]*LMGC, Université de Montpellier 2*

ABSTRACT

During a Loss of Coolant Accident (LOCA), fuel rods are heated by the residual power. The resulting increase of internal pressure leads to a ballooning of the cladding which allows the fuel to relocate and, if there is a rupture, to disperse into the primary circuit. The exact amount of relocation and dispersal must be assessed precisely.

Here, we propose to assimilate the fragmented fuel to a granular medium and implement a Discrete Element Method (DEM) to model the behavior of fragments within the rod. The aim is to describe their relocation in the swollen areas through the analysis of key parameters, notably the packing fraction of relocated fuel along the rod.

This model echoes previous DEM-focused numerical simulation works on fragment relocation [1], [2]. Some of these models have limitations in terms of representation (2D model, spherical shape of fragments, fluid effect not considered), which we aim to overcome by creating a realistic 3D model to represent the main features of the fuel rod during a LOCA:

- The complex shape of the fragments;
- The deformation of the cladding and the interaction of fragments with the inner wall;
- The interaction of fuel fragments with fission gases and the confinement gas;

The initial developments aimed to adapt the discrete element method to arbitrary polyhedral geometries, adopting a method based on sphero-polyhedra. This method allows to facilitate the contact detection stage, which is computationally expensive and challenging to implement for complex geometries.

Verification and validation test cases of the polyhedral DEM method have been conducted. They serve as benchmarks for applied simulations aimed at studying the effect of various parameters (size and shape distribution of fragments, polydispersity, deformation of the swollen zone) on fuel relocation in the case of a dry granular medium.

Further developments are in progress to address the effects of fragment interaction with cladding walls and fission gases. Various coupling methods with DEM are being explored, and their selection is the subject of current research efforts.

ON IN-PLANE FLOW THROUGH FRACTURE PHENOMENA USING STABILIZED FINITE ELEMENT METHODS

Nils Betancourt[*1] and Robert Gracie*[1]

[1]*University of Waterloo*

ABSTRACT

A reduced dimension fracture flow model (GG22) derived from the Navier-Stokes equations was recently proposed [1]. This model accounts for time-space varying apertures, transient flow, moderately high Reynolds numbers, turbulence, and satisfies conservation of energy. In comparison with the standard Poiseuille flow model, the GG22 equations capture transient and inertial phenomena. The solution of this system of nonlinear partial differential equations was previously obtained for one dimensional [2] and axisymmetric fractures [3] using the finite volume method. In this context, the present research focused on extending the solution of the GG22 equations to two dimensional fractures. The model resembles the compressible two-dimensional Navier-Stokes equations as the aperture acts as a pseudo-density in the balance of mass equation. The solution was obtained using stabilized finite element methods to avoid instabilities generated by advective terms in the balance of linear momentum equation. The verification of the solution was done against analytical solutions [1] in both one and two-dimensional examples. The model could capture re-circulation effects that were not addressed in previous research that appear due to changes in the aperture, high flow rates and discontinuities in the mesh.

GENERIC-BASED MIXED FINITE ELEMENTS FOR COUPLED THERMOMECHANICAL PROBLEMS

Peter Betsch[1], Marlon Franke[1], Moritz Hille[1] and Felix Zähringer[1]*

[1]*Karlsruhe Institute of Technology*

ABSTRACT

The GENERIC formalism provides a versatile framework for the formulation and structure-preserving discretization of coupled multiphysics problems. GENERIC (General Equation for Non-Equilibrium Reversible-Irreversible Coupling) relies on an additive decomposition of the evolution equations into reversible and irreversible processes. After the selection of appropriate state variables, GENERIC is formulated as state space model of the coupled problem under consideration. Correspondingly, related numerical methods for coupled thermomechanical problems typically rely on an approximation of the state variables at hand. Using the finite element method for the discretization in space, the GENERIC-based formulation can be viewed as generalization of displacement-based finite elements for isothermal mechanical problems. To improve the numerical approximation capabilities of displacement-based finite elements a plethora of mixed finite element formulations has been developed over the last decades. The goal of the present work is to extend the GENERIC framework to accommodate mixed finite elements for the structure-preserving discretization in space and time. The GENERIC-based application of mixed finite elements is illustrated with the problem of large strain electro-thermo-elastodynamics.

A REDUCED ORDER MODELING BASED FETI-DP SOLVER FOR MECHANICAL METAMATERIALS

Federico Betti[*1], Pablo Antolin Sanchez[1] and Annalisa Buffa[1]*

[1]*EPFL*

ABSTRACT

The recent advances in additive manufacturing technologies are pushing the development of architected cellular materials, such as the so-called mechanical metamaterials, to a new stage. These multiscale heterogeneous lattice structures can be tailored at the level of the unit-cell to achieve exceptional mechanical properties that are difficult to find in conventional materials. However, because of the possibly huge number of cells, the evaluation of their mechanical response is challenging due to high computational cost and memory requirements. In this work, we develop a fast and accurate solver for the full fine-scale analysis of gyroid-like mechanical metamaterials. Our strategy is based on unfitted domain methods, which avoid computationally costly meshing routines. Upon this choice, our main purpose is to exploit the natural domain decomposition of the macro-structure into unit-cells by designing an efficient FETI-DP solver. Importantly, we apply localized projection-based reduced order models for the approximation of the main substructuring operators. Ultimately, this results in an accurate and scalable algorithm which avoids a significant number of local factorizations and considerably reduces the online computational cost. The applicability of our methodology is shown on a variety of 2D and 3D examples, for different geometries and load terms: the developed solver shows excellent accuracy on large enough test problems, with good gains in running time with respect to a high-fidelity solver.

A COUPLED FLOW-FLEXURE-FRACTURE MODEL FOR SHALLOW ICE SHELVES

Chris Bezu[*1], Daniel Shapero[1], Alison Banwell[2] and Brad Lipovsky[1]*

[1]*University of Washington*
[2]*University of Colorado Boulder*

ABSTRACT

Glacier ice deforms via a combination of viscous flow and viscoelastic flexure. However, due to the computational complexity of modeling viscoelastic materials, global ice sheet models currently treat glacier ice as purely viscous. This pragmatic approach renders ice sheet models unable to describe large-scale phenomena emerging through the viscoelastic properties of ice, such as the chain-reaction lake drainage events which have been proposed to help disintegrate enormous swaths of Antarctic ice shelves. This project builds on MacAyeal et al. (2021, Journal of Glaciology) to develop a process-scale ice shelf model coupling viscous flow with viscoelastic flexure, while using approximations which are computationally cheap enough to eventually incorporate into global ice sheet models. We solve the two-dimensional Shallow Shelf Approximation (SSA) for viscous ice shelf flow alongside a thin-plate approximation for viscoelastic flexure. Additionally, we apply a continuum damage description to approximate the effect of fracture on rheology. Since most global models already solve the SSA to describe the viscous flow of ice shelves, our coupled flow-flexure model will be easily adaptable into ice sheet models. Ultimately, our work will help elucidate large-scale ice shelf behaviour which emerges through the viscoelastic properties of ice.

UNCERTAINTY QUANTIFICATION OF LARGE STOCHASTIC NONLINEAR DYNAMICAL SYSTEMS USING A NOVEL NON-INTRUSIVE ROM

Chandan Bharti[*1] and Debraj Ghosh*[1]

[1]*Indian Institute of Science*

ABSTRACT

Uncertainty quantification (UQ) or reliability analysis of large nonlinear stochastic dynamical systems demands huge computational costs. Often, these systems are solved using commercial software or a black-box solver, where access to the source code is restricted. In this situation, UQ of such systems becomes computationally challenging. The cost has two components: (i) cost due to large physical dimension, and (ii) cost due to large stochastic dimension. While the first issue is addressed using a non-intrusive reduced order model (ROM), the latter is still a challenging problem within the framework of a non-intrusive ROM. While the literature on non-intrusive ROMs [1] is growing, their applicability in large stochastic dimension is still an unaddressed issue. This work is aimed at addressing this issue.

The key challenge lies in building a high-dimensional interpolation or approximation scheme between random variables or process to reduced space solutions. In our recent previous work [2], we have addressed this challenge for a linear problem with random process excitation. The interpolation was carried out using feed-forward neural network in tandem with principal component analysis. In the proposed work this methodology is extended to nonlinear systems. Here we have developed a proper orthogonal decomposition-based ROM that uses a long short-term memory (LSTM) network for the interpolation. An LSTM has a memory cell that remembers important information from the past, which is crucial in the analysis of nonlinear dynamical systems. The accuracy of the developed ROM is numerically validated on a beam on a nonlinear Winkler foundation model subjected to both stationary and non-stationary random excitations. The nonlinearity in the foundation is modeled using Mostaghel's spring, which shows bilinear hysteresis behavior. The ROM is later used in estimating the failure probability for different thresholds. The numerical results show that the proposed ROM is accurate and efficient in estimating the failure probabilities. The ROM gains a speed-up of about 300 in the online stage.

ABSTRACT

Global Climate Models are instrumental in informing and providing insights into climate systems over larger time scales, although at a coarse resolution. Many applications of weather and climate data such as risk assessment, regional climate change studies require higher resolution, km-scale forecasts. Machine Learning for dynamic downscaling for regional simulation is attractive, but computationally expensive. Statistical downscaling, an inexpensive alternative, lacks the fidelity of dynamic downscaling. Here, we present a cost effective, generative diffusion model, Corrector Diffusion (CorrDiff) for downscaling coarser resolution (25km) global weather data to a higher resolution (2km) over a subset of the globe. With basic GPU hardware and with an unoptimized code, CorrDiff inference is about 38x faster, and 1800 x more energy efficient than running Weather Research and Forecasting (WRF) on CPU. With the current focus on generation quality, and not on optimizing inference speed, more gains on GPU could be easily anticipated.

CRYSTAL PLASTICITY FINITE ELEMENT CREEP MODELING OF POWDER BED FUSED 316H STEEL

Sagar Bhatt[*1] and Mark Messner[1]*

[1]Argonne National Laboratory

ABSTRACT

316H Stainless steel is a popular material for high-temperature applications. However, accurately predicting the long-term performance of additively manufactured components in service environments remains challenging due to a lack of understanding of very long-term microstructural stability under load. In this study, we investigate the anisotropic creep deformation behavior of an additively manufactured 316H polycrystal, produced using the laser powder bed fusion method. To do so, we generate a high-fidelity finite element mesh, using data received Manufacturing Demonstration Facility at Oak Ridge National Laboratory, that accurately represents the microstructure of the material. Creep is modeled using a MOOSE-based crystal plasticity finite element framework, DEER, to study the role of grain structure and orientations in the creep response of the AM microstructure. In this work, we study the effect of grain morphology, the aspect ratio of grains, strategies to incorporate the complex orientation distribution within the microstructure into the FE mesh of the polycrystal, and the effect it has on creep performance. Through this investigation, we aim to improve our understanding of the structure-property relationship in additively manufactured in 316H stainless steel, thus helping us predict and optimize its long-term performance.

DATA-DRIVEN CONSTITUTIVE RELATIONS: MULTISCALE MODELING AND EXPERIMENTAL INFERENCE

Kaushik Bhattacharya[*1]

[1]*California Institute of Technology*

ABSTRACT

The talk addresses the challenge of computing complex phenomena at the scale of applications. In addition to the universal laws (balance of mass, momenta etc.), these phenomena require a constitutive (closure) relation that describes the behavior of the medium at the scale of applications. Such behavior can be nonlinear, nonlocal, anisotropic, history dependent etc., and thus impossible to characterize to the desired level by the classical approach of postulating a parametrized relation and fitting the parameters to selected experiments. The talk describes two broad approaches to using data-driven methods to overcome this challenge. The first approach is multiscale modeling where one recognizes that the effective behavior at the scale of applications is determined by physics at multiple length and time scales: electronic, atomistic, domains, defects etc. The data-driven constitutive relation is obtained as a neural approximation is trained using data generated by repeated solution of the small scale problem. The second approach seeks to infer it from automated experiments that are not amenable to easy inversion. The talk will describe these approaches, challenges they raise and strategies to overcome them. The ideas will be illustrated with applications from materials science and geology.

ASSESSMENT OF FULLY EULERIAN PHASE-FIELD FRAMEWORK FOR SHIP HYDRODYNAMICS WITH ICE INTERACTION

Sabiha Bhuiyan[1], Xiaoyu Mao[1] and Rajeev Jaiman[1]*

[1]*University of British Columbia*

ABSTRACT

With ice cover in the Arctic region shrinking over time, the region has garnered strategic interests for shipping activities. The development of robust ice-going ships, that can navigate ice fields with minimal resistance and extreme load on the hull, is an emerging application of multiphase fluid-structure interaction. The complex and coupled nonlinear dynamics associated with ship-ice contact on a free surface is challenging to predict and analyze sufficiently via theoretical and experimental methods. High-fidelity numerical models for ship-ice interaction on a free surface, and the resulting force analysis, are therefore imperative for the optimization of ice-going ship hull design for Arctic region operations.

Ship-ice interaction is a complex system involving interaction between floating structures and surrounding free surface, and contact between solids. These interactions happen amid large translational and rotational motions of the floating structures. When using an arbitrary Lagrangian-Eulerian (ALE) framework [1] to model the contact dynamics of structures on a free surface, maintaining the mesh quality in the region between the approaching structures poses a major challenge. A multiphase fully-Eulerian framework is therefore advantageous for this application, as it is able to model the continua of all fluids and solids involved in a Eulerian frame. A novel multiphase fully-Eulerian framework employing a phase field formulation to describe the interfaces between the phases has been developed [2]. Rigorous validation and a complete force analysis flow are now required to apply it to study ship-ice interaction.

Accurately modeling how an afloat solid interacts with surrounding free surface flow is a premise for studying the contact between structures on a free surface. We consider the hydrodynamics arising from flow across a Wigley hull as a relevant benchmark problem and solve the problem with the fully Eulerian framework. We study the wave run-up profile on the hull and build a workflow to analyze the resulting resistance and extreme load on the hull. We finally present a simple ship-ice interaction on a free surface simulated with the solver to investigate the contact force between solids.

MATERIAL CHARACTERIZATION AND PARAMETER IDENTIFICATION OF PERIODONTAL LIGAMENT CONSIDERING TENSION-COMPRESSION ASYMMETRIC MODULI AND NONLINEAR BEHAVIOR

Shaoyang Bi[*1] and Guangyu Shi*[1]

[1]*Tianjin University*

ABSTRACT

Background and purpose: Periodontal ligament (PDL) is a complex biological soft tissue that connects teeth and alveolar bone. The hydrostatic stress in the PDL are generally considered as a key factor to trigger orthodontic tooth movement. Accurate characterization of the material properties of the PDL holds the potential to influence the stress in the PDL during orthodontic simulations using finite element analysis, therefore to impact the clinical orthodontic treatment plan. Studies on the material properties of the PDL has been ongoing for decades. However, previous research has not adequately taken into account the distinct properties of the PDL under tension and compression. PDL is softer under compression than tension, and has greater compressibility under compression, which significantly affects the hydrostatic stress within it. The proposed work considers the different elastic modulus and Poisson's ratio of the PDL under tension and compression, and further introduces nonlinearity to the tension stage.

Methods: Using the commercial finite element solver Abaqus, a customized constitutive model UMAT, and the simulation automation software Isight, the nonlinear tension-compression asymmetric constitutive model is achieved. By utilizing in-vivo experimental data, the material properties of the PDL are characterized. Based on the constitutive model, an orthodontic process is simulated and the hydrostatic stress in the PDL is evaluated.

Results and conclusions: The results show that considering the nonlinear and asymmetric mechanical behavior of PDL in tension and compression can significantly reduce the evaluated compressive stress in the PDL, which is more realistic and closer to the orthodontic theory.

A VARIATIONALLY-CONSISTENT PHASE-FIELD COHESIVE ZONE MODEL FOR MIXED-MODE FRACTURE BASED ON ENERGY DECOMPOSITION SCHEME

Pei-Liang Bian[*1], Hai Qing[2], Siegfried Schmauder[3] and Tiantang Yu[1]*

[1]*Hohai University*
[2]*Nanjing University of Aeronautics & Astronautics*
[3]*University of Stuttgart*

ABSTRACT

In rocklike materials, mode I and II fracture toughness are distinctive while the compressive strength is much greater than the tensile strength. Besides, mixed-mode fractures instead of pure mode I or II fractures occur under complicated load cases in those materials. Therefore, to capture the mixed-mode cracking process, we developed a mixed-mode phase-field cohesive zone model based on the unified phase-field theory proposed by Wu. The model was built based on a strain energy decomposition scheme, and for each mode, there is an independent degradation function. Thus, independent values of strength and toughness can be given for different failure modes. A simple mixture rule of fracture toughness was introduced to describe the transition between different failure modes. The model can keep variational consistency perfectly and governing equations for displacement- and phase-field, which was never reported in other works. Several numerical examples verified the effectiveness and flexibility of this work. The present work showed a simple but effective way to simulate mixed-mode fracture.

CHARACTERIZING THE EFFECTS OF INFLOW TURBULENCE ON THE UNSTEADY LOADS AND WAKES OF WIND TURBINES

Shreyas Bidadi[*1], Ganesh Vijayakumar[1] and Michael Sprague[1]*

[1]*National Renewable Energy Laboratory*

ABSTRACT

Wind turbines operating under extreme wind conditions are subjected to high wind speeds and turbulent intensities. In this scenario, the turbine blades experience high degree of unsteady loading due to flow separation. If the frequency of the vortex shedding due to the massively separated flow from the blades coincides with the blade's natural frequency, stall or vortex induced vibrations occur which can lead to fatigue or failure of the turbine blades. In this study, the effects of varying the inflow wind speed and turbulent intensity on the unsteady loads and wake characteristics are investigated for the rigid NREL Phase VI turbine under axial-flow conditions. Blade-resolved simulations are performed using the Improved Delayed Detached Eddy Simulation (IDDES) hybrid RANS-LES turbulence model. We consider two methods to generate the inflow turbulence. In the first approach, turbulent conditions are specified at the inlet, and the decay of turbulent kinetic energy is estimated from the inlet to the turbine. The second method injects resolved turbulence using a synthetic turbulence generator. A preliminary investigation was performed for wind speed of 20m/s and inflow turbulent intensity of 0.5%. The IDDES turbulence model accurately predicted both the mean and unsteady loads, and the flow separation. To further validate the performance of the model, the power spectral density (PSD) based on the thrust coefficient was compared with the experimental data [1] at five spanwise locations on the blades. The model correctly captured the primary shedding frequencies at all locations. Additionally, the slope of PSD curve in the high frequency range shows good agreement with -5/3 slope. In addition to predicting the unsteady loads and performing comparison studies of power spectral density, the effects on velocity deficit and turbulent intensity are also examined both in the near- and far-field wake regions.

ACCURATE SOLUTION OF LINEAR OPERATOR APPROXIMATIONS USING GREEN'S FUNCTIONS BY A MULTI-LEVEL NEURAL NETWORK APPROACH

Ziad Aldirany[1], Charlélie Bilodeau[1], Régis Cottereau[2], Marc Laforest[1] and Serge Prudhomme[1]*

[1]Polytechnique Montréal
[2]Aix-Marseille Université

ABSTRACT

The solution of boundary-value problems using deep learning approaches, such as the physics-informed neural networks [1] or the deep operator networks [2], have been extensively investigated in recent years. However, achieving high accuracy in the approximations obtained from these methods often remains a significant challenge. A multi-level neural network approach was proposed in [3] that allows one to iteratively reduce the errors, sometimes within machine precision, when approximating a solution using PINNs. In this work, we extend the multi-level approach to approximate linear operators using the Green operator networks (GreenONets) as described in [4]. Starting with an initial approximation of the operator, we correct the solution by considering a different Green operator network involving higher frequencies. The method enables one to iteratively reduce the high-frequency contributions present in the residuals. Numerical examples will be presented to demonstrate the efficiency of the proposed multi-level approach.

CAN MULTISCALE MICROMECHANICAL MODELS EXPLAIN THE EXPERIMENTALLY OBSERVED VARIATION IN MECHANICAL PROPERTIES OF CLEAR WOOD?

Eva Binder[*1], Michael Schweigler[1] and Thomas K. Bader[1]*

[1]*Linnaeus University*

ABSTRACT

The forests in Europe are changing in response to climate shifts and thus the ratio of hardwood in mixed forests will increase. Hardwood properties, an understudied area in the past, are now gaining prominence in research. Our investigation of the mechanical properties of South Swedish wood encompasses the softwoods species spruce as a reference and the hardwood species beech and birch. Experiments on stiffness and strength perpendicular to the grain and rolling shear exhibited considerable variation [1]. Wood, whether softwood or hardwood, is a hierarchically organized geomaterial, where the macroscopic, anisotropic mechanical properties are governed by the microstructure. The presented application of multiscale models aims to explore the influence of microstructural characteristics for an explanation of the observed macroscopic variations. A validated multiscale micromechanical model for the stiffness of softwood was presented by Bader et al. [2] and further extended to hardwood by de Borst and Bader [3]. In the latter study, the model was validated for beech and nine other hardwood species.

The experiments were conducted on prismatic clear wood specimens (50 mm width, 20 mm thickness, and 60 mm height), enabling material-level testing. However, due to thickness and annual ring distribution of the raw material, the inclination of the annual rings of early- and latewood, defining the radial and tangential direction (RT-plane) of the idealized orthotropic material, varies in the test series. The influence of this RT-plane rotation and the variation in microstructural parameters, like microfibril angle, lumen, vessel, and ray cell properties, on the global stiffness, are modelled based on multiscale models for the three investigated species. The micromechanical models are applied to obtain mean values of the nine independent components of the stiffness tensor with corresponding realistic modelling variations. These tensors are then rotated within the RT-plane to investigate the influence on the global clear wood behavior. The modelled global stiffness values are subsequently compared with the experimental results.

DYNAMIC CRACK PROPAGATION DUE TO THERMAL LOADS MODELED USING SCALED BOUNDARY POLYGON ELEMENTS

Muhammad Danish Iqbal[1], Carolin Birk[1] and Hauke Gravenkamp[2]*

[1]University of Duisburg-Essen
[2]International Centre for Numerical Methods in Engineering (CIMNE)

ABSTRACT

Thermal shock leads to thermally-induced stresses that can trigger rapid crack propagation in brittle materials. Predicting and preventing failure due to thermal shock is therefore required in the context of designing pressure tanks or reactors for thermal power plants or in aerospace engineering. The numerical modeling of thermally-induced dynamic crack propagation is challenging for several reasons. Thermal shock problems are characterized by extreme variations of the coupled thermal and mechanical quantities with respect to space and time. In a brittle material, stress singularities occur near crack tips that need to be resolved using a suitable numerical method. Crack propagation is associated with geometry evolution, which must be captured using efficient re-meshing approaches in discrete crack modeling scenarios.

In this contribution, the above challenges are addressed using the scaled boundary finite element method (SBFEM). Being a semi-analytical technique, it excels at representing stress singularities efficiently and accurately. Stress intensity factors are obtained semi-analytically directly in the solution process. They can be evaluated on relatively coarse meshes and without the need for costly post-processing techniques. Moreover, the scaled boundary finite element method can be used on polygon meshes that facilitate local re-meshing as cracks propagate. Applications to steady-state thermally-induced crack propagation modeling can be found in [1], for example.

The fully coupled transient thermoelastic problem is solved using scaled boundary shape functions, where the displacement approximations are enriched with semi-analytical solutions of the linear-elastic thermal stress problem [2]. In the context of crack propagation modeling, mesh mapping is required when the geometry changes. This is not trivial for the auxiliary degrees of freedom associated with the supplementary scaled boundary shape functions mentioned above. We, therefore, propose an extrapolation-based mesh mapping scheme, which is suitable for thermally-induced dynamic crack propagation modeling using SBFEM. The proper choice of crack propagation increment and time step and their interplay with the crack velocity are also discussed. The proposed procedure is verified and illustrated using various numerical examples.

ABSTRACT

When using machine learning (ML) methods in engineering, interpretability and robustness to noise are essential as it enhances model trust. Here, we use genetic programming based symbolic regression (GPSR), which generates free-form equations from provided mathematical operators and data. Previously, we demonstrated how using Bayesian methods such as sequential Monte Carlo (SMC) within the GPSR framework allows the generation of yield surface models with uncertainty quantification (UQ). We now look to extend SMC-GPSR to differentiate intrinsic (e.g., material scale variability) and extrinsic (e.g., measurement imprecision) sources, further enhancing model interpretability.

Our implementation for differentiating potentially confounding sources of uncertainties relies on a priori analysis of the material microstructure to identify intrinsic uncertainty terms and uniquely inform corresponding prior distributions for associated parameters within the evolving GPSR models. This is accomplished by using a thermodynamic-based analysis [1] to produce a composite function within which each sub-function connects to a microstructural characteristic of the material. The prior distributions inform the intrinsic uncertainty, while uncertainty from extrinsic sources is defined using an uninformed prior. This implementation is tested by generating training data from a known yield surface model for porous metals, the Gurson-Tvergaard-Needleman (GTN) model. Noise is artificially added to the parameters as well as the output data to simulate sources of intrinsic and extrinsic uncertainty, respectively. Assessment of the algorithm performance is determined by the successful determination of the known uncertainties in this verification test.

A QUASI-MESHFREE METHOD FOR NONLINEAR SOLID MECHANICS ON GEOMETRICALLY COMPLEX DOMAINS USING BOUNDARY-AWARE REPRODUCING BASIS FUNCTIONS AND A PROJECTED-GRADIENT QUADRATURE SCHEME

Joseph Bishop[*1]

[1]*Sandia National Laboratories*

ABSTRACT

In many applications, domains of interest are geometrically complex containing numerous small features. These features are typically removed in a manual process to facilitate a conventional element-based meshing process. This manual defeaturing process is dependent upon the goals of the simulation and typically involves subjective heuristics. To provide a flexible and easily adaptable discretization process that is independent of the domain discretization, an element-free method is proposed in which a fine-scale triangulation of the domain is used to first discretize the fully featured geometry but then a coarse-scale element-free discretization is used to approximate the solution of the governing equations. The fine-scale triangulation can be of poor quality and extremely refined since it is not used directly to approximate the solution. The coarse-scale element-free basis can be adapted through refinement or coarsening without the need to alter the fine-scale triangulation or other geometric considerations. The element-free basis functions are constructed using a traditional moving-least-squares procedure, but the initial weighting functions are constructed using manifold geodesics for general applicability to non-convex domains.

The weak form of the governing equations is integrated using a secondary coarse-scale element-free basis and a gradient projection technique. The projected-gradient methodology ensures the necessary consistency properties to pass the patch test. The dimension of the secondary basis is chosen to be of sufficient size to ensure stability of the overall method. The overall method is termed quasi-meshfree since both meshfree and mesh-based concepts are used. Several 2D verification problems and nonlinear application examples are presented to demonstrate the overall method.

ON THE USE OF FINITE ELEMENTS WITH A HIGH ASPECT RATIO AND COUPLING FINITE ELEMENTS FOR MODELING THE FAILURE PROCESS IN SFRC WITH DISCRETE TREATMENT OF FIBERS

Luís A.G. Bitencourt Jr.[1] and Osvaldo L. Maznoli*[2]

[1]*University of São Paulo*
[2]*São Paulo State University*

ABSTRACT

This paper describes a multiscale approach for modeling the failure processes of steel fiber reinforced cementitious materials with discrete treatment of fibers. The material is described as a composite made up by three phases: the cementitious matrix, discrete discontinuous fibers, and fiber-matrix interface. Special finite elements (named coupling elements) [1] were developed to couple independent meshes of the matrix (2D or 3D solid elements) and a cloud of steel fibers (modeled with truss elements). The complex nonlinear behavior of the interaction between concrete and fibers is modeled through a damage constitutive model and a non-rigid coupling procedure. Regular reinforcement bars can also be modeled with this technique. Initially, numerical examples with a single fiber are presented to validate the technique and to investigate the influence of its geometrical properties and its position related to crack surface. Then, more complex examples involving a cloud of steel fibers are considered. In these cases, special attention is given to analysis of the influence of the fiber distribution on the composite behavior related to the cracking process. With this proposed coupling technique any existing method to model cracks in the concrete matrix can be used without changes. In this paper the formation and propagation of cracks are modeled using solid finite elements with high aspect ratio [2,3] and a tension damage model to represent the behavior of interfaces associated to potential crack surfaces. Those interface elements are inserted in between all regular (bulk) solid elements of the concrete mesh, so that multiple cracks can also be considered.

FLEXIBLE INFINITE ELEMENTS FOR DIGITAL TWIN DEVELOPMENT OF UNBOUNDED VIBRO-ACOUSTIC MODELS

Davide Bizzarri[*12], Onur Atak[1], Hadrien Beriot[1] and Sjoerd van Ophem[23]*

[1]Siemens Digital Industries Software
[2]KU Leuven
[3]Flanders Make

ABSTRACT

In the evolving landscape of digital modelling, there is a growing interest on incorporating 3D simulations into Digital Twin scenarios [1]. A Digital Twin is characterized by the continuous exchange of data with its physical counterpart. This introduces the need of a compact representation of high-fidelity time-domain models. Therefore, the development of numerical schemes that are compatible with model order reduction (MOR) is of paramount importance.

In the realm of unbounded vibro-acoustics, the pursuit of these compact representations becomes pivotal, enabling the Digital Twin creation for an array of objects, such as loudspeakers, gearboxes and electric motors. Combining the Finite Element Method (FEM) with infinite elements is a common way to simulate unbounded vibro-acoustic phenomena. The Astley-Leis formulation, in particular, produces frequency-independent system matrices, which are readily applicable for transient simulations. Such formulation has been successfully used, in combination with Krylov-based MOR techniques, to produce accurate and time-stable reduced order models [2].

However, in the time domain, the Astley-Leis infinite elements must be attached to (semi-) spherical FEM volumes. This lack of geometrical flexibility severely limits the efficiency of the method, especially in the case of elongated radiating/scattering objects. This study presents the flexible infinite element [3], which can be connected to arbitrarily shaped convex domain FE boundaries for transient simulations, without sacrificing accuracy.

A workflow for the automatic generation of the FEM domain around sources of interest and the runtime extrusion of the infinite elements is presented. From a software implementation perspective, the proposed element can be considered as a specialized FEM element and can be seamlessly integrated into a high-order FEM code.

The computational benefits of using the flexible formulation are highlighted. Additionally, we demonstrate how integrating the proposed method with existing MOR strategies enables cost-effective and precise transient simulations. This combination paves the way for new Digital Twin applications in the field of unbounded vibro-acoustics.

MULTISCALE STRUCTURAL OPTIMIZATION WITH STRAIN GRADIENT EFFECTS USING SECOND-ORDER HOMOGENIZATION

Nolan Black[*1] and Ahmad Najafi*[1]

[1]*Drexel University*

ABSTRACT

Topology optimization and multiscale structural optimization have traditionally relied on numerical homogenization techniques to describe an evolving material domain. These homogenization techniques estimate the effective properties of a composite material through analysis of a microscale domain subjected to loading defined by the macroscale's mechanical state. The transition from the macroscale (observable) space to the microscale (material) space often requires restrictions on the size, form, and deformation modes of the microarchitecture. The most widely used form of homogenization in structural design defines these restrictions in terms of the (first-order) macroscale strains, assuming a strict separation of the macro- and microscales. In contrast, second-order homogenization introduces the macroscale strain-gradient in the formulation of microscale boundary conditions to relax the scale separation conditions. With their slightly relaxed model of scale separation, second-order techniques aim to model structures with observable hierarchy, modeling structures composed of many spatially varying substructures at a manufacturable scale.

The second-order formulation introduces several challenges for design optimization that will be the focus of this work. The strain gradient introduces higher order stresses in the macroscale which require special treatment. In this work, we implement a mixed finite element scheme to enforce C1 continuity in the macroscale. In the microscale, where deformation is a function of the macroscale strain and strain gradient, more considerations are required for the application of periodic boundary conditions with ersatz materials. We present the numerical implementation of the second-order homogenization model in the context of structural optimization. Through comparison with first-order methods, the ability to model hierarchical structures is evaluated. We show the behavior of second-order stress-strain relationships with the effective density of microstructural designs, producing the effective higher order properties of an evolving second-order material. Using this model, design optimization is performed using the second-order homogenization model.

OPEN-SOURCE HIGH-ORDER RESOLVED CFD-DEM FOR NON-SPHERICAL PARTICLE-LADEN FLOW

Lucka Barbeau[1] *and Bruno Blais**[1]

[1]*Polytechnique Montréal*

ABSTRACT

Particulate flows play an important role in the chemical industry. They are used in reactors (e.g., fluidized beds, spouted beds), in the transport of material (e.g., slurry transport and pneumatic conveying), separation operation (e.g., cyclone separators), and atomization operation (e.g., spray drying) to name a few. The sharp interface immersed boundary method (SIBM) is a powerful tool to simulate the flow around moving objects. Recently, our group has developed a SIBM which has many desirable properties for the direct numerical simulation of particle-laden flow: it uses a fully implicit coupling scheme, it is compatible with high-order schemes in both space and time, and it is compatible with a resolved CFD-DEM formulation, enabling the capture of particle-particle and particle-wall contacts. To achieve this, it uses a streamline upwind Petrov–Galerkin and pressure-stabilizing Petrov–Galerkin (SUPG/PSPG) stabilized formulation of the Navier-Stokes equations.

In this talk, we briefly introduce this high-order resolved CFD-DEM scheme which is implemented within the open-source CFD software Lethe [1]. We verify the high order of convergence of the scheme, and validate it using benchmark cases. The first validation case is the sedimentation of a lone particle with a Reynolds number smaller than 32. The second validation case is the rise of a positively buoyant particle at a high Reynolds number (2500). The third validation case demonstrates the stability of the scheme when particles are in contact and exhibit the classical drafting, kissing, and tumbling (DKT) behavior. Using this case, we discuss challenges related to the capture of the lubrication forces. Then, we present the extension of this scheme to non-spherical, but convex, particles. We validate the capabilities of the scheme on a benchmark sedimentation test case and discuss current challenges and future directions for this highly efficient computational model.

DATA-DRIVEN COMPACT PHOTOCURRENT MODELS

Pavel Bochev[*1] and Biliana Paskaleva*[1]

[1]*Sandia National Laboratories*

ABSTRACT

Understanding radiation response of microelectronic circuits is facilitated by high-level circuit simulations of radiation effects, which require computationally efficient compact radiation models. Currently, development of such models is dominated by analytic approaches, which invoke physical assumptions to render the governing equations solvable in closed form. Violation of these assumptions can reduce the accuracy of the models and/or limit their scope.

This talk will focus on alternative, data-driven approaches for the development of compact radiation models. We will first review recent efforts to develop such models using projection-based model order reduction (POD-based ROM), dynamic mode decomposition (DMD) and operator inference (OpInf). All these models are discrete or continuous time dynamical systems simulating the internal state of the device and so, their learning requires snapshots of this state and for the ROM model – access to the discretized governing equations. Dependence of the model development process on the availability of this information presents some problems because the internal state of a device cannot be measured in a laboratory setting and the discretized equations may be too complex or unavailable for commercial codes.

Gray-box models (GBM) informed by device physics provide an effective way to resolve many of these issues. GBMs can be viewed as a non-intrusive ROM that does not require access to the discretized governing equations and/or snapshots of the internal device state. GBMs are particularly attractive when (i) the main simulation goal is a quantity of interest (QoI) such as device response to radiation, rather than the internal state of the device itself, and (ii) the dynamics of this QoI can be represented by a small number of latent states.

In this talk we demonstrate the appropriateness of the gray-box approach for the development of compact radiation models by formulating and testing a GBM for the delayed photocurrents in a PN-junction diode. The GBM is based on a state-space system representation in which the structure of the state equation is informed by the nonlinear Ambipolar Diffusion Equation. We also compare this GBM with a purely black-box neural ODE model, which does not assume any prior physics knowledge and attempts to learn the dynamics of the device response solely from data. In so doing we aim to assess how well such black-box models can perform under the model and data size constraints inherent to compact radiation modeling.

EXPLICIT SYNCHRONOUS PARTITIONED SCHEME FOR COUPLED REDUCED ORDER MODELS BASED ON COMPOSITE REDUCED BASES

Amy De Castro[1], Pavel Bochev[2], Paul Kuberry[2] and Irina Tezaur[2]*

[1]Clemson University

[2]Sandia National Laboratories

ABSTRACT

In this talk we will present a method for the partitioned solution of coupled interface problems involving combinations of projection-based reduced order models (ROM) and/or full order methods (FOMs). The method builds on a reconstruction-based partitioned scheme, which starts from a well-posed formulation of the coupled interface problem and uses its dual Schur complement to obtain an approximation of the interface flux. Explicit time integration of this problem decouples its subdomain equations and enables their independent solution on each subdomain.

Extension of this partitioned scheme to coupled ROM-ROM or ROM-FOM problems requires formulations with non-singular Schur complements. To obtain these problems, we project a well-posed coupled FOM-FOM problem onto a composite reduced basis comprising separate sets of basis vectors for the interface and interior variables, and use the interface reduced basis as a Lagrange multiplier.

Our analysis confirms that the resulting coupled ROM-ROM and ROM-FOM problems have provably non-singular Schur complements, independent of the mesh size and the reduced basis size. In the ROM-FOM case, analysis shows that one can also use the interface FOM space as a Lagrange multiplier. We will illustrate the theoretical and computational properties of the partitioned scheme through reproductive and predictive tests for a model advection-diffusion transmission problem.

A HYBRID STRUCTURAL OPTIMIZATION APPROACH FOR MULTISCALE DESIGN OF ARCHITECTED COMPOSITES

Narasimha Boddeti[*1]*

[1]*Washington State University*

ABSTRACT

Fiber reinforced composites (FRCs) are the most widely used multiscale materials owing to their excellent mechanical properties. Despite their simple microstructure, FRCs can accommodate a wide range of property variations. However, they are typically restricted to simple designs due to limitations of the conventional manufacturing processes. Advanced manufacturing methods such as material extrusion additive manufacturing can realize FRCs with complex microstructural variations (e.g., via controlled orientation and deposition of fiber-filled polymers) akin to those found in natural composites like wood and bone. This paves the way for optimal multiscale design of composites specifically tailored to prescribed performance requirements through simultaneous optimization of macroscale topology and the microscale fibrous microstructure, thus leading to architected composites. Architected composites can unlock the full potential of FRCs and lead to lighter, stiffer, stronger, and more durable structures with applications in sectors such as aerospace, automotive, and infrastructure.

Homogenization-based structural optimization methods for multiscale design of architected composites have been popular due to their computational efficiency. These methods typically optimize the distribution of microstructure orientation in conjunction with the macroscale topology and necessitate a dehomogenization step to realize a manufacturable two-scale design. However, the dehomogenization step typically introduces a discrepancy between the optimal and dehomogenized designs due to unavoidable singularities in the orientation field. To overcome this problem, we developed a hybrid optimization approach that combines nested and simultaneous analysis and design formulations (NAND and SAND). Specifically, we employ the SIMP formulation to parametrize the macroscale topology while using the level sets of a distance field for the local fiber orientations. Following the traditional topology optimization approach, the design-dependent response of the structure is obtained from solving the elasticity equations sequentially in a nested fashion. However, the fiber orientation encoding distance field is obtained implicitly by concurrently minimizing the residual of the Eikonal equation alongside the desired optimization objective, thus forming the simultaneous aspect. This hybrid approach ensures that the optimal and realized designs have no discrepancies, retains the design freedom (which is otherwise restricted in level set based formulations), and ensures that a feasible design is available provided the Eikonal equation residual is fully minimized. We demonstrate the efficacy of this approach in 2D and 2.5D (i.e., laminates) with optimal stiffness requirement driving the designs.

ACCOUNTING FOR ELASTO-PLASTICITY IN CONSTITUTIVE ARTIFICIAL NEURAL NETWORKS

Birte Boes[1], Jaan-Willem Simon[1] and Hagen Holthusen[2]*

[1]*University of Wuppertal*
[2]*RWTH Aachen University*

ABSTRACT

In today's industry, we are facing constantly advancing manufacturing processes that result in new materials with improved characteristics such that the material behavior can be better and better exploited. However, the question arises on how to accurately predict the mechanical behavior of these new materials. Thus, new material models are required. But with increasing complexity of the material, the formulation of a material model is equally becoming more complex. New material models are often designed as a combination of new models and a combination of already existing, sophisticated formulations. With this, we may ask which model fits best to the material behavior that should be modeled. To facilitate the choice, we make use of machine learning to predict the mechanical behavior through constitutive artificial neural networks (CANNs). This approach has been successfully applied for elastic material behavior for example by Linka et al. [1]. The extension to inelasticity has recently been published by Holthusen et al. [2].

However, elasto-plastic behavior has not yet been captured but is one major inelastic effect. The lack of this extension leads to a novel formulation presented in this work. We propose a constitutive artificial network based on the works given above that captures not only elastic but also plastic material behavior. For this, we combine two separate feed-forward networks for the Helmholtz free energy and a potential from which we define the yield function in a recurrent neural network. The model’s performance is demonstrated on training and testing on artificial data in a first step. With this, the efficiency of the novel formulation is presented.

ON THE STABILITY OF A FICTITIOUS DOMAIN APPROACH FOR FLUID STRUCTURE INTERACTION PROBLEMS

Daniele Boffi[*1], Fabio Credali[2] and Lucia Gastaldi[3]*

[1]*King Abdullah University of Science and Technology*
[2]*IMATI CNR, Pavia*
[3]*University of Brescia*

ABSTRACT

We review the stability properties of our fictitious domain approach for fluid structure interaction problems.
Some properties are already well known, including the unconditional stability in time and the well posedness of the discrete system for several choices of finite element spaces.
In this presentation we focus on the coupling terms that, as known, require a careful computation of the intersection of the meshes related to the fluid and the solid. We will show that, as expected, the presence of small intersections does not cause problems on the quality of the approximation.

ABSTRACT

Artificial Neural Networks (ANNs) can solve many (un)supervised learning tasks by virtue of the universal approximation theorem. In the context of on-line process control for manufacturing processes, ANNs are an ideal approach for e.g., on-line monitoring or prediction tasks. However, since they are trained on experimental input-output pairs, the governing physical relations are only implicitly included. This, for instance, can cause inaccuracies when extrapolating to out-of-sample data points. On the other hand, the numerical approximation of the governing physical laws via numerical methods holds strong potential for the accurate simulation of physical phenomena that occur during manufacturing processes. However, the corresponding computational effort is an impediment that arises with the need for numerous simulations [1]. This makes the application of such numerical schemes computationally intractable within an on-line monitoring context. As such, it is clear that ANNs and numerical simulation models have strong potential, but are fundamentally different models. However, their combination serves as a potentially efficient and accurate aggregated predictor, the so called grey box model. Such grey box model is based on highly efficient machine learning algorithms, the black box member, and backed by validated data with respect to physics generated by the numerical model, the white box member. A grey box model capable of defining a trustworthy prediction, including a measurement of uncertainty on the estimator, remains a challenging research topic.
In this paper, we introduce an ensemble machine learning method based on the residual modelling approach [2] that is able to provide a best-estimate under scarce data. We do so by combining the predictions of the white box, stemming from partial differential equations implemented in a multi-physics numerical solver, with the black box, representing the residual error between the white-box predictions and available experimental data. The novelty of this work is in the contribution of each counterpart in the grey box. The weight of each counterpart is based on distance metrics between available data in each model. We use real data sample points, generated by an experimental resistance pressure welding process to demonstrate that the proposed technique has a mean-squared error that is up to a constant lower than the error of corresponding estimators based on existing machine learning algorithms.

ENABLING TABULATED FLAMELET PROGRESS VARIABLE METHODS TO SOLVE THE REACTING NAVIER-STOKES EQUATIONS ON MULTIPLE ARCHITECTURES

Brian Bojko[1], David Kessler[1], Kamal Viswanath[1], Ryan Johnson[1], Andrew Kercher[1] and Andrew Corrigan[1]*

[1]*Naval Research Laboratory*

ABSTRACT

The partial differential equations used to describe the reacting Navier-Stokes equations scale with the number of species being transported. This increases the numerical burden when solving combustion simulations using large reaction mechanisms that model real-world fuels of interest. Aside from the additional transport equations, numerical stiffness is also introduced into the system as different reaction rates progress on various time-scales throughout the domain. One method to increase computational efficiency and maintain a detailed description of the combustion physics is to utilize a flamelet progress variable (FPV) approach. The FPV approach reduces the number of species transport equations from N-1, N being the number of species, to three transport equations. In a diffusion flame scenario, the transported scalar quantities of mixture fraction (Z), reaction progress variable (Cpv), and mixture fraction variance (Zv) replace the species transport equations and fully describe the thermochemical state of the mixture. This method has been previously applied to multi-phase combustion phenomena of a reacting interface and extended to multi-phase spray flame configurations. A downside of the FPV approach for large combustion mechanisms, is the need to store large data tables which are loaded onto memory during simulations. This can potentially limit the number of species that can be cataloged in the table used to store the information, defeating some of the draw of this approach. Recent developments will be discussed on the use of a FPV dynamic source term and total energy transport approach to limit the need for multiple independent variables by decoupling the progress variable source term from the tables. Additionally multiple methods, including artificial neural networks (ANNs) will be discussed as a means of enable graphical processing unit (GPUs) for conducting simulations by reducing the memory storage of tables from the order of GBs to KBs. The FPV approach will be compared to the full reacting Navier-Stokes equations with detailed finite-rate chemical kinetics on multiple architectures for a set of canonical flames.

A HIGH-ORDER FLUX RECONSTRUCTION FRAMEWORK FOR INCOMPRESSIBLE FLOWS ON DEFORMING DOMAINS

Marie-Pier Bolduc[1] and Brian Vermeire*[1]

[1]*Concordia University*

ABSTRACT

A wide range of applications require accurate, efficient, and stable solution of incompressible flows around complex deforming geometries. For example, bio-flows, aerodynamics, and hydrodynamics. These prove challenging due to large deformations and intermittent flow separation, requiring unsteady scale-resolving solution techniques, Specifically Large Eddy Simulation (LES) and Direct Numerical Simulation (DNS).

Conventional computational frameworks rely on low-order finite volume methods, which require a prohibitively large number of degrees of freedom to resolve a range of turbulent length scales. Furthermore, enforcing incompressibility constraints typically relies on either exact incompressibility, via coupled global non-linear solvers, or artificial compressibility, via a number of pseudo iterations. Hence, performing scale-resolving simulations of incompressible flows on deforming domains is computationally expensive.

In this presentation, we will outline a novel high-order framework for incompressible LES/DNS flows on deforming domains. This framework utilizes the high-order flux reconstruction approach, enabling arbitrarily high-order accuracy on mixed-element unstructured meshes, combined with the Entropically Damped Artificial Compressibility (EDAC) method, weakly enforcing incompressibility without global solvers or pseudo stepping. Primary focus will be placed on the role of free stream preservation, order of accuracy preservation, enforcement of incompressibility constraints, and sub grid scale modelling via Implicit LES (ILES).

Numerical results will include canonical flows, such as the Taylor-Green vortex and turbulent channel flow, and practical industrial flows including moderate Reynolds airfoils, wing tip vortices, dynamic stall, and cardiovascular flows for the design of ventricular assist devices. These results demonstrate that the proposed framework maintains high-order accuracy, free stream preservation, enforces incompressibility, and is suitable for LES/DNS on deforming domains for a range of practical applications.

BAYESIAN SYMBOLIC REGRESSION: ADDRESSING CHALLENGES IN ESTIMATING FRACTIONAL BAYES FACTORS AND APPLICATION TO FATIGUE CRACK GROWTH MODELING

Geoffrey Bomarito[*1], Patrick Leser[1], Paul Leser[1] and Heather Hickman[1]*

[1]*NASA*

ABSTRACT

This research pioneers advancements in computational mechanics by integrating Bayesian-based uncertainty quantification into symbolic regression, specifically focusing on the critical task of accurately estimating the fractional Bayes factor for selecting arbitrary equations. In our exploration, we rigorously study two prominent methods—sequential Monte Carlo and the Laplace approximation—employed for computing the fractional Bayes factor.

Our findings underscore the limitations of the Laplace approximation, revealing its diminished accuracy in nonlinear and multimodal scenarios. Specifically, the Laplace approximation is shown to underpredict fractional Bayes factor on a wide set of equations associated with a symbolic regression benchmark. This comparative analysis sheds light on the nuanced performance of these techniques, guiding researchers toward more informed choices in uncertainty quantification within symbolic regression. Furthermore, we showcase the practical utility of these enhanced symbolic regression tools through their application to a real-world problem in fatigue crack growth modeling, emphasizing their efficacy in capturing the complexities of mechanical systems.

AN ENERGY-CONSISTENT DISCRETIZATION OF HYPER-VISCOELASTIC CONTACT MODELS FOR SOFT TISSUES

*Francesco Bonaldi**[1], Mikaël Barboteu[1], Serge Dumont[1] and Christina Mahmoud[2]*

[1]*Université de Perpignan*
[2]*Université de Montpellier*

ABSTRACT

We propose a mathematical model of hyper-viscoelastic problems applied to soft biological tissues, along with an energy-consistent numerical approximation. We first present the general problem in a dynamic regime, with certain types of dissipative constitutive assumptions. We then provide a numerical approximation of this problem, with the main objective of respecting energy consistency during contact in adequacy with the continuous framework. Given the presence of friction or viscosity, a dissipation of mechanical energy is expected. Moreover, we are interested in the numerical simulation of the non-smooth and non-linear problem considered, and more particularly in the optimization of Newton's semi-smooth method and Primal Dual Active Set (PDAS) approaches. Finally, we test such numerical schemes on academic and real-life scenarios, the latter representing the contact deployment of a stainless-steel stent in an arterial tissue. This is a joint work with Mikaël Barboteu, Serge Dumont, and Christina Mahmoud.

[2]*Michigan Medicine*
[3]*King's College London*

ABSTRACT

Surgical aortic valve replacement (SAVR) is the most effective treatment for patients with severe aortic stenosis (AS). However, patient-prosthesis mismatch is prevalent in up to 80% of cases and can lead to left ventricular hypertrophy and diastolic heart failure.[1] Aortic root enlargement (ARE) allows the implantation of larger valves, decreasing pressure gradients while providing a larger annulus for potential future transcatheter AVR (TAVR).[2] However, it has been suggested that ARE may also increase the risk of hemostasis and thrombus formation. In this study, we use computational modeling to understand the impact of an ARE on hemodynamics, assessing AV transvalvular pressure gradients, peak velocities, and hemostasis through residence times.

To assess the hemodynamic impact of ARE, we performed patient-specific CFD analysis of 4 pairs of matched AS patients. Each pair consists of a AVR+ARE patient matched with a AVR-no-ARE patient based on age, sex, ejection fraction, and native annulus size. For each AVR+ARE patient, we virtually deployed a SAV into their pre-operative geometry to act as another control model (virtual-AVR-no-ARE). These models provide a mechanism to assess hemodynamics across treatment strategies. Hemodynamic parameters, including heart rate and stroke volume, were standardized for all patients to isolate the effects of root anatomy. The 3D models are coupled to 2-element Windkessel models at the coronary arteries and aortic outflow and CFD simulations were performed on the finite-element multiphysics solver Cheart.[3] Transvalvular peak velocities and pressure gradients were calculated, and blood residence time was computed over 5 cardiac cycles.

AVR+ARE decreased the mean AV pressure gradient by 507% and 542% relative to the AVR-no-ARE and virtual-AVR-no-ARE matched controls. It also decreased the peak velocity by 74% and 56% relative to the AVR-no-ARE and virtual-AVR-no-ARE models. There was less than a 2.7% difference in blood residence time and all models had complete blood washout within 5 cardiac cycles. Hemodynamic simulations of AVR+ARE showed an expected marked reduction in the pressure gradients and peak velocity. Importantly, this came with only a minimal difference in blood stasis in the sinuses, suggesting a limited risk of thrombosis with ARE. Furthermore, the ARE procedure, followed by a simulated valve-in-valve, showed better hemodynamic outcomes over cases without enlargement, highlighting the long-term benefits of ARE.

EFFECTIVE ELASTIC AND VISCOELASTIC PROPERTIES OF TUBULAR-ARCHITECTURED MATERIALS: ANALYTICAL AND NUMERICAL SIMULATIONS

Li-Wei Liu[1], Kuan-Ting Li[2] and Marco Bonopera[*1]*

[1]National Taiwan University
[2]National Cheng Kung University

ABSTRACT

Several biological materials, such as bighorn sheep horns, hooves and human teeth, have the same micromechanical structure formed by neatly arranged tiny tubes. This microstructure is called tubular architecture and such natural materials generally exhibit ductility, high strength, impact and puncture resistance. This observation has attracted scholars to investigate the mechanical behavior of bioinspired structural materials with such microstructure. In this work, the effective elastic and viscoelastic properties of the material with tubular architecture, which were called tubular materials hereafter, were studied. The unit cell method was implemented in conjunction with an analytical solution and finite element simulations. Specifically, the analytical solution of the effective Young's and shear modulus in the displacement field was derived taking into consideration the state of the tubular material as a two-dimensional plane strain problem. Based on the analytical solution of the effective elastic moduli, the influence of the matrix properties on the tubular material, with different dimensions of normal circular or square holes distributed internally, was firstly investigated. Secondly, the relationships between the elastic moduli of the tubular materials and their corresponding volume fraction of holes were studied. The size effect of the tubular material in terms of relative density was also analyzed. On the other hand, the viscoelastic relaxation and creep response of the tubular materials were gained with aid of the same analytical theory and finite-element simulations. This fact has enabled us to obtain the viscoelastic model of the tubular material and then explore its time-dependent behavior under various loading paths and relative densities. By comparing the finite-element results with those obtained by the analytical solution, both effective elastic moduli showed a tendency to converge under higher deformations while, focusing on the size effect, their trend changed nonlinearly with the variation of the relative density in the displacement field. Moreover, changing the dimension of the normal holes, different variations in the time-dependent relaxation and creep responses of the tubular material were observed.

THERMOMECHANICAL TOPOLOGY OPTIMIZATION OF ROVER CHASSIS UNDER EXTREME CONDITIONS WITH BUCKLING LOAD CONSTRAINTS

Murtaza Bookwala[*1], Alexandre T.R. Guibert[1], Matteo Pozzi[2] and H. Alicia Kim[1]*

[1]*University of California San Diego*
[2]*Politecnico di Milano*

ABSTRACT

This study addresses level-set topology optimization of a rover chassis subjected to both thermal and mechanical loads with buckling constraints. The critical context of this research lies in the demanding conditions of space missions, where the equipment faces extremely low temperatures. The rover is also subjected to an exceedingly high range of temperatures, which leads to non-uniform material properties like coefficient of expansion throughout the domain. Maintaining the operational temperature range of this equipment necessitates a substantial amount of energy, which, if conserved, could be allocated towards enhancing instrument functionality for a more efficient mission outcome. Therefore, a key focus of this investigation is to develop a rover chassis that is not only structurally sound and thermally efficient but also lightweight, with a stringent volume fraction requirement of less than 5%. Topology optimization problems associated with low target volume fractions often result in designs featuring thin members prone to buckling. To ensure the stability of the optimized structure, one common approach involves conducting an eigenvalue analysis and imposing a lower limit constraint on the minimum buckling load. This ensures that the resulting design not only adheres to volume fraction limitations but also exhibits stability against buckling. The primary objective of our optimization problem is to minimize structural compliance, thereby enhancing the overall efficiency of the rover chassis. To meet the design goals, specific constraints are applied to volume fraction and minimum buckling load. Additional constraints on criteria like mean temperature are also considered. By incorporating these constraints, we ensure a holistic approach to the optimization problem, accounting for both structural integrity and thermal performance. A modular framework is developed that enables the implementation of multiple constraints and is compatible with legacy and/or open-source solvers and optimizers. For this work, PETSc and SLEPc libraries are used to implement linear boundary value problem solver and eigenvalue solver respectively.

COMMBINI: A NOVEL IN SILICO APPROACH TO STUDY MECHANO-BIOLOGICAL REGULATION OF INFLAMMATION IN BONE FRACTURE HEALING

Edoardo Borgiani[*12], Gabriele Nasello[1] and Liesbet Geris[12]*

[1]*KU Leuven*
[2]*University of Liège*

ABSTRACT

Bone fracture healing is a convoluted process that involves many biological and mechanical factors working at different time- and length-scales. In the last decades, the investigation of this process has taken advantage of computer methods to simulate the hidden multiscale interactions which are challenging to explore experimentally. The initial inflammatory stage is rarely included in those computer studies of bone fracture healing [1]. With COMMBINI (Computational Model of Macrophage dynamics in the Bone Injury Immunoresponse) we filled this gap by using a hybrid modeling methodology that combines finite element analysis and agent-based models to simulate the mechanical and biological dynamics, respectively. To date, the biological part of COMMBINI has been developed for a standardized fracture set-up of a 0.7 mm fracture in mice tibia [2]. The interactions between immune cells and inflammatory cytokines have been simulated within the agent-based model to predict their spatio-temporal evolution during the inflammatory stage. The model has been parametrically calibrated and its results have been validated with a dedicated in vivo experiment [2]. The results highlighted the necessity to use the computational approach to have a more complete knowledge base of the numerous processes that regulate the process, which cannot be readily explained by experiments performed on immune cell cultures alone. For example, the model showed that a more realistic scenario, in line with in vivo macroscopic observation, has been captured when a macrophage proliferation rate was used that was higher than that reported from (in vitro) experiments [2]. Currently, the biological model of COMMBINI will be coupled with a finite element model to simulate the role of murine gait mechanics as the inflammatory stage of bone healing has been observed to be sensitive to mechanics [3]. The model will be extended to 3D and the macrophage regulation will be further influenced by mechanical cues. Macrophage mechano-regulation rules will be experimentally tested with dedicated macrophage-on-chip experiments under different user-defined mechanical conditions and implemented in COMMBINI. The overall model will be validated under alternative mechanical conditions with in vivo experiments on murine tibia stabilized with fixators of different rigidity. Once the model is validated and translated to the clinical sphere, it will provide the possibility to preliminary evaluate the rightful mechano-biological therapies to treat an injured patient, supporting bone healing from the initial inflammatory stage onwards.

CHEMO-MECHANICAL MODELLING OF BIOGENIC SULFIDE CORROSION OF CONCRETE

Frits Rooyackers[1], Akke Suiker[1], Francois Clemens[2] and Emanuela Bosco[1]*

[1]Eindhoven University of Technology
[2]Norwegian University of Science and Technology

ABSTRACT

This study presents a chemo-mechanical model for simulating biogenic sulfide corrosion in concrete sewer pipes [1]. The chemical model is based on a system of coupled diffusion-reaction equations that describe the processes of calcium hydroxide dissolution, calcium silicate hydrate dissolution, and gypsum formation. The chemical problem is two-way coupled with a mechanical model that captures the damage processes caused by mechanical deformations, calcium silicate hydrate dissolution, and gypsum formation. Numerical analyses demonstrate that the model realistically simulates the growth of a gypsum corrosion layer and the consequent damage development in the concrete material in in-situ sewer pipes. Validation experiments finally confirm that the chemo-mechanical model adequately simulates the shape of the experimental corrosion profile and the square root time development of the corrosion depth.

OPERATOR LEARNING VIA NEURAL NETWORKS WITH KERNEL-WEIGHTED CORRECTIVE RESIDUALS

Carlos Mora[1], Amin Yousefpour[1], Shirin Hosseinmardi[1] and Ramin Bostanabad[1]*

[1]University of California, Irvine

ABSTRACT

Over the past few years, a novel class of methods known as physics-informed machine learning (PIML) has emerged as a promising alternative to traditional numerical methods for solving partial differential equations (PDEs). These PIML models typically rely on variants of neural networks (NNs) or kernel methods such as Gaussian Processes (GPs). In this presentation, we introduce NNs with kernel-weighted corrective residuals (CoRes, https://arxiv.org/abs/2401.03492) which integrate the best of both worlds: the scalability and extrapolation power of NNs with the superior local generalization properties of kernel methods. We demonstrate that our approach can (1) exactly satisfy the prescribed boundary and initial conditions, thereby simplifying the optimization process, (2) address inverse problems by incorporating additional measurements in the kernel structure, and (3) solve complex PDEs such as the Navier-Stokes equations as well as operator learning tasks. Through a diverse set of benchmarks, we show that our framework consistently outperforms state-of-the-art PIML methods in terms of accuracy, robustness and development time.

ABSTRACT

Deployable structures are increasingly used in engineering and architecture, driven by the need for transportable and adaptable designs. Inspired by origami, the traditional art of paper folding, innovations arise in various fields such as micro and nanoscale systems, architected materials, biomedical applications, origami robots, reconfigurable structures for space exploration, and temporary settlements. The understanding of origami from mathematical models and the growing interest in computer-aided design have enabled the creation, analysis, and simulation of these foldable structures. This research focuses on simulating the behaviour of some fundamental origami patterns—Yoshimura, Miura, Waterbomb, Kresling, and Resch. This delves into the geometric properties, actuation forces, stresses, and deformations of these origami pattern. By simulating and comparing with physical models, we gain insights of how various origami patterns behave under different conditions and can estimate parameters such as folding ratio and useful volume. This comprehension of origami's basic units is key to selecting the most suitable patterns for the development of complex and space-efficient structures. The study can lead to the application of these patterns in practical scenarios such as origami-based deployable habitats, targeting key challenges in transportability, stability, and human safety, especially in extreme environments on Earth and space missions.

ABSTRACT

Human induced pluripotent stem cells-derived cardiomyocytes (hiPSC-CMs) have revolutionized the field of regenerative medicine, offering unparalleled potential for in-vitro modeling of normal and pathological human cardiomyocytes(1). The ability to produce stem cardiac myocytes in abundance has opened new avenues for drug efficacy and safety testing. The development of atrial fibrillation, for instanace, is influenced by ion channel mutations, genetic variants, and other risk factors. hiPSC-CMs hold promise in personalized medicine, as they share the genetic heritage of the donor.

In recent years, mathematical models of the ionic currents through the hiPSC-CM's membrane have focused on immature phenotypes, developing a system of stiff ordinary differential equations (ODEs). Previous studies characterizations of the CM's phenotype were based on action potential (AP) morphology, but the classification criteria were still undefined. Thus, the forerunner Paci2013(2) model was based on recordings obtained from a mixture of ventricular-like (VL), atrial-like (AL), and nodal-like hiPSC-CMs and the phenotypical heterogeneity was reproduced considering different scalings, instead of phenotype-specific currents.

Nowadays, the employment of electronic maturation highlights the chamber-specific AP phenotype of the cells and a phenotype-specific in-silico model is needed. In this direction, the latest version Paci2020 provides a developed ventricular-specific model. In this talk, I will present the first atrial-specific in-silico model of the hiPSC-CM ionic currents, based on experimental data provided by Altomare et al. Starting form an updated version of the ventricular Paci2020 model for AL hiPSC-CM, we incorporated the atrial-specific IKur and IKCa currents and a different IK1 formulation, inspired by the Koivumaki 2014 model of human adult atrial CM. Thus, the fine tuning of the model parameters was performed by means of an automatic optimization technique, in order to reproduce realistic AP transient shape and to speed up the parameter tuning phase(3).

The resulting model accurately reflects the experimental rate dependence data and demonstrates the expected response to a specific current blocker.

ABSTRACT

Numerical simulation of structures is a major pillar of industrial development. Indeed, numerical tools are used in very early stages of product development in order to achieve solutions that meet specifications as quickly and cost-effectively as possible. To meet growing industrial demand, we need to develop fast, robust numerical solvers. This calls for the development of new simulation methods such as the Virtual Element Method (VEM) which offers a very interesting framework to tackle common industrial issues such as mesh coarsening, node compatibility at contact interface and parallel mesh-generation on complex geometries.

Until the very recent work presented by [1], three-dimensional Virtual Element formulations required numerical stabilization terms to avoid the apparition of hourglass modes. Therefore, this study builds upon the recent developments on two-dimensional
stabilization-free Virtual Element formulations to introduce a stabilization-free Virtual Element Method for three-dimensional linear elasticity. To this end, a Hu-Washizu variational approach such as the one presented by [2] is used to define the weak forms of the equilibrium, compatibility, and constitutive laws in a three-field paradigm. The space for the independent strain field is then chosen to ensure the correct order of singularity of the local stiffness matrix. Finally, in this approach, the computation of the forementioned
matrix is done by the mean of additional degrees of freedom and carefully chosen projections.

The developed three-dimensional stabilization-free Virtual Element formulation have been tested on benchmark problems as well as in industrial contexts. Star-convex polyhedrons with planar faces have been used for meshing and the results shows robustness of the formulation including in the case of non-convex element geometry.

STATISTICAL MECHANICS-BASED GRADIENT-ENHANCED DAMAGE FOR ELASTOMERIC MATERIALS

[1]Air Force Research Laboratory
[2]Cornell University
[3]Lawrence Livermore National Laboratory

ABSTRACT

To design increasingly tough, resilient, and fatigue-resistant elastomers, a detailed understanding of the underlying damage cascade that leads to fracture needs to be found. To that end, we propose a statistical-mechanics based gradient-enhanced damage model for elastomeric materials and discuss the benefits and drawbacks between selecting a gradient enhanced damage approach and a phase field approach towards tackling this problem. The phase field fracture model has emerged as a popular computational method to study the fracture behavior of elastomers. In phase field fracture, a sharp crack is regularized via a diffuse crack phase field variable that minimizes the total potential energy of the system accounting for the (known) energy per unit cracked area for the specific material. Notably, the regularization length, functional form of damage modulation, and fracture toughness of the material must all be prescribed as model inputs in phase field fracture. However, the connection between essential network-level model components to fundamental polymer chain statistical mechanics has yet to be established, as the Lake and Thomas model is known to overestimate the fracture toughness and recent experiments by Slootman et al. (2020) have shown that chain scission can be physically delocalized away from the crack surface during the fracture process in elastomers. In this vein, an anisotropic stress-based gradient-enhanced continuum damage model grounded in elastomer statistical mechanics is formulated. Polydisperse elastomer chains are described by a statistical mechanics-based and thermodynamically-consistent polymer chain model accounting for bond extensibility. Chain scission and its corresponding dissipated energy are calculated via the principles of mechanochemistry. The non-local aspect of the model accounts for network level effects that influence the damage and fracture response connecting directly to a chain level damage criterion which is well established. This allows for fracture toughness to be recovered from our model, contrary to the phase field model where it would have to serve as an input. This is exceedingly important as one has to inherently consider rate dependence for the chain level rupture response. Furthermore, an imperfection sensitivity analysis is performed, connecting the non-local interaction length, introduced in this modeling framework, to the fractocohesive length scale.

COUPLED MULTIPHYSICS SIMULATIONS FOR HIGH ENERGY DENSITY PROBLEMS

Adam Bouma[*1] and Mikhail Mesh*[1]

[1]*Sandia National Laboratories*

ABSTRACT

Research to understand high energy density physics (HEDP) phenomena is often conducted using pulsed power machines that are capable of producing powerful bursts of energy in a very short time. Particle accelerators, lasers, ITER and other devices such as National Ignition Facility (NIF) at Lawrence Livermore National Labs (LLNL) and Z machine at Sandia National Labs (SNL) are the examples. Energy is typically produced in the form of a particle beam or burst of radiation of the various spectra, from thermal to visible light to X-rays, which is directed towards target being studied, but is also absorbed by the components of the machine, measurement devices and other equipment. Sudden deposition of that energy can result in rapid local heating of the materials, followed by expansion and, if sufficient amount of energy is absorbed, ablation of the thin layer of the material. Both phenomena result in stress waves that propagate through potentially sensitive equipment.

Understanding of this phenomenon is necessary for proper design and safe and reliable operation of the pulsed power machines and measurement devices used in the experiments, yet complexity of the physics involved makes prediction of such behavior difficult. Different temporal and geometric scales present in the problem only further complicate things.

To address this problem we developed two step simulation approach where physics associated with energy deposition (very short duration and small dimensions) is modeled using multiphysics Arbitrary Lagrangian-Eulerian (ALE) code ALEGRA followed by structural analysis on typical structural and temporal scales using SIERRA/SM. Both codes have been developed at the SNL. Different temporal and spatial scales allow to use simple one way coupling between the codes by initiation of structural analysis using results of the multiphysics simulation.

In our presentation we will describe details of both problems formulations and explore different ways of coupling of the two models, discuss pitfalls and advantages of the approach and evaluate accuracy of the different ways performing simulations.

EXPLORING HIGH-DIMENSIONAL TURBULENT DYNAMICAL SYSTEMS WITH AUTOENCODERS

Rémi Bousquet[*1], Didier Lucor[1] and Caroline Nore[1]*

[1]*Laboratoire des Sciences du Numérique*

ABSTRACT

We investigate the exploration of high-dimensional dynamical systems, following incompressible Navier-Stokes equations in the turbulent regime, using Machine Learning (ML) dimension reduction techniques. We will review recent methods based on different AutoEncoders (AEs) to efficiently analyze and understand turbulence through dimensionality reduction. The primary objective is to employ AEs architectures to find a parametrisation of the large phase space expressed in a lower-dimensional representation, unraveling key variables of the flow. Essentially, AE-methods map the system phase space to a sub-space (called latent space) and back, by optimizing two large parametric transformation functions (Neural Networks) through gradient descent. If this optimisation process converges, it means that some redundancy, correlations, or symmetries allow a dimension reduction without loss of information.

Recent work have taken advantages of different AE architectures to highlight some general properties that need to be enforced in the model architecture or at the optimisation level [1], to better capture non-linearity of the system phase space. While further advances are needed to model with robustness the system trajectory in the latent space, due to chaos, it remains possible to sample accurately the flow steady state in the long run [2]. Overall, the last decade has shown that ML methods like AEs perform at least an order of magnitude better than classical linear methods, such as Proper Othogonal Decomposition (POD) and Dynamical Mode Decomposition (DMD). The use of AE-based methods for dimension reduction offers a promising avenue for Reduced Order Modelling (ROM) of turbulent flow.

Our contribution beyond previous work will be to propose new Machine Learning metrics, based on the sub-space statistical distributions and correlations in a data augmentation setup, to constraint the latent space local geometry and symmetry. The method is showcased on the von Kármán turbulent flow [3]. The aim is to characterize precisely system trajectories in the latent space and better estimate the turbulent attractor dimension, and dynamic at play.

MULTISCALE MODELING OF THE BALLISTIC PERFORMANCE OF UNCONFINED AND CONFINED POLYMERS

Andrew Bowman[*1] and DeBorah Luckett*[1]

[1]*U.S. Army Engineering Research and Development Center*

ABSTRACT

Due to their high strain rate dependence and high specific energy dissipation, polymers and polymer composites are good candidates for advanced lightweight protection against high velocity impacts and shocks. Confinement has been shown to play an important role in enhancing the performance of certain ballistic resistant materials (such as concrete and ceramics). However, less is known about the effects of confinement on the response of polymers, especially during ballistic impact. Polymers under confinement exhibit notable changes to their molecular structure and material properties as the free space between polymer chains is reduced. Reduced free volume leads to higher interchain friction, which increases strength and stiffness and can provide enhanced energy dissipation. In this work, molecular dynamics (MD) and finite element (FE) simulations are conducted to investigate the multiscale ballistic performance of a ductile polymer with and without confinement. For the unconfined polymer, the energy absorbed (EA) per unit mass predicted through MD simulations is shown to scale well from the nanoscale to the macroscale, matching closely with predictions from macroscale FE simulations of ballistic impact. Under the confinement of a thin graphene backing plate, ballistic MD simulations exhibit drastic increases in the amount of EA due to enhanced interchain friction. Macroscale FE simulations predict a smaller EA increase due to confinement compared to the nanoscale, suggesting that size scale could play an important role in understanding confinement effects in polymers.

EFFICIENT AND FLEXIBLE SHAPE SENSITIVITY CALCULATIONS FOR FINITE ELEMENT METHODS VIA AUTOMATIC DIFFERENTIATION

Jamie Bramwell[*1], Christopher White[1], Samuel Mish[1], Brandon Talamini[1] and Alex Chapman[1]*

[1]Lawrence Livermore National Laboratory

ABSTRACT

Direct optimization of the nodal positions in a computational mesh in conjunction with various filtering schemes is a promising methodology in shape optimization [3]. To support these methods, analysis schemes with derivatives with respect to nodal coordinates are needed. These derivatives are often difficult to calculate and require either complex manual derivation or inaccurate finite difference techniques.

In this talk, we outline a new framework used to calculate these derivatives flexibly and efficiently. On top of the reference finite element mesh, we define a new shape displacement field that translates the reference coordinates to their new optimized location. This field is discretized using standard finite element basis functions and can now be interpolated at quadrature points. We exploit the structure of the finite element method to efficiently calculate sensitivities of the finite element residual with respect to this shape displacement field via forward-mode automatic differentiation at each quadrature point. Once these modifications to the shape field are made, we expose the quadrature point functions directly to the user. This enables rapid development of novel nonlinear shape optimization problems within an HPC-ready code. We describe the implementation of this methodology in Serac [2], an open-source thermomechanical simulation engine built on the MFEM finite element framework [1]. Finally, we conclude with some current applications of our code including sensitivity analysis of nonlinear responsive liquid crystal elastomer structures and porous electrodes.

NUMERICAL AND EXPERIMENTAL ANALYSIS OF THE EFFECT OF GEOMETRIC NONLINEARITY ON AEROSPACE STRUCTURES SUPPORTING NON-IDEAL ROTATING MACHINES

*Reyolando Brasil**[1]

[1]*Federal University of ABC*

ABSTRACT

We present a numerical and experimental study of the effects of geometric nonlinearities on vibrations of rotating machines aerospace slender support structures. The initial stiffness of a structure, computed in its unloaded state, is affected by the applied forces, the so-called geometric stiffness. Here we study these effects via numerical and experimental methods designed to evaluate previous mathematical models. Our model is a slender three members metal portal frame, under compression of its columns and beam, supporting a non-ideal rotating machine. The presence of large axial compressive force will reduce the structure's stiffness and natural frequencies, leading to unexpected, potentially dangerous, resonance states. Experimental imperfections led to observation of interesting phenomena not predicted in our previous theoretical and numerical studies. We also observe, as expected, occurrence of the so called Sommerfeld Effect, when underpowered excitation sources get their rotation regime stuck at resonances and are subjected to jump phenomena.

ABSTRACT

Introduction
Fracture non-unions are associated with a high burden of disease. The two main determinants of non-union outside of infected situations are biology and local mechanics. Aim of this study was to test the capability of our in vivo simulation workflow to calculate the mechanical environment of a non-union situation pre and post revision surgery, determine the mechanical adequacy of the treatments and compare the simulation results to the healing course of the patient.

Methods
In a clinical case series of non-union patients requiring operative revisions a musculoskeletal simulation was performed. Clinical CT imaging was used to construct a three-dimensional CAD-model of the treatment situation before and after non-union revision. Resulting forces are then computed in a simulation-driven workflow (Braun et al. Frontiers in Surgery 2021) based on motion capturing data. The forces are used to simulate the mechanical fracture environment. From the simulation implant stresses for the initial and revision situation, as well as interfragmentary movement and resulting strain are calculated and compared to the clinical course.

Results
Over 40 patients have been included to date in different non-union locations of the upper and lower extremity. The simulation workflow was able to calculate and visualize implant mechanics, interfragmentary strain and resulting tissue differentiation probability based on the Claes bone healing boundaries. The changes through implant revision could be accurately calculated. Especially in mechanically addressed hypertrophic non-union situations the mechanical changes in relation to fracture healing could be highlighted (Fig. 1).

Discussion/Conclusion
The presented workflow was able to visualize critical non-union mechanical conditions both pre and post revision surgery. Mechanical adequacy towards non-union healing can be calculated in relation to patient specific motion capturing. The simulation has the potential to help determine the most appropriate revision strategy in complex non-union situations.

EXPERIMENTAL ANALYSIS OF THE MECHANICAL PROPERTIES OF 3D PRINTED POLYMER COMPOSITE SPECIMENS

Marino Brcic[1], Domagoj Vrtovsnik[1] and Josip Brnic[1]*

[1]*University of Rijeka*

ABSTRACT

Additive manufacturing (AM) technologies are defined according to ASTM standard f2792-12A [1] as a process in which materials are joined to produce objects from a 3D model. One of the most popular AM techniques is Fused Filament Fabrication (FFF), commonly known as 3D printing, which is classified as a material extrusion process because the material is applied through a nozzle or extruder. Several materials are the most popular filaments for 3D printing. These include polylactide or polylactic acid (PLA), acrylonitrile butadiene styrene (ABS) and acrylonitrile styrene acrylate (ASA). Recently, researchers have focused on investigating the mechanical properties of blends of several of these base materials. In this work, one such composite/blend is presented, namely a mixture of ABS and mainly thermoplastic polyurethane (TPU), with ABS serving as the matrix and TPU as the reinforcement, i.e. a composite material, as investigated in [2]. Several different infill patterns are considered, while all blend combinations having similar volume fractions. The basic mechanical properties are investigated and reported in the form of a stress – strain curve together with the modulus of elasticity. In addition, low-cycle fatigue (LCF) is investigated and performed as follows. Three different load percentages were considered, namely 50 %, 70 % and 90 % of the maximum tensile force, according to the results of the tensile tests. The threshold value for the number of cycles was set at 1000 cycles at a speed of 5 mm/min. If the specimen withstood 1000 cycles, the test was continued with the static tensile test until the specimen broke. The maximum force and maximum displacement were recorded. If the specimen did not withstand 1000 cycles, i.e. if the fracture occurred before the 1000 cycles were reached, the maximum number of cycles was recorded. Such a test method is proposed in [3] and was suitable as a reference method.

AN APPROACH INTEGRATING SIGNED DISTANCE FUNCTIONS WITH THE ADJOINT METHOD TO ESTIMATE TISSUE MATERIAL PROPERTIES USING CLINICAL IMAGING DATA

Elaheh Mehdizadeh[1], Amin Pourasghar[1], Timothy Wong[1], Arvind Hoskoppal[1] and John Brigham[1]*

[1]University of Pittsburgh

ABSTRACT

A computational method will be presented for estimating the spatial distribution of mechanical properties of soft tissues within the body, particularly the heart wall, using clinical imaging data. The core innovation lies in a newly devised shape-based approach that utilizes a signed distance function method to measure the difference between image-derived target and simulated tissue mechanical behaviors. This approach is an extension of prior work by the authors that used a standard discretized version of the Hausdorff distance as an objective function in an iterative approach to material parameter estimation [1]. As such, a novel level-set framework is introduced for the objective function that is differentiable and is implemented into an optimization framework to identify the material parameters that minimize the difference with respect to a “target” shape with relative computational efficiency. The adjoint method is employed to calculate the gradient throughout optimization, further enabling efficient minimization of the shape-based objective function. In additional to presenting the computational procedure, the method will be evaluated via simulated inverse problems based on estimating passive heart wall mechanical material properties from standard cardiac clinical imaging data and hemodynamics (i.e., intraventricular pressure). These computational tests consider a simplified system of a two-dimensional (slice) of the bi-ventricular wall with the diastolic process estimated by applying intraventricular pressure, and considers only elastic material properties. Assessment of the results will include the capability to minimize the shape-based objective function effectively and consistently, the accuracy of the estimated material parameters, and the effects of model error on the inverse solution estimation process. Longer-term objectives involve integrating the computational approach with more realistic in vivo conditions, including geometry and boundary conditions. Moreover, the approach will be extended to have the capability to estimate more generalized heterogenous properties and/or alternate constitutive models.

NONLINEARLY STABLE HIGH-ORDER METHODS FOR WALL-BOUNDED FLOWS

Julien Brillon[1] and Siva Nadarajah*[1]

[1]*McGill University*

ABSTRACT

Following the work on viscous free shear flows [1] using the PHiLiP code [2], an assessment of large eddy simulation (LES) approaches for wall-bounded flows using nonlinearly stable flux reconstruction (NSFR) [2] is presented. For all approaches, the filtering is accomplished implicitly by using an under-resolved computational mesh. These implicitly filtered LES (iLES) approaches include: (1) wall-resolved iLES (WRiLES) without a sub-grid scale (SGS) model, (2) WRiLES with an SGS model, (3) wall-modelled iLES (WMiLES) without an SGS model, and (4) WMiLES with an SGS model. The performance of several different SGS models is assessed, including the: wall-adapting local eddy-viscosity (WALE) model, the Vreman model, the high-pass filtered Smagorinsky model, and the dynamic Smagorinsky model. In terms of the wall-models, we consider: (1) the analytical Reichardt law-of-the-wall, and (2) the ordinary differential equation (ODE) compressible equilibrium model. The assessment is performed using the canonical turbulent channel flow case. The findings of this study aim to answer several open research questions in regard to what the best LES strategy for simulating wall-bounded flows is when using a provably-robust high-order discretization scheme.

PHASE-FIELD MODELING AND EFFECTIVE SIMULATION OF NON-ISOTHERMAL REACTIVE TRANSPORT

Carina Bringedal[*1] and Alexander Jaust*[2]

[1]*Western Norway University of Applied Sciences*
[2]*University of Stuttgart*

ABSTRACT

We consider non-isothermal single-phase flow with solute transport where ions in the fluid can precipitate and form a solid mineral, and where the mineral can dissolve and release solute into the fluid. The model is quasi-compressible, hence non-matching fluid and solid densities are allowed in the model formulation. The evolving fluid-solid interface is approximated by a conservative Allen-Cahn equation. This equation includes a non-local term, which makes the use of standard Newton iterations for solving the resulting non-linear system of equations inefficient. We instead apply L-scheme iterations, which are cheaper to perform and is proven to converge for any starting guess. However, L-scheme iterations give only linear convergence. The coupled equations for diffuse interface, solute transport and heat transport are solved via an iterative coupling scheme, which is proven to converge under mild restrictions on the time-step size and on an added regularization parameter. This coupling scheme allows the model equations to be solved more efficiently compared to a monolithic scheme, and numerical experiments show that only few iterations are needed to obtain high accuracy.

Part of this work is available in [1].

VISCONET – A MACHINE LEARNING FRAMEWORK FOR POLYMER NANOCOMPOSITE VISCOELASTIC PROPERTY PREDICTION AND MATERIAL DESIGN

Catherine Brinson[*1], Anqi Claire Lin[1] and Richard J. Sheridan[1]*

[1]*Duke University*

ABSTRACT

Polymer-based nanocomposites (PNCs) are formed by dispersing nanoparticles (NPs) within a polymer matrix, which creates polymer interphase regions that drive property enhancement. However, data-driven PNC design is challenging due to limited data and poor understanding of the impact of the interphase region. To address the challenge, we present ViscoNet, a surrogate model for finite element analysis (FEA) simulations of PNC viscoelastic (VE) response.

ViscoNet leverages the pre-training-then-fine-tuning training scheme, inspired by successful approaches used in the natural language processing (NLP) domain. Pre-training the model with a large dataset from finite element analysis (FEA) simulations covering a wide parameter space enables it to build a general understanding of VE response (see Figure). Subsequently, the model is finetuned with a smaller dataset specific to the materials system of interest, refining its knowledge for accurate material-specific predictions. We utilize a simple multilayer perceptron (MLP) architecture, offering fast training and inference times. To address the issue of reducing the VE response to an ANN input vector, we employ a frequency-fixing technique, transforming the 2D spectral response curve into a 1D series.

We explore ViscoNet's effectiveness through generalization tasks, both within qualitatively different thermoplastics and from thermoplastics to thermosets, reporting a mean absolute percentage error (MAPE) of < 5% for rubbery modulus and < 1% for glassy modulus in all cases and 1.22% on tan(δ) peak height prediction. With only 500 FEA simulations for finetuning, ViscoNet can generate over 20k VE responses within 2 minutes with 1 CPU, compared to 97 days with 4 CPUs via FEA simulations. This fast, low-resource, yet reliable approach significantly enhances the accessibility of data-driven materials design of PNCs, since neither cloud compute nor even GPU resources are required for fast training, fine-tuning, and inference. In a VE material design loop, ViscoNet will enable insights and discoveries by either replacing the FEA simulation component as a surrogate or fill the design space directly thanks to its lightning-fast inference speed.

By predicting the entire VE response, ViscoNet surpasses previous scalar-based surrogate models for FEA simulation, offering better fidelity and efficiency. The training data for ViscoNet is being curated into a materials repository, MaterialsMine, and ViscoNet will be made available as a tool on the MaterialsMine website for researchers to use.

A PERSONALIZED MULTISCALE MODEL OF BIVENTRICULAR CARDIAC MECHANICS

Aaron Brown[*1], Lei Shi[2], Matteo Salvador[1], Fanwei Kong[1], Vijay Vedula[3] and Alison Marsden[1]*

[1]*Stanford University*
[2]*Kennesaw State University*
[3]*Columbia University*

ABSTRACT

Numerical simulations of the biomechanics of the heart are useful for non-invasive investigations of cardiovascular disease mechanisms and treatments. In such simulations, modeling the circulatory system is essential for capturing physiological cardiac behavior. To reduce the computational cost, blood circulation is typically represented with a zero-dimensional (0D) lumped-parameter network (LPN). Recently, we described a novel scheme to couple three-dimensional (3D) cardiac mechanics models with 0D circulatory models, demonstrating the method with an idealized left ventricle coupled to an open-loop LPN. Here, we extend the coupling scheme to an image-derived, biomechanical model of the ventricles coupled to a closed-loop LPN, which is further personalized to clinical measurements.

Phase-resolved (3D+t) computerized tomography images are obtained for an adult male at 10 time points during the cardiac cycle. We then apply a deep-learning approach to segment the images [1] and calculate time-dependent cardiac chamber volumes. Other clinical measurements, including cuff blood pressures and electrocardiogram waveforms, are also obtained. For the ventricular myocardium, the equations of hyperelastodynamics, with the fiber-based Holzapfel-Ogden material law, are solved using a recent finite element method suitable for incompressible finite deformations [2]. The circulatory system is modeled using a closed-loop LPN. The two submodels –- 3D biventricular mechanics and 0D blood circulation –- are coupled using our recently published method [3]. To personalize the model to clinical measurements, we first tune the LPN parameters, then determine the stress-free configuration and passive material parameters of the myocardium, and finally optimize the parameters of the active contraction model.

This work provides a methodology and a baseline model for simulating personalized biventricular mechanics. Using a high-fidelity 3D model for the myocardium, but a simplified 0D circulation model, permits a physiological yet computationally tractable simulation of the heart function. Our preliminary results exhibit physiological cardiovascular behavior, including the downward motion of the atrioventricular plane, reasonable pressure-volume loops, and equalization of stroke volumes after several cardiac cycles. The isovolumic phases of the cardiac cycle, which traditionally pose numerical challenges, are captured by our coupling method without any ad hoc special treatment [3]. One can modify this model to investigate the effect of congenital heart defects, as well as surgical interventions to address such diseases. The method may also be extended to four-chamber heart models to simulate whole-heart cardiac mechanics.

ACCURATE AND ROBUST MAPPING ALGORITHMS FOR GENERAL MULTI-PHYSICS COUPLING

David Brown[1], James Thunes[1] and Daniel Williams[1]*

[1]*Ansys Inc.*

ABSTRACT

Mapping, in a multi-physics context, is the problem of transferring data from the source to target side of a geometric interface of two physics solvers. Accurate mapping technology is critical to any multi-physics coupling engine. Many technologies exist for accomplishing this, with various properties, often well-suited to particular applications, but often not well-suited to problems outside of their target application. One mapping technology in particular, radial basis functions (RBFs) , is a popular choice due to its wide applicability, requiring as input only points and data, thus being applicable to any type of source mesh or point cloud. Unfortunately, this approach frequently encounters pathologies depending on the particular RBF formulation and arrangement and profile of the source data. We encounter a wide range of source data profiles in real-world applications due to different interface topologies, which can be surface mesh, volume mesh, or point cloud; data location provided by the solver, which can be element centroid, integration point, or node; and different physics applications, which can affect the mesh profile as well as the profile of the source data itself . These different features can result in Runge phenomenon, poor conditioning of the RBF matrix, or even an ill-posed interpolation problem. It can be very challenging to design an accurate and reliable mapping algorithm for general applications.

The presentation will focus on new algorithms for mapping non-conservative data for real-world industrial multi-physics applications. The presentation will begin with a technical presentation of the interpolation problems targeted, and the general approach to the mapping. We demonstrate several pathologies encountered by standard RBF formulations in specific cases, their root causes, and new solutions to these problems. The proposed solutions include modification to the RBF formulation, pre- and post-processing techniques for source and target data, and a detection-correction approach to dimensionality reduction to avoid ill-posedness. We also present our analysis of the conditions needed to conserve the minimum order of accuracy of the coupled solvers, and demonstrate how this information can be used to develop a regularity-favorable source point cloud for the RBF algorithm.

The algorithms as described will be commercially available as part of the Ansys System Coupling version 2025R1 multi-physics engine.

SECOND-ORDER PYRAMIDS SUPPORTING EXPLICIT SOLID DYNAMICS FOR SIMULATION OF EXTREME EVENTS

Robert Browning[*1], Kent Danielson[2] and David Littlefield[3]*

[1]*Battelle Memorial Institute*
[2]*U.S. Army Engineer Research and Development Center*
[3]*University of Alabama at Birmingham*

ABSTRACT

Explicit dynamic methods are frequently used to simulate extreme events, such as car crash and other severe impacts, as well as weapon effects and accidental explosions. Frequently, the structural geometry can be tedious to mesh, which has given rise to hex-dominant meshing algorithms. Leveraging such methods, however, typically requires the use of not only hexahedral (hex) and tetrahedral (tet) elements, but also transition elements providing compatible faces with each. When the parts being meshed contain curved edges and/or surfaces, second-order elements also become advantageous by allowing geometric features to be modeled more accurately with fewer elements. Such approaches have been more prevalent in implicit models, but are gaining attention in explicit methods. A key to successful hex-dominant meshing with second-order elements for explicit nonlinear solid dynamics, was the development of a robust 19-node pyramid element (PYR19), that is compatible with other robust second-order solid elements. The PYR19 has been shown to behave well in flexure with very few elements. It also resists volumetric locking in problems involving metal plasticity and shows no signs of hourglassing by virtue of its robust quadrature. The PYR19 and its compatible elements are available for use in parallel explicit solid mechanics codes. The elements are also supported in popular meshing and visualization software.

LEVERAGING DATA AND THE KOOPMAN OPERATOR TO CONTROL SOFT ROBOTS

Daniel Bruder[*1]

[1]*University of Michigan*

ABSTRACT

Soft robots are able to safely interact with delicate objects, absorb impacts without damage, and adapt to the shape of their environment, making them ideal for applications that require safe robot-human interaction. However, their use in real-world applications has been limited due to the difficulty involved in modeling and controlling soft robotic systems. In this talk, I'll describe a modeling approach aimed at overcoming the limitations of previous methods. This data-driven approach leverages Koopman operator theory to construct models that are linear, which enables the utilization of linear control techniques for nonlinear dynamical systems like soft robots. Using this Koopman-based approach, a pneumatically actuated soft arm was able to autonomously perform manipulation tasks such as trajectory following and pick-and-place with a variable payload without undergoing any task-specific training. In the future, these approaches could offer a paradigm for designing and controlling all soft robotic systems, leading to their more widespread adoption in real-world applications.

NUMERICAL ANALYSIS OF DAMAGE AND FAILURE BEHAVIOR OF ANISOTROPIC ALUMINUM SHEETS UNDERGOING BIAXIAL LOADING

Michael Brünig[*1], *Sanjeev Koirala*[1] *and Steffen Gerke*[1]

[1]*University of the Bundeswehr Munich*

ABSTRACT

In the presentation the effect of stress state and loading direction with respect to the principal axes of anisotropy on damage and failure behavior of the anisotropic aluminium alloy EN AW-2017A is investigated. New experiments with biaxially loaded specimens and corresponding numerical simulations have been performed to develop a damage criterion and a damage rule predicting macroscopic strains caused by different damage mechanisms on the micro-level. During the tests digital image correlation is used to monitor evolution of strain fields in critical parts of the specimens. Failure modes on fracture surfaces are visualized by scanning electron microscopy. In addition, numerical calculations on the micro-level considering void-containing representative volume elements reveal further information on damage and failure processes. Based on the experimental data and numerical results of three-dimensionally loaded unit-cells damage laws depending on the stress state and on the loading direction are developed. They are validated by numerical simulation of the tests with biaxially loaded specimens showing good agreement of experimental and numerical results. It is shown that the stress state, the load ratio and the loading direction with respect to the principal axes of anisotropy have an influence on the width and the orientation of localized strain fields as well as on the formation of damage processes and fracture modes on the micro-scale.

ROBUST NUMERICS AND SUB-GRID MODELS FOR MULTI-PHYSICS CFD AT EXASCALE

Anand Radhakrishnan[1], Benjamin Wilfong[1] and Spencer Bryngelson[*1]*

[1]Georgia Institute of Technology

ABSTRACT

Multi-phase flows arise broadly, from cavitation around high-speed underwater vehicles to biomedical treatments for kidney stones. The combination of scales in these problems, and others like them, lead to simulations with large grid sizes and small time steps. Still, understanding multiphase flow phenomenologies and the quantities of interest that buttress them are required to develop sub-grid models for them, such as those of Euler-Euler and Euler-Lagrange types. This work presents the use of CFD software at exascale to conduct full-resolution simulation for computational modeling.

We show that exascale supercomputers, like OLCF Frontier, can enable unprecedented resolution and simulation of compressible multi-phase problems. These simulations are conducted via the Multi-component Flow Code (MFC; Bryngelson et al. Comp. Phys. Comm. (2021)). MFC is open-source and GPU-accelerated. The MFC solver uses high-order accurate numerics and marshals different multi-component diffuse interface (4-6 equation models) and sub-grid models for particles, bubbles, and droplets.

Efficient use of exascale systems requires performant numerics on NVIDIA- and AMD-GPU-based supercomputers. We accomplish this via high-order WENO reconstructions and HLL-type approximate Riemann solvers. Flux computations are dimensionally-split and array reshaping enables performant nested loop computation in the most expensive kernels: reconstructions and Riemann solves. These methods are offloaded to GPU devices via OpenACC, achieving about a 300-times speedup in the most expensive kernels over single CPU cores. Our combination of numerics and GPU acceleration has weak scale nearly ideally (within 95%) to all of Frontier, the first exascale GPU supercomputer (66K GPUs).

GRAPH NEURAL NETWORKS FOR 3D GEOMETRY-AGNOSTIC PREDICTIONS OF MATERIAL BEHAVIOR

Robert Buarque de Macedo[*1], Kevin Potter[1], Kyle Johnson[1] and Craig Hamel[1]*

[1]*Sandia National Laboratories*

ABSTRACT

The FEM (finite element method) has seen tremendous success in the last few decades for accurately modeling complex material behavior. However, simulations can become prohibitively computationally expensive for real-world use cases. This is particularly true when simulations must be run with a range of parameters. In recent years, surrogate modeling with neural networks has been researched to accelerate physics-based simulations. In this data-driven paradigm, networks are trained to predict the results of expensive FEM runs. Once trained, the networks can quickly forecast the simulation results in a fraction of the time, trading off accuracy for speed. In this work, we investigate a particular type of neural network – graph neural networks (GNNs) – as surrogate models for notoriously hard to capture geometries in solid mechanics FEM simulations. Unlike convolutional neural networks (CNNs), which assume a fixed-sized input and output across all data, GNNs process graph objects with arbitrary numbers of nodes and edges. As such, a GNN is “geometry agnostic”: it can input and output an FEM mesh rather than being constrained to predictions on fixed sized voxelated representations of models. We investigate the efficacy of GNNs as FEM surrogates for two use cases. First, we attempt to learn the behavior of porous metal microstructures. GNNs are used to predict the evolution of equivalent plastic strain in these domains. It is studied what features the GNNs can predict, and to what extent the graph connectivity and nodal values contribute to the predictions. Secondly, we apply GNNs towards estimating mechanical behavior of complex geometries such as fasteners. From these results, it is investigated how well GNNs can generalize across a range of geometries. This research represents a critical step in applying data-driven surrogate modeling towards general, complex 3D geometries of practical interest.

PROGRESS AND CHALLENGES IN THE DEVELOPMENT OF THE COMPOSITE WEDGE LOCALIZATION ELEMENT

Michael Buche[1], Michael Veilleux[1], Ellen Wagman[1], John Emery[1], Alejandro Mota[1] and James Foulk[1]*

[1]*Sandia National Laboratories*

ABSTRACT

Localization elements were originally developed to regularize sub-grid localization processes occurring in finite element analyses while utilizing the same constitutive model as the bulk. The 10-noded composite tetrahedral element has been recently improved to provide accuracy under large isochoric deformations while enabling practical meshing. In order to extend the ductile failure capabilities of composite simplices to include strain localization and fracture, a 12-noded composite wedge localization element has been developed. The mathematical formulation of this element is a relatively complicated but direct combination of the 10-noded composite tetrahedral element and the original localization elements. As opposed to the original localization elements, which use a variational scheme to determine the localization length scale, here it is treated as a material parameter that can be calibrated to material properties like the fracture toughness. Recent progress in developing this composite wedge localization element includes the introduction of a second length scale to provide some stabilization through independent control of membrane forces. Ongoing work considers the possibility of in-plane locking and implementation of projection-stabilization strategies similar to the 10-noded composite tetrahedron, as well as pathologies that are unique to the 12-noded composite wedge localization element.

[1]Sandia National Laboratories

ABSTRACT

Rapid generation of accurate electrical device models is important to many disciplines, including those tasked with quantifying the effects of aging on commercial off the shelf (COTS) components. Traditionally, compact device level models use idealized expressions for current and charge response of the device from an applied voltage. These models require subject matter experts with proprietary tools to perform calibration from collected data. Because there is no guarantee that the idealized expressions precisely represent the observed data, it is possible that even more time must be spent heuristically adding additional components to an existing model to achieve the desired fit. Certain classes of data-driven models allow for automated use of data collected in the field or laboratory, thus enabling rapid circuit level simulations. The modeling approach and workflow described in this presentation are demonstrated in the context of NPN bipolar junction transistors (BJT) in an LM741 operational amplifier for low frequency, non-capacitive regimes. We use Xyce-PyMi Python-based modeling interface to develop and evaluate our data-driven device models in a Xyce circuit simulator and use the Sandia Analysis Workbench (SAW) to capture and fully automate the entire process from data to circuit simulation. The successful implementation of the data-driven device and circuit levels modeling approach into a workflow sets the stage for continued development of data driven modeling into capacitive regimes and a wider range of devices, including MOSFETS. Both development extensions will be discussed in the presentation.

COMPARING TWO NONLOCAL BIHARMONIC OPERATORS

Nicole Buczkowski[*1], Mikil Foss[2], Michael Parks[3], Petronela Radu[2] and Jeremy Trageser[4]*

[1]*Worcester Polytechnic Institute*
[2]*University of Nebraska-Lincoln*
[3]*Oak Ridge National Laboratory*
[4]*Sandia National Laboratories*

ABSTRACT

Nonlocal operators are advantageous in modeling given their flexibility in handling discontinuities, incorporating nonlocal effects, and modeling a range of interactions through different choices for kernels. Using these operators in models has several applications, including peridynamics. The biharmonic operator appears in many models including deformations of beams and plates. The nonlocal biharmonic operator can be formulated in at least two ways: using a fourth difference operator or iterating the nonlocal Laplacian. In this talk, we discuss various aspects of the two operators, including convergence of the operators to their classical counterpart and requirements for asymptotically compatible schemes.

EFFECT OF REGION-DEPENDENT MATERIAL PROPERTIES OF HUMAN BRAIN TISSUE DURING SURGICAL PROCEDURES

Emma Griffiths[1], Nina Reiter[1], Jan Hinrichsen[1], Jayaratnam Jayamohan[2] and Silvia Budday[1]*

[1]Friedrich-Alexander Universität
[2]John Radcliffe Hospital

ABSTRACT

Accurate finite element models of the human brain reliably predicting its response under loading offers great possibilities for brain injury prevention, disease prediction, and surgical guidance. Such models can provide access to data inaccessible through current medical technology, e.g., local stresses and strains within the tissue. However, the brain is an extremely complex organ and shows high structural and mechanical heterogeneity. Therefore, the identification of material parameters that accurately describe the region-dependent mechanical behavior of human brain tissue is crucial. To this end, we have performed multi-modal mechanical testing on human brain tissue from 19 anatomical regions and have used an inverse parameter identification scheme to identify mechanically distinct regions with corresponding material parameters [1]. In a second step, we have investigated the importance of using region-specific material parameters when modelling the full human brain during two exemplary surgical procedures, an indent to the brain surface occurring during needle insertion [2], and brain retraction using different medical devices [3].

Our results show that accounting for region-dependent properties leads to significant differences in the predicted stress and strain state compared to simulations assuming homogeneous material properties. During brain retraction, tubular retractors result in lower average predicted stresses than traditional spatulas, especially in the subcortical structures and corpus callosum. Additionally, we show that changing the location of retraction can greatly affect the predicted stress results.

Our investigations demonstrate how finite element simulations of neurosurgical techniques can provide valuable insight, e.g., when aiming to minimize trauma during surgical procedures. The identified parameters can contribute to more precise computational models enabling spatially resolved predictions of the stress and strain states in human brains.

PHYSICS-GUIDED IDENTIFICATION OF DATA-DRIVEN HYPERELASTIC MATERIAL PARAMETERS FROM FULL-FIELD DEFORMATION DATA

Vahidullah Taç[1], Manuel Rausch[2], Francisco Sahli-Costabal[3] and Adrian Buganza Tepole[1]*

[1]Purdue University
[2]The University of Texas at Austin
[3]Pontificia Universidad Católica de Chile

ABSTRACT

Obtaining accurate mathematical descriptors of the nonlinear mechanical behavior of soft heterogeneous materials remains an open challenge in many fields such as biomechanics. While a number of data-driven strain energy functions have been proposed in the last few years, the models have thus far been only applied to learning from homogenized stress and strain data. However, in most realistic scenarios, stress-strain relations vary spatially and material parameters have to be identified from full-field deformations caused by measurable boundary conditions. We develop a physics-guided approach for identifying the parameters of data-driven material models from full-field deformation data. While the method can be readily applied to any data-driven model, we demonstrate its utility via the Neural ODE based model previously proposed by our group [1]. The method relies on minimization of the strong form of the balance of linear momentum. The method is verified by performing finite element simulations with the predicted parameters and comparing to the data collected from the experiments. A number of synthetically-generated and experimental strain fields are used to demonstrate the performance of the proposed method. The method is also compared to existing methods such as the virtual fields method.

MODELLING THAWING-TRIGGERED LANDSLIDES USING A MULTI-PHYSICS SPH FRAMEWORK

Yanjian Lian[1], Ha H. Bui[1] and Giang D. Nguyen[2]*

[1]Monash University
[2]University of Adelaide

ABSTRACT

Thawing-triggered slope failures and landslides have become a growing concern in colder regions due to climate change. This has resulted in an increased interest in researching and predicting the behaviour of frozen soils in recent years. However, predicting these phenomena is challenging for computational simulations because they involve complex behaviour of different phases (e.g., soil, water, ice and air), as well as their interactions and phase transformations. Several advanced mathematical models have been developed to tackle these problems, but they are either demonstrated at the constitutive level or incorporated into the standard finite element method (FEM), which is limited to small-deformation problems. On the other hand, rapid mass movements, such as debris flows, caused by thawing permafrost have been reported as typical failure mechanisms. Predicting these phenomena goes beyond the capability of the standard FEM and requires an advanced computational framework that can handle the fully coupled thermal-hydro-mechanical (THM) process, along with the large deformation and flow-failure behaviour of unfrozen soils. This talk discusses the possibility of tackling this challenge using recent advances in multi-physics and multi-phase modelling using the smooth particle hydrodynamics (SPH) method. Frozen soils are considered a tri-phase mixture (i.e., soil, water, and ice), and a robust mathematical framework to describe the fully coupled THM process in this system is derived within the continuum mixture theory and solved using the advanced THM-SPH framework. The proposed computational framework is demonstrated through several numerical verifications and demonstrations, highlighting its usefulness in addressing challenging problems involving thawing-induced large deformation and failures of slope and thawing settlement/consolidation for engineering scale applications.

EFFICIENT APPROXIMATION OF NONLOCAL ALLEN-CAHN EQUATIONS WITH THE DOUBLE-OBSTACLE POTENTIAL

Olena Burkovska[*1] and Ilyas Mustapha*[2]

[1]*Oak Ridge National Laboratory*
[2]*Kansas State University*

ABSTRACT

In this talk, we present an efficient discretization of a nonlocal Allen-Cahn model with the double-obstacle potential.
We propose first and second-order time-stepping schemes with the spectral approximations in space based on a Fourier collocation method. We provide energy stability estimates for the temporal discretization schemes. A particular structure of the model and nonlocal kernel allow for the characterization of the solution in terms of a projection formula. This provides an efficient way to evaluate the solution that avoids solving a nonlinear and nonlocal system. We present several numerical experiments to support our findings.

EQUILIBRIUM THEORY OF BIDENSITY PARTICLE-LADEN SUSPENSIONS IN THIN-FILM FLOW DOWN A SPIRAL SEPARATOR

Lingyun Ding[1], Sarah Burnett[*1] and Andrea Bertozzi[1]*

[1]University of California, Los Angeles

ABSTRACT

Spiral gravity separators are devices designed to separate slurry components based on density and size. Previous work explored equilibrium solutions to mixtures of liquids and a single particle species in thin-film flows. Our new analysis extends existing theory to two particle species of different densities. This research unveils a new layer of complexity: particle separation. We expand upon existing theory to understand how particles of different densities segregate within a spiral separator based on its specific configuration. We model gravity-driven bidensity slurries on an inclined spiral by considering particle interactions using empirically obtained formulas for the particle fluxes from previous bidensity studies. In this investigation, we examine a thin-film bidensity particle slurry down a rectangular channel helically wound around a vertical axis. By applying a thin-film approximation, we derive an equilibrium profile for the concentration of each particle species and fluid depth. We identify the influence of design parameters (spiral radius, channel width) on particle concentration profiles in spiral separators. Our work provides an avenue for determining optimal designs for spiral separators across diverse mixtures and flow conditions, revolutionizing particle separation technology.

PERIDYNAMIC MICROMECHANICS OF COMPOSITES

Valeriy Buryachenko[*1]

[1]*Micromechanics & Composites LLC*

ABSTRACT

Due to the identical operator form of the general integral equation (GIE, forming computational analytical micromechanics, CAM, see 20min video https://lnkd.in/gYp3SJmy) proposed for both local micromechanics (LM, [1], pp. 277-308, 504-510, [3]) and a wide class of nonlocally elastic (strongly weakly nonlocal and strongly nonlocal, [1], pp. 607-794) media, the methods of LM have easily recast into the following peridynamic micromechanics (PM) methods. Nonlinear GIE for LM and PM is obtained [3].

For periodic media, the Discrete Fourier Transform (DFT) is proposed in PM [3] (including the nonlinear problems) as a generalization of LM's counterparts. Many nonlinear phenomena (such as e.g., plasticity, damage, and fatigue) in both the LM ([1], pp. 521-568) and PM are described by energy-based criteria, which, in turn, depend on the second moments of the local fields. Due to the identity of the GIE for LM and PM, the mentioned methods of nonlinear LM are generalized to PM [3].

One proved that Transformation field analysis (TFA) by Dvorak (1992) in LM is a background of clustering discretization method which was generalized to PM [3].

One of the most popular areas of LM is the laminate theory based on the reduction of the equilibrium equation to 1D equation due to the vanishing of the partial derivatives in the transversal directions. Peridynamic counterpart [3] of this vanishing is the integration over the transversal directions. Applications are random and deterministic media, multiphysics, and nonlinear phenomena.

One [2] demonstrated that a body force with compact considered is a very prospective tool for data-driven learning of the surrogate nonlocal constitutive laws of CMs. It gives opportunities to estimate a surrogate nonlocal operator for the field concentrator factors in the phases rather than only an effective operator. Applications are random and periodic media, MD simulations, and machine learning.

CAM (and PM) is presented as a fundamentally new blocked (or modular) structure [3] that is perfectly adapted for the joint development of PM by teams of experts from different scientific areas (e.g. block “peridynamics” and block “micromechanics”). Any knowledge inside one block is not required in another block.

STRUCTURAL INFLUENCE OF SHIMS ON METALLIC SINGLE-STRAP JOINT

Ana Carolina Coutinho Silva[12], Flavio Luiz de Silva Bussamra[2] and Priscila Barros Soares[1]*

[1]EMBRAER
[2]Instituto Tecnologico de Aeronautica

ABSTRACT

Aircraft structures are composed of many parts with different shapes, materials, and manufacturing methods. As gaps between parts are unavoidable, shims are often required to fill these apertures. However, shims increase the eccentricity of the joint, intensifying the effects of secondary bending, so they must be considered in structural and fatigue analyses.

Several authors have conducted experimental and numerical studies to understand the influence of shims on the structural behavior of lap joints. There are many other works on the shims on lap joints, but few have addressed the presence of shims in single-strap joints. This work aims to evaluate the influence of solid shims on the stress concentration factor of this type of joint subjected to shear loads.

In this work, 60 configurations of single strap joints submitted to shear loads were analyzed to determine the influence of shims on the stress concentration factor. Three geometrical variables were considered: shim thickness, plate thickness, and fastener diameter D.

The joints were simulated using the finite element software Femap for a linear static solution SOL101. The models were created using hexahedral 8-node solid element CHEXA8 and considering the linear contact BCONTACT method to represent the interface between surfaces. The relative loss of stiffness was presented for every analyzed joint.

The finite element model results showed that an important reduction of joint stiffness can occur when thick shims are used. The stress concentration factors with and without shims, Kt and Kt0, respectively, were obtained. The increase of the stress concentration factor due to the presence of shims was evaluated, resulting in three diagrams that can be used in the aeronautical industry. Diagram #1 presents the Kt/Kt0 for joints with D=4mm, considering several plate and shim thicknesses. Diagram #2 presents the Kt/Kt0 for joints with D=8mm, considering different plate and shim thickness values. For some plate thickness values, the influence of the fastener diameter on the relative stress concentration factor was practically negligible, so Diagram #3 was created. These diagrams and correspondent curves presented a maximum fitting error of 3.4%, showing that they are suitable for primary stages of stress concentration factor predictions.

The use of these diagrams avoids the execution of time-consuming numerical analysis with significant savings for companies that have to deal with shimmed joints frequently, as in the aeronautical industry.

AN INVESTIGATION OF THE FLUID STRUCTURE INTERACTION IN ARTICULAR CARTILAGE ACROSS DISPARATE SCALES

Emily Butler[1], David Head[1], Mark Walkley[1], Michael Bryant[1] and Greg de Boer[1]*

[1]*University of Leeds*

ABSTRACT

Articular cartilage (AC) is found at opposing surfaces in mammalian joints. It provides a smooth bearing surface, promoting low friction articulation and facilitating continuous operation under relative motion. A lack of cells within AC renders a low capacity for intrinsic healing or repair. This leaves it prone to degeneration and disease, resulting in a high clinical demand for cartilage repair [1]. To streamline treatment, an accurate computational model of the tissue is essential to inform rapid pre-screening of therapeutic interventions. Current models generally use a single-scale approach, which fails to capture the complex multi-scale features of the tissue, including its intrinsic heterogeneity and depth dependant properties [2]. Instead, this project aims to couple an immersed fibrous network (micro-scale) model with a continuum (macro-scale) model, using the Heterogeneous Multi-scale Method [3] to create a multi-scale poroelastic model that can capture the fluid-structure interaction arising within AC across disparate scales. The novelty of the approach lies with using homogenized stress, strain, and velocity from the micro-scale, alongside superposition, to populate the macro-scale elasticity and permeability tensors.

A continuum-continuum model has been developed for validation of the multi-scale poroelastic framework. Currently, a fibrous network representation of the micro-scale behaviour is being integrated into the multi-scale model to include anisotropy and depth dependent properties. Once this continuum-fibre coupling has been established, zonal structuring will be introduced, and the resulting model will be validated against experimental data.

The micro-scale fibre model is based on a regular spring lattice in which lattice bond occupation and spring stiffness can be freely varied, making it an advantageous choice for damage modelling, as fibre anisotropy and damaged tissue can be incorporated by selective modification of the micro-scale elastic elements. Modelling weakening areas of tissue and eventual lesions that arise in damaged cartilage tissue will inform an understanding of the change of behaviour and mechanical properties of the damaged tissue, which could be a critical step to inform clinical interventions for cartilage repair and future replacement.

COMPUTATIONAL MODELING OF CUTTING DISC-ROCK INTERACTION IN MIXED GROUND CONDITIONS

Sahir Butt[*1] and Günther Meschke*[1]

[1]*Ruhr University Bochum*

ABSTRACT

In this contribution, we present a simulation tool based on the state-based peridynamic theory, developed to model the interaction between cutting discs of a TBM (Tunnel Boring Machine) and the ground being excavated. As compared to existing TBM performance prediction models, this computational models allows to consider various heterogeneous and mixed ground conditions, different TBM and disc designs, as well as the direct coupling with wear models. Furthermore, the consequences of wear in terms of partially degraded or damaged discs on the excavation performance can be assessed numerically.

The developed model is thoroughly validated using several benchmarks, including indentation tests on sandstone specimens and biaxial strength tests for concrete. The simulation model was further tested by simulating a full-scale LCM (Linear Cutting Machine) test conducted on Colorado Red granite, and the resulting cutting forces at various disc spacings are compared with experimental data.

To investigate excavation in mixed ground conditions, which can lead to abnormal tool wear and even failure, an LCM experiment is performed where the cutting disc excavates through a series of rocks with a high contrast in UCS (Uniaxial Compressive Strength). These experiments successfully identify an overshoot in the cutting force as the disc enters the rock domain with a higher UCS which can cause localized damage to the cutting disc. The cutting forces obtained from scaled-down simulations using the developed model for mixed ground excavation scenarios exhibit qualitative agreement with the aforementioned LCM experiment.

Additionally, the simulation model is equipped with an abrasive wear model, which is verified using analytical solutions. This implemented wear model is able to identify the changes in wear rates as the cutting disc excavates through varying rock formations. Finally, the versatility of the simulation model is demonstrated by investigating various aspects of the cutting disc-ground interaction, including the efficiency of excavation with varying disc geometries.

FREE AND FORCED VIBRATIONS OF SHEAR DEFORMABLE CRACKED BEAMS

Salvatore Caddemi[*1], Francesco Cannizzaro[1], Ilaria Fiore[1] and Ivo Caliò[1]*

[1]*University of Catania*

ABSTRACT

The presence of concentrated cracks has gained over the years a great deal of attention in view of their strong influence on the vibrational properties of beam structures. The latter influence is due to the local flexural stiffness decay around the damaged cross section that has been widely modelled by making use of the Euler-Bernoulli beam model. Although analogous crack models have been formulated for shear deformable beams, only recently researchers working on the subject focused on convenient formulations of advanced procedures to deal with multiple cracks [1].
Recently, the authors have contributed to the problem by providing an exact distributional model for free vibrations of shear-bending multi-cracked Timoshenko-Ehrenfest beams [2]. The original contribution consists in the adoption of the theory of distribution to treat multi-cracked beams as undamaged beams leading to exact closed form solution of the relevant mode shapes.
The latter achievement is exploited in this work to provide explicit expressions of the so-called Green's functions delivering the forced response in the case of harmonic concentrated loads considering both the undamped and damped vibrations. Spatial convolution of the Green's functions allows the evaluation of the response of multi-cracked beams to distributed loads.
Finally, the proposed exact distributional approach is adopted for assessing the response when the beam is subjected to a generic intensity time history. The latter result is obtained via combination of the Green's functions with the direct and inverse Discrete Fourier Transform (DFT), and allows evaluating the response of shear deformable beams with multiple cracks to arbitrary loading conditions.

OPTIMIZING STRUCTURES THROUGH GENERATIVE ARTIFICIAL INTELLIGENCE: CASE STUDY ON A CANTILEVER BEAM MADE OF DIFFERENT MATERIALS

Lorenzo Miele[1], Luca Lomazzi[1], Rafael Junges[1], Marco Giglio[1] and Francesco Cadini[1]*

[1]Politecnico di Milano

ABSTRACT

Conventional topological optimization techniques focus on deriving optimal structures through a predefined set of constraints and objectives, often limiting the modifications to changes to already existing designs. Notably, these methods operate within the constraints of a known material composition, restricting the ability to alter materials. Another traditional constraint lies in the inability to generate structures from scratch, necessitating initial designs for subsequent reduction to achieve specific performance goals. To overcome these limitations, novel approaches involving machine learning, specifically deep learning techniques, have been proposed in the literature. However, state-of-the-art solutions have not been adopted yet in the field of structural mechanics. In this context, this work aims to develop a generative artificial intelligence-based framework for an enhanced topological optimization of structures. Variational autoencoder were considered to the purpose. Such algorithms learn from diverse structures and subsequently generate optimized designs. This expands the optimization scope to generating structures from scratch and allows including multiple objectives, such as maximum stress, weight reduction, vibration modes, or mechanical wave propagation. The framework's transformative impact on topological optimization was exemplified through a specific case study involving a fixed end beam. The model was trained over a numerical dataset including the response of structures made of different materials, developing the capability to generate optimal designs for a fixed end beam configuration. This innovative approach not only broadens the scope of topological optimization, but also showcases its adaptability to specific structural configurations, offering promising prospects for a more comprehensive and versatile structural design process.

NUMERICAL STUDY OF FORCED VIBRATIONS OF FLAX-EPOXY COMPOSITE STRUCTURES WITH A PERTURBATION METHOD.

Jean-Marc Cadou[*1], Laetitia Duigou[1], Khaoula Chikhaoui[1], Vincent Couillard[1], Yann Guevel[1] and Mathias Ziapkoff[1]*

[1]*Institut de Recherche Dupuy de Lôme*

ABSTRACT

This study deals with response curves computations for forced vibration of composite structures made of a flax fiber-reinforced epoxy matrix. This kind of bio-based composites has the advantage to present greater damping compared to synthetic fibers. Moreover, this damping is frequency-dependent[1], meaning that it is different for each vibration mode. So, one have to consider a viscoelastic law to describe this property in the case of bio-based composites. In this study, two different constitutive equations are considered : the generalized Maxwell model and the fractional derivative Zener model[2]. As these laws are nonlinear in frequency, this leads to a nonlinear forced vibration problem. To solve this problem, the asymptotic numerical method [3] is used. It combines a perturbation technique and a finite element method. The nonlinear initial problem is transformed into a succession of linear ones that admit the same tangent matrix and different right-hand sides. This permits to reduce the computational costs compared to classical iterative methods. Numerical results obtained with this approach are compared, in terms of damping frequencies and structural loss factors, to those obtained when considering the free vibration case.

THE QUEST TO FIND THE ANALYTICAL SOLUTION OF COOK'S MEMBRANE WITH NEURAL NETWORKS

Huijian Cai[1] and Steve WaiChing Sun*[1]

[1]*Columbia University*

ABSTRACT

Cook's membrane has been a popular boundary value problem used to benchmark performance of incompressible elasticity. Despite its popularity, the analytical solution of this linear elasticity problem is not known and hence Richardson's extrapolation is often used to check convergence. This talk presents a technique that uses multiple neural networks to generate basis functions to span the solution space. By mapping the irregular domain onto a square, we introduce a technique where a finite element solution is first used to provide the useful inductive bias to generate the appropriate basis that generates an accurate approximate solution. Following this step, a genetic algorithm is then used to convert the neural network learnt basis function into the analytical form, thereby enabling the analytical solution to be expressed as a polynomial in a feature space. This generalized version of the neural additive method [1][2] is crucial to overcome the curse of high-dimensionality of the symbolic regression problem in multi-dimensional settings. While the heuristic nature of the search does not yield the exact solution for Cook's membrane, we find a few close approximations of the solutions that yield 0.01% collocation errors. The analytical solutions expressed in both Airy stress function and as displacement field are compared.

PHYSICS-INFORMED DATA-DRIVEN RANS FRAMEWORK FOR WALL-BOUNDED FLOWS: A PRIORI AND A POSTERIORI VALIDATION

Jiayi Cai[*1], Pierre-Emmanuel Angeli[1], Guillaume Damblin[1] and Didier Lucor[2]*

[1]*CEA Paris-Saclay*
[2]*LISN-CNRS*

ABSTRACT

Numerous Tensor Basis Neural Network (TBNN) frameworks [1] have recently emerged in the literature as data-driven constitutive models, embedding inherent physical invariance properties to augment turbulence Reynolds-Averaged Navier-Stokes (RANS) modeling. Despite their proven success, persistent uncertainties surround the choice of the integrity tensor basis [2], coupled with a notable lack of attention and transparency in data analysis and training strategies. This paper aims to rectify and tailor TBNN through a comprehensive application to two distinct wall-bounded flows of increasing complexity: Plane Channel Flow (PCF) and Square Duct Flow (SDF).

In the present work, thorough analyses on the integrity tensor basis and the raw training data are conducted for each flow case to establish optimal and physically sound tensor basis models. Subsequently, augmented TBNNs based on this modeling are trained using state-of-the-art strategies to achieve a balanced prediction of the full Reynolds stress anisotropy tensor (RST). A priori results obtained by the proposed framework are in very good agreement with the reference data from Direct Numerical Simulations (DNS) in both interpolation and extrapolation scenarios [3]. When the learning becomes more challenging, we suggest some numerical strategies (e.g. based on Transfer Learning (TL) in order to leverage our prior knowledge and mitigate this problem.

A challenge might arise when incorporating data-driven RST closures into RANS equations, as maintaining model consistency becomes crucial. This concern, particularly evident in potential inaccuracies related to the mean velocity profile, is addressed in our approach. The proposed neural network models are seamlessly integrated into a customized, in-house RANS solver for a posteriori validations, employing an iterative substitution framework. A comprehensive set of case studies is meticulously examined by introducing TBNN contributions in varying components of the RANS solver to scrutinize error propagation. Initial findings at this stage provide valuable insights, positioning the proposed approach as a competitive alternative to traditional RANS models.

A CAUSALITY-DEEPONET FOR CAUSAL RESPONSES OF LINEAR DYNAMICAL SYSTEMS

Wei Cai[*1], Lizuo Liu[2] and Kamaljyoti Nath[3]*

[1]*Southern Methodist University*
[2]*Dartmouth College*
[3]*Brown University*

ABSTRACT

In this talk, we will present a DeepONet structure with causality to represent causal linear operators between Banach spaces of time-dependent signals. The theorem of universal approximations to nonlinear operators is extended to operators with causalities, and the proposed Causality-DeepONet implements the physical causality in its framework. The Causality-DeepONet considers causality (the state of the system at the current time is not affected by that of the future, but only by its current state and past history) and uses a convolutiontype weight in its design. To demonstrate its effectiveness in handling the causal response of a physical system, the Causality-DeepONet is applied to learn the operator representing the response of a building due to earthquake ground accelerations. Extensive numerical tests and comparisons with some existing variants of DeepONet are carried out, and the Causality-DeepONet clearly shows its unique capability to learn the retarded dynamic responses of the seismic response operator with good accuracy.

INVESTIGATION OF OFF-AXIS TENSION FAILURE MECHANISMS IN TRIAXIAL BRAIDED COMPOSITES THROUGH MESOSCALE SIMULATION

Yinglong Cai[12], Zhenqiang Zhao[12], Peng Liu[12] and Chao Zhang[12]*

[1]*Northwestern Polytechnical University*
[2]*Joint International Research Laboratory of Impact Dynamics and Its Engineering Applications*

ABSTRACT

The intricate braided architecture makes the two-dimensional triaxial braided composites (2DTBC) exhibit distinct local stress states under uniaxial tensile load and also causes their failure mechanisms to be complex and dependent on the loading angle [1-2]. This study develops a full-scale mesoscale finite element model matched to experimental specimens to investigate the mechanical response and damage characteristics of the 2DTBC under off-axis tensile loadings. The numerical simulation successfully predicts the mechanical performance across five off-axis angles: 0°, 30°, 45°, 60°, and 90°. By capturing the diverse loading responses, the model reveals the transformation of failure behaviors and damage morphologies as the loading angle varies. The results demonstrate that when the external load is applied in alignment with the fiber bundle direction of the specimen, the primary failure mechanism involves the fracture of the load-bearing fiber bundles. Conversely, when the loading direction forms an angle with any of the fiber bundles, the failure mechanism shifts to local shearing of bias fiber tows. Furthermore, both the numerical results and experimental observations emphasize the substantial impact of the free-edge effect [3], which causes premature failure of the specimen on the off-axis tensile loading. In addition, the discussion of the Hashin shear factor further clarifies the mechanism of the influence of shear stress on the failure behavior under different off-axis loadings. This study provides valuable engineering insights for optimizing the performance of 2DTBC in advanced applications.

EFFICIENT GRAPH NEURAL NETWORKS FOR STRUCTURAL ANALYSIS OF STIFFENED PANELS

Yuecheng Cai[*1] and Jasmin Jelovica*[1]

[1]*The University of British Columbia*

ABSTRACT

Machine learning (ML) and deep learning (DL) techniques have gained significant attention as reduced order models (ROMs) to computationally expensive structural analysis methods, such as finite element analysis (FEA). Graph neural network (GNN) is a particular type of neural network which processes data that can be represented as graphs. This allows for efficient representation of complex geometries that can change during the conceptual design of a structure or a product. In this study, to address such computational challenges in structural analysis, we propose a novel graph embedding for the efficient representation of 3D stiffened panels by considering separate plate domains as vertices. This approach not only simplifies the representation of complex geometries but also adapts to changes during the design phase. Employing Graph Sampling and Aggregation (GraphSAGE), our model predicts stress distributions in stiffened panels under varying geometrical configurations, material properties, and loading conditions.

One feature of our research is the comparative analysis against traditional finite element-vertex graph representation. This comparison showcases the computational efficiency of our GNN-based model, particularly in saving GPU memory and GNN training time. In addition, a comprehensive parametric study is performed to examine the effect of structural variables on stress predictions. A wide range of geometries is considered, including material nonlinearity, a few boundary conditions, together with uniform and patch loading at various positions. Our results reveal the GNN model's remarkable efficiency in predicting stress distributions, often surpassing the performance of traditional methods in complex scenarios. These results not only demonstrate the potential of GNNs as a robust, reduced-order modeling tool for structural analysis but also pave the way for their application in the early stages of structural design.

VIBRATION CONTROL AND ANALYSIS OF CABLE-DRIVEN DEPLOYABLE TRUSS STRUCTURE MAST

Binbin Cao[1] and Zhiqin Cai[1]*

[1]Dalian University of Technology

ABSTRACT

In recent years, due to the gradual complex trend of space missions, the space structures have gradually developed in the direction of large scale and flexibility. Space deployable masts are often used as supporting structures for working platforms of spacecrafts due to their light weight and high expansion-to-retract ratio. However, spacecrafts are often affected by external factors such as space gravity gradient, temperature variation and solar light pressure in space environment. In addition, during active working process such as position and attitude changes or space operations, low-frequency vibration of the extended truss structure is easy to be caused, which decays very slowly in space environment with low damping. If the vibration energy is not controlled, it may adversely affect the entire system. Therefore, implementing an appropriate vibration control is crucial for ensuring the deployable mast's operation. This study specifically focuses on a deployable truss structure mast that employs cables as actuators. The research includes the optimization of actuator positions and the design of control laws, taking into account both unilateral and saturated constraints of the cable actuators. First, modal information about the structure is obtained using the commercial software ANSYS. And the model of the truss structure is established with the second Lagrange equation based on finite-element-method. Second, the criteria of position optimization of actuators and sensors is constructed using Gramian matrices that can describe the controllability and observability of the control system. The actuator position optimization method is devised by the controllability principles and the genetic algorithm. Finally, a deployable truss structure mast consisting of four units is simulated and analyzed. The results demonstrate that the proposed actuator optimization position and the control law effectively mitigate the vibration and ensure the stable operation of the deployable mast.

SENSING VEHICLE DESIGN OPTIMIZATION FOR BRIDGE INDIRECT STRUCTURAL HEALTH MONITORING BASED ON SURROGATE MODEL

Andres Felipe Calderon Hurtado[*1], Mehrisadat Makki Alamdari[1], Elena Atroshchenko[1], Chul-Woo Kim[2] and Kai Chun Cahng[2]*

[1]University of New South Wales
[2]Kyoto University

ABSTRACT

Bridge indirect structural health monitoring (BISHM) using drive-by bridge inspection has been widely studied over the last decade. Such methodologies consist of assessing bridge damage from the coupled bridge-vehicle response measured by an instrumented vehicle. Certainly, most studies consider commercial vehicles as sensors, which limits the applicability of this technology since the damage assessment performance depends on the sensing vehicle characteristics. Looking forward to a future in which autonomous vehicles are designed and used specifically for bridge inspection, this work presents a sensing vehicle design optimization to maximize the damage assessment performance using drive-by inspection in a numerical case study. First, a methodology based on the analysis of the frequency domain representation of the signal recorded by the vehicle is presented to identify bridge damage at different locations. The output of the framework corresponds to two probability distributions, one for healthy samples and one for damaged samples, respectively. The distance between these distributions is used as the objective function of optimizing the vehicle properties. Then, a Kriging meta-model of the distance between probability distributions is constructed from the results obtained from multiple vehicle configurations. Such a model is then used to perform the optimization of the vehicle characteristics that maximize the distance between the healthy and damaged samples' distributions. Finally, vehicle design guidelines are presented in terms of non-dimensional parameters that relate to the vehicle and bridge properties.

QUANTIFYING UNCERTAINTIES IN MODELING CHOICES FOR TIME-SENSITIVE APPLICATIONS

Wendy Caldwell[*1]

[1]*Los Alamos National Laboratory*

ABSTRACT

“Quantifying uncertainties in modeling choices for time-sensitive applications”
Wendy K. Caldwell
Los Alamos National Laboratory
wkcaldwell@lanl.gov

Multiphysics simulations involve a number of modeling choices, including material strength, meshing strategies, and equation of state. These methods are often verified using ideal scenarios (e.g., uniform mesh, analytic solutions available), but there are scenarios during which this approach is not feasible. Planetary defense, a research subject focused on protecting Earth from impacts from potentially hazardous objects (PHOs), is a matter of both national and global security. Simulations of planetary defense applications involve spatial scales of hundreds of kilometers and temporal scales on the order of seconds or longer. Thus, modeling choices must be made to ensure that knowledge can be obtained in a timely manner, as mission design can take years and flight time from Earth to a PHO can take from 6 months up to years. Understanding how these choices (e.g., a varied mesh resolution that is more resolved around the impact point and less resolved at the edges) contribute to overall uncertainty is of utmost importance in preparation for a variety of potentially catastrophic scenarios. In this work, we examine how specific modeling choices contribute to uncertainties in numerical simulations as a means of better understanding how to best interpret results and apply the appropriate error bars given a time-sensitive scenario, such as an impending meteor strike. We also discuss the simulations run as part of the Near Earth Object Table Top Exercise of 2024, which considered a number of possible mitigation strategies and associated timelines.

TRANSIENT NONLINEAR RESPONSE OF RESONANT METAMATERIAL ARRAYS UNDER IMPACT LOADING

Erdem Caliskan[1], Weidi Wang[2], Willoughby Cheney[2], Alireza Amirkhizi[2] and Reza Abedi[1]*

[1]*University of Tennessee*
[2]*University of Massachusetts, Lowell*

ABSTRACT

Metamaterials (MM) can be designed to attenuate the energy transfer induced by impact and blast loadings. These materials employ local resonance with resonators tuned for a range of frequencies for stress wave mitigation. Even though traditional Frequency Domain (FD) methods are commonly used to analyze the idealized conditions, understanding the time domain response is crucial for more realistic results the transient response of wave propagation in periodic media can more naturally be modeled in Time Domain (TD). Moreover, TD analysis is necessary when nonlinear processes such as fracture are considered. This work analyzes the time domain response of a low-frequency resonant ceramic MM under impact loading using the Johnson-Holmquist II (JH-2) material model. The performance of the MM is compared to monolithic slabs and other microstructured designs in terms of stress wave mitigation, peak load retardation, and energy transfer. The simulations are conducted with different boundary conditions and domain sizes. Loading is applied as plate impact and point impact for two different MM designs. Results show that the MM performed better in delaying and reducing the peak energy transfer than the other designs. Additionally, we found that the wave anisotropy of the metamaterial design further improved its performance in terms of stress wave mitigation. The unique directional properties of the metamaterial sample allowed for more efficient energy transfer, resulting in overall enhanced performance compared to the other designs. The study concluded that resonant ceramic metamaterials are a promising new class of materials with unique and tunable properties that can be used for protective and structural applications.

ANALYSIS OF A MIXED FEM WITH EXACTLY DIVERGENCE-FREE MAGNETIC FIELD FOR THE STATIONARY MHD PROBLEM

Ana Alonso-Rodriguez[1], *Jessika Camaño**[2] *and Ricardo Oyarzúa*[3]

[1]*University of Trento*
[2]*Universidad Católica de la Santísima Concepción*
[3]*Universidad del Bio-Bio*

ABSTRACT

In this work we analyze a mixed finite element method for the stationary incompressible magneto-hydrodynamics problem providing an exactly divergence-free approximation of the magnetic field. The method is based on the introduction of the volume current density as a further unknown leading to a mixed formulation where the primary magnetic variables consist of the volume current density, the magnetic field, and a Lagrange multiplier included to enforce the divergence-free constraint of a magnetic field, whereas the hydrodynamic unknowns are the velocity and pressure. Then the associated Galerkin scheme can be defined by employing Nédélec and Raviart-Thomas elements of lowest order for the volume current density and magnetic field, respectively, discontinuous piecewise constants for the Lagrange multiplier and any inf-sup stable pair of elements for the velocity and pressure, such as the Mini-element. The analysis of the continuous and discrete problems are carried out by means of the Banach-Nečas-Babuška theorem and the Banach fixed-point theorem, under a sufficiently small data assumption and quasi-uniformity of the mesh, the latter for the discrete scheme. Finally, we derive the corresponding Cea's estimate and provide the theoretical rate of convergence.

THEORETICAL DEVELOPMENTS ON A KINEMATICALLY-EXACT ROD MODEL FOR THIN-WALLED MEMBERS WITH CROSS-SECTIONAL DEFORMATION AND FINITE STRAINS

Marcos Pires Kassab[1], Eduardo de Morais Barreto Campello[1] and Adnan Ibrahimbegovic[2]*

[1]University of Sao Paulo
[2]Universite de Technologie Compiegne – Alliance Sorbonne Universite

ABSTRACT

This work presents theoretical developments on a kinematically-exact rod model to incorporate cross-sectional deformation (warping and distortion) degrees of freedom for thin-walled members, with associated shell bending effects of the walls and a polyconvex constitutive equation for finite strains. The model´s weak form and associated tangent operator are derived, aiming for future numerical implementation through the finite element method (this is currently under development and will be addressed in a subsequent work; some preliminary results may be shown). We believe the model is useful for developing a robust framework for the simulation of frame structures consisted of thin-walled members, in which local effects (e.g. web and flange local bending and buckling) are prone to arise and stand as typical design constraints in most design standards worldwide. The model´s displacement field allow for the traditional cross-sectional rigid body motion, along with the walls´ mid-line in- and out-of-plane deformations (first-order in-plane distortion and out-of-plane warping, respectively, herein called primary deformations) and a kinematically-exact rotation for the walls´ out-of-mid-line points (herein called secondary deformation). The rigid body motion is parametrized as usual for geometrically-exact beams, whilst primary deformations are described by linear combinations of distortion modes, borrowed from the so-called Generalized Beam Theory (GBT). The (shell-like) rotation that defines the secondary deformation is described as a function of the walls´ mid-line displacement field and is parametrized using Kirchhoff-Love shell assumptions. The use of a polyconvex hyperelastic constitutive equation guarantees material stability for the solution at finite strains situations. Although rod models with cross-sectional deformation may be found in the literature (see, e.g., Gonçalves, Rito-Côrrea and Camotim [1]), they invariably neglect higher order strain and/or constitutive terms, which may be relevant to capture some usual global buckling modes, as shown in [2]. Enabling these higher order deformations with local effects is the novelty of this work.

PROBOOST: PROBABILISTIC BOOSTING FOR FORECASTING RARE AND EXTREME EVENTS. CASE STUDIES IN SPACE WEATHER PREDICTION

Enrico Camporeale[*1], Andong Hu[1], Greg Lucas[1], Jennifer Knuth[1] and Thomas Berger[1]*

[1]*University of Colorado*

ABSTRACT

In the field of space weather, we are interested in forecasting rare and extreme events, while most of the time the output of interest is in quiet-time condition. Hence, the typical space weather dataset is highly imbalanced with the interesting events being very rare. In such a scenario typical machine learning (ML) regression methods fail to perform well on the events of interest. Moreover, in order to be actionable any forecast needs to come with a estimate of its uncertainty. Once again, typical ML methods for regression output a single scalar value, with no indication of confidence intervals.

In this work we present ProBoost (Probabilistic Boosting), which is inspired by the popular Gradient boosting method and whose aim is to simultaneously: 1) boost the performance of weak learners, especially in the presence of rare events; 2) provide a reliable uncertainty estimate of the predictions.

The engine under the hood of ProBoost is ACCRUE (Accurate an Reliable Uncertainty Estimate), an a-posteriori, model agnostic method for uncertainty quantification, which will be introduced (Camporeale, E., & Carè, A. (2021). Accrue: Accurate and reliable uncertainty estimate in deterministic models. International Journal for Uncertainty Quantification, 11(4).)

Finally, we will present examples of applications of ProBoost in the context of real-time space weather predictions, developed and operationalized by the Deep Learning Laboratory at the University of Colorado, Boulder, and freely available to the general public (https://swx-trec.com/)

SPH CONTINUUM-BASED MODELLING OF FLUVIAL ICE DYNAMICS

Gabriel Camporredondo-Diaz[*1] and Ahmad Shakibaeinia*[1]

[1]*Polytechnique Montreal*

ABSTRACT

Numerical modelling of river ice dynamic processes, such as ice jams along large river extensions can help to better understand and predict these natural incidents and their impacts. However, the numerical methods, associate to these simulations, demand the ability to process vast amount of data at large spatial scales. The smoothed particle hydrodynamics (SPH) method offers the ability to deal with the highly dynamic ice-water interaction due to its lagrangian nature at reasonable computational cost. For such reason, in this work, we proposed a two-phase fully Lagrangian continuum-based SPH numerical method to simulate river ice dynamics. The method solves the depth-averaged Navier- Stokes equations, also known as the shallow water equations (SWE), for both water and continuum. A SWE solver offers a greater computational affordability for large scale simulation with a dominant horizontal dimension. The computation domain is represented by a set of particles that are used to represent a fixed-volume column of material. The riverbed is defined as a set of fixed particles that are coupled to the fluid particles in a well-balanced scheme that allows to simulate riverbed slopes properly by using a variational approach and a bed filter [1]. Likewise, ice is modelled with SPH, where each particle is defined as column of ice volume that interacts with fluid particles by applying ice driving forces. These forces include the water drag, the riverbank contact and the gravity as external forces, and the ice resistance as an internal force. This internal force is adopted from a viscous-plastic constitutive law, allowing to simulate ice accumulation processes such as those in the presence of ice jams [2]. As part of the results, the proposed method was validated with different 1D and 2D benchmark cases. The agreement between the mathematical formulation and the motion evolution of ice in the river is of primary importance to the purpose of this work. Factors like bed friction, wind force, ice-growth and de-icing also influence the dynamics of ice and fluid, and these can be included in further work using this simulation as a base model.

THREE-FIELD MODEL FOR WAVE PROPAGATION IN POROUS MEDIA BASED ON MIXTURE THEORIES

Bruna Campos[*1] and Robert Gracie*[1]

[1]*University of Waterloo*

ABSTRACT

Simulations of wave propagation in porous media are important to the understanding of various phenomena, such as seismic effects and non-destructive testing. The derivation and implementation of finite element analysis for a fully dynamic three-field deformable porous media model based on the de la Cruz and Spanos (dCS) theory [1] is presented. The dCS theory accounts for the fluid viscous dissipation mechanism and nonreciprocal solid-fluid interactions, which are neglected in Biot theory [2]. While the Biot theory is based on experimental data, the dCS theory is derived from mixture theories associated with the volume fraction concept and representing the connection between micro and macro pore scales. dCS results presented build upon recent FE model for quasi-static analysis [3]. Here, for the fully dynamic case incorporating both fluid and solid inertia, the accuracy and robustness of the FEA model is verified by wave propagation examples in one and two dimensions. Time integration scheme utilized and the changes in convergence rates according to how strongly coupled is the system will be discussed. The required element approximation order for all variables to ensure numerical stability will be demonstrated. The presented model is compared with the results from Biot theory, allowing one to observe the differences between the two theories and their relevance. The solutions in the time and frequency domain are also discussed, where the analysis of the correspondent eigenproblem leads to important information regarding wave velocity and attenuation.

ABSTRACT

We will discuss some recent results on the well-posedness of a nonlinear fluid-structure interaction problem involving multi-layered poroelastic media interacting with the flow of a viscous, incompressible fluid.

THE SPECTRAL ELEMENT METHOD FOR THE VIBRATIONS OF CRACKED FRAMES

Francesco Cannizzaro[*1], Ilaria Fiore[1], Salvatore Caddemi[1] and Ivo Caliò[1]*

[1]*University of Catania*

ABSTRACT

The presence of damage or impairments in frames can strongly influence its dynamic properties and, subsequently, its response when subjected to external loads. For the evaluation of the dynamic response of structures, approximate solutions based on the Finite Element (FE) models are usually employed, considering additional nodes at the cracked sections. Within this framework, assemblage of stiffness and mass matrices is required based on the static shape functions of the elements. Subsequently, an eigenvalue problem has to be solved to infer the eigenproperties of the structure; in addition, when external loadings are applied, direct integration or modal superimposition are usually employed to assess the response. Alternatively, a continuous approach can be adopted to get rid of the approximations of the FE strategy. More precisely, a continuous strategy, namely Dynamic Stiffness Method (DSM), requires the assemblage of a frequency dependent dynamic stiffness matrix, whose zeros represent the eigenfrequencies of the structure [1]. Within this context, the forced vibrations are usually treated with the so-called Spectral Element Method (SEM), which employs the dynamic stiffness matrix and frequency dependent shape functions.
This study, based on a closed-form solution proposed for Timoshenko beams with multiple cracks [2], extends the SEM to the case of cracked structures. The mentioned exact distributional approach is adopted to formulate an exact explicit expression of the frequency dependent dynamic stiffness matrix accounting for multiple concentrated cracks. The closed form expression of the DSM allows the assemblage of the global DSM of a structure to conduct the free vibration analysis of damaged framed structures. This approach has the advantage to avoid any numerical procedure for the construction of the DSM as well as the introduction of further degrees of freedom in correspondence of the damaged sections, keeping the size of the problem the same as in the intact configuration. Frequency dependent shape functions are subsequently inferred, thus allowing the evaluation of the nodal forces and the application of the SEM to cracked structures without adding degrees of freedom at the discontinuous sections.

MULTISCALE MODELLING OF SHOCK ABSORBING HYPER-ELASTIC METAMATERIALS

Juan Cante[1,2], Alejandro Nuñez-Labielle[1,2] and Javier Oliver[1,2]*

[1]*Universitat Politècnica de Catalunya (UPC)*
[2]*International Center for Numerical Methods in Engineering (CIMNE)*

ABSTRACT

Metamaterials are artificial designed materials that exhibit apparent exotic properties at the macroscopic scale which are presently a topic of large interest in material science. The goal of this work is the development of computational tools for designing a specific branch of metamaterials: shock-absorbing dissipative metamaterials, aiming at two goals. The fast (macroscopic) shape recovery after impact from an external impactor and the subsequent loading release. This is a very appealing property to absorb high-frequency impacts: the absorbing device readily recovers, immediately after any impact, its original shape and its energy-absorbing capacity becoming available to absorb the next mass impact.

Standard hyper-elastic materials fulfil the non-dissipation paradigm, but, if this paradigm is broken, they may exhibit relevant mechanical dissipation as the free energy turns non-convex. This work focuses on these cases at the macroscopic scale, yielding shock-absorbing metamaterials exhibiting dissipative behaviour at the upper scale, but made of polyconvex hyper-elastic materials at the low scale. The coupling between both scales is, then, responsible for the exotic dissipative behaviour at the macroscale.

In this work, a microscale made of a buckling lattice of periodic cells is conceived as a mechanism to achieve the non-convexity of the free energy at the macro-scale, where some of their elastic members exhibit an appropriated buckling behaviour. The structural behaviour of the slender buckling members in the lattice (typically beams) is described in terms of degenerated kinematics, and, in turn, the upper scale is naturally described using standard 2D/3D solid formulations. The problem of translating the standard multi-scale formulations, established for settings in which the macro-scale and the micro-scale domains are described in a unique dimension space, into the intended unmatched dimensions case is solved by introducing an Ersatz material into the formulation. The lattice is designed as a sequence of sufficiently dimension-perturbed buckling layers so that instabilities arisen when the RVE is constituted by a number of a homogeneous set of layers is precluded. As for the structural modelling of the buckling-beam members in the microscale lattice, the elastic large strain Timoshenko-like beam combined with a least energy bifurcation criterion is considered. in order to represent the microstructure.

ENERGY ABSORPTION DESIGN AND WORKING MECHANISM FOR SOLID/LIQUID HYBRID COMPOSITE

Guoxin Cao[*1]*

[1]*Tongji University*

ABSTRACT

Besides conventional solid-based energy absorption/damping materials, the solid-liquid hybrid system potential applications in mitigating impact/blast loadings. It was reported that a solid-liquid hybrid system including water and hydrophobic nanoporous materials shown an energy absorption/damping ability. The energy absorption process is performed through liquid phase transformation induced by the applied pressure: from the original macro-phase (with a low potential state) to the nano-phase with a high potential state (the liquid inside nonwettable nanopores). In addition, the reverse phase transformation process might be possible after unloading, suggesting that the hybrid system can be fully recovered after unloading. The above energy absorption procedure closely depends on (1) the wetting behavior of nanopore; (2) the infiltration behavior of nanopore; (3) the transport behavior of liquid inside nanopore. Based on computational simulations, the above important scientific issues can be clarified, and the energy absorption/damping mechanism as well as the influence factors of the system energy absorption density are further identified. The present study will provide an important help on designing new energy absorption materials, and can also boost the development of the multiscale theory associated with mechanics in multi-disciplinary areas.

ZERO-GROUP-VELOCITY LAMB WAVES GENERATED AND DETECTED BY PIEZOELECTRIC DIRECT-WRITE TRANSDUCERS FOR CONTINUOUS MONITORING OF FASTENER TIGHTNESS

[2]*Institute of Materials Research and Engineering (IMRE), Agency for Science, Technology and Research, (A*STAR)*

ABSTRACT

Continuous monitoring of the tightness status of a fastener structure is of paramount importance in many industries, as a slight loosening may pose a significant threat to the integrity of structure. In this paper, we propose using Zero-Group-Velocity (ZGV) Lamb waves generated and detected by in-situ piezoelectric Direct-Write transducers (DWTs) to monitor fastener loosening status and evaluate stress distribution around fastener holes. Unlike the conventional bulk wave method, the ZGV Lamb wave based method with confined energy could effectively reveal the stress level near the fastener hole at low frequency. Usually, the ZGV Lamb wave is excited and detected by non-contact laser ultrasonic techniques, which may have a few issues for real-time inspection. With features of high conformability, low cost, low profile, etc., the piezoelectric DWTs are directly printed on the fastener structure to generate and detect ZGV Lamb waves for real-time inspection. To demonstrate the proposed method, the suitability of DWTs to generate and detect ZGV Lamb waves is first discussed. Next, the dispersion relation of a fastener plate structure is investigated with various preloading force. Acoustoelastic effects from out-of-plane stresses are considered in this study. A circular array of DWTs is then printed around the fastener hole and the loosening status of the fastener is determined by examining the frequency shift of the ZGV Lamb Wave. This circular array reflects stress levels near the hole region, which overcomes the disturbances caused by multi-mode conversions and wave scattering. The developed method has great potential applications in providing very reliable and accurate continuous monitoring of the tightness of fastener structures.

NUMERICAL METHODS FOR IMMISCIBLE INCOMPRESSIBLE MULTIPHASE FLOWS WITH THERMAL CONVECTION.

Loic Cappanera[*1], An Vu[1] and Caroline Nore[2]*

[1]*University of Houston*
[2]*LISN-CNRS*

ABSTRACT

We present a numerical approximation method for immiscible incompressible multiphase flows problems with thermal convection. The fluids properties (e.g. density, viscosity, thermal conductivity) vary in space and time and are assumed to be dependent of the density, thus the resulting problems are governed by a mass conservation equation, the incompressible Navier-Stokes equations and the temperature equation. The formulation uses the density, pressure, momentum and internal energy as primary unknowns which allows us to introduce a scheme with time-independent stiffness matrices. The spatial discretization is based on continuous finite element methods. Stability and space-time errors estimates will be discussed before we present numerical investigations with manufactured solutions and setups with turbulent thermal convection.

[3]*Universitat Politècnica de Catalunya (UPC)*

ABSTRACT

Most engineering techniques used to stabilise slopes are very carbon intensive: concrete piles, gabions, crushed rock, geogrids or meshes, steel anchors and shotcrete, etc. Moreover, climate change is believed to have an adverse effect on the stability of slopes due to the degradation of the soil strength and the increase of water pressure. Therefore, the use of carbon-intensive techniques does not seem consistent with the current greenhouse gas emission targets.

The use of green engineering techniques, such as the use of plants to stabilise slopes, can be a clean and sustainable solution to this problem. The use of plants has a direct benefit in stopping deforestation, sustainable land use and restoring nature.

The current state of the art for characterising the mechanical effects of plant roots in soils is limited. This has direct implications for the application of vegetation in slope stability.

Numerical analysis of this problem can bring light into the darkness. The analysis of soil-root interactions requires advanced techniques: modelling the hydromechanical properties of rooted soils coupled with the mechanical strength contribution of the roots. Furthermore, a large-deformations framework is needed to validate the results with experiments (modelling of plant extraction or landslides).

Our contribution in this area is the development of the Geotechnical Particle Finite Element Method (G-PFEM) for modelling soil-root interactions. Different modelling approaches are investigated for the modelling of structural roots and the constitutive behaviour of the soil and the rooted soil. Simulation results are compared with interaction tests and slope stability models are presented.

QUALIFICATION OF A PRM CONNECTION FROM ASSEMBLED I-BEAM TO ASSEMBLED COMPOSITE TUBULAR COLUMN WITH FILLET WELDS

Alejandro Cardona Jiménez[*1], Jairo Andres Paredes Lopéz*[1] *and Luis Garza Vasquez*[1]

[1]*Universidad Nacional de Colombia*

ABSTRACT

The high level of implementation in steel structures in the infrastructure field, has led that the industry and academic institutions do research on the topic. This, with the aim of creating reliable and feasible methodologies in factories devoted to the construction area.
A crucial aspect of steel structures has been the design and manufacture of connections as they have a great participation in the response of dynamic and static loads. The type of connection which requires to be researched in depth are rigid connections. In other words, these can provide lateral stability in structures against seismic forces. For this reason, the current investigation emphasizes on these group of connections. Similarly, connections are studied to be resistant and functional, which can guarantee a satisfactory behavior to endure seismic loads. Also, it is necessary to evaluate manufacturing methodologies that are cheap and easy to apply. Weld in connection is a fundamental aspect for its construction, and it is one of the most expensive components in the whole connection due to the material preparation and rigorous quality controls.
The main purpose of this research is to assure that a composed tubular column type connection throughout fillet welding processes connected to a I beam shape with fillet weld too, present a structure stability; this is achieved through a connection qualification where it is exposed to a cyclic load controlled in a lab. It is expected that the dynamic response has an acceptable behavior established in the specifications of the American Institute of Steel Construction AISC chapter AISC-348 about seismic provisions.

Although similar connections have been pre-qualified, these have presented some difficulties to the industries since the weld allowed in these connections is a complete penetration weld which requires the material preparation by bevels; additionally, tests are more rigorous resulting in more expensive processes for its construction. Therefore, this research aims analyzing the dynamic structural response of connections where fillet weld is used to build columns and beams.

During the qualification process, it is determined to evaluate the connection dynamic behavior and the generation of the plastic articulation as an energy dissipation mechanism. Due to this, it is recommended to make the comparison between the lab results and the finite element numerical modeling.

POLYCRYSTALLINE MATERIAL DESIGN: A DATA-DRIVEN APPROACH WITH BAYESIAN OPTIMISATION

Rui Pedro Cardoso Coelho[*1], Miguel Vieira de Carvalho[1] and Francisco Andrade Pires[1]*

[1]*University of Porto*

ABSTRACT

Over the past decades, the modelling of complex material systems has been widely explored, which has led to accurate and efficient representations of the constitutive response of materials employed in the automotive, aeronautical and aerospatial industries. Coupled with this advent, the rapidly growing computational power available allows running an increasing number of simulations at a fast pace, which is required to match industrial needs. The combination of these topics leveraged the application of the so-called inverse problems, where numerical tools are used to find solutions for real-world optimisation problems, such as parameter identification, topological optimisation and material design.

In this work, we explore a data-driven framework for the design of polycrystalline materials, inspired by [1]. Microstructural properties such as phase volume fractions and grain orientation and distribution are analysed, and crystal plasticity models [2] are used to derive the macro- and micro-scale response of the material. For ease of generalisation with available solvers, the task is formulated as a gradient-free optimisation problem, where Gaussian Process regression and Bayesian optimisation are used as the pillars for its numerical solution. The framework allows for the optimisation under uncertainty and its quantification throughout. This strategy efficiently explores the design space and outperforms classical space-filling design of experiments (DoE) strategies, leading to faster optimisations with fewer function evaluations. An in-house tool for the optimisation of numerical responses is used for solving the inverse problem. Finally, given the recent breakthroughs in the solution of the parameter identification problem using composite Bayesian optimisation strategies, as shown in [3], a similar approach is also explored for the material design problem to improve the quality of the used surrogate models.

ABSTRACT

Emerging beyond Von Neumann computing paradigms such as neuromorphic computing and probabilistic computing are gaining traction as conventional systems approach performance saturation. Neuromorphic computing takes inspiration from the organizing principles of the brain (e.g. co-location of memory and compute elements, massively parallel computation, online learning, etc.) to efficiently exploit the physics of computation in hardware. Probabilistic computing is another emerging field that can benefit from the inherent stochasticity found in neuromorphic systems and these approaches can be complimentary. Typically, solutions in both these fields can span digital, analog, mixed-signal, and emerging beyond-CMOS devices. However, diverse approaches pose significant codesign challenges across the full design stack. For effective collaboration and codesign, we need abstracted device and circuit models that can be co-optimized keeping both hardware, algorithm, and system constraints in mind.

In this talk, I will present two exemplars in multilevel codesign in neuromorphic, and probabilistic computing. I will illustrate how device and circuit abstractions enable faster computation and can be scaled easily for further design space exploration. I will also introduce AI-guided methods to accelerate discovery and codesign.

Our neuromorphic exemplar is a dendrite simulation model based on an analog dendrite circuit. We have demonstrated two different applications using this model. First, we use this model to emulate device behavior in a computational dragonfly model for interception. Second, we have developed a library within the PyTorch framework to add the dendritic circuit component in spiking neural networks (SNNs). Dendrites make SNNs more expressive and improve performance. Current and future work entails further optimizing this library for faster simulation. We are also exploring techniques such as neural ODEs to automate circuit modeling providing useful and fast abstractions.

In our probabilistic exemplar, we use AI-guided codesign techniques like reinforcement learning (RL) and evolutionary optimization (EA) to accelerate device discovery and optimization of probabilistic circuits for true random number generation (tRNG). We leveraged reinforcement learning to optimize device and material properties of a magnetic tunnel junction (MTJ) for a given application task. The RL agent leveraged an abstracted device model of the MTJ to vary key device and material properties for optimal performance. We also utilized evolutionary algorithms to optimize a given tRNG probabilistic circuit for different MTJ device types.

These exemplars demonstrate that codesign tools are important to facilitate cross-pollination and accelerate research across different emerging fields.

LBM MODELLING OF NON-ISOTHERMAL DRYING OF POROUS MEDIA

Linlin Fei[1], Dominique Derome[2] and Jan Carmeliet[*1]*

[1]ETH Zurich
[2]Université de Sherbrooke

ABSTRACT

Convective drying at the pore scale is modelled using a two-component two-phase pseudopotential lattice Boltzmann model (LBM). Two lattice Boltzmann equations are solved, one for liquid water and its vapour and one for dry air. Water vapour is assumed to be well mixed with air forming wet air, while air can also be dissolved in liquid water at low concentration. The approach is shown to be able to model the binary diffusion of vapour and air in the gas phase following Fick's law. The model is validated based on microfluid drying experiments showing good agreement. The LBM model has been extended to non-isothermal conditions, where the heat transport including latent heat is modelled using a finite difference approach and coupled to LBM through the equation of state.

Convective drying of a dual-porosity medium shows two drying regimes, a first drying period at a higher drying rate followed by a second drying period at reduced drying rate. The transition from the first to the second period is observed when capillary pumping from large pores to fine pores at the surface fades out. Based on the capillary pumping principle, we design layered porous media with different pore size and contact angle that guarantee capillary pumping to the surface until low degree of saturation, showing high drying rate and short drying period. The evaporative cooling effect of the wet porous medium during drying is assessed as a potential mechanism in cooling technologies. In real environmental conditions, the convective drying of wet materials, like soils and building materials, may be influenced by solar radiation imposing a temperature gradient. It is found that imposing a temperature gradient can strongly influence the length of the first drying period and the drying rate during the second period.

A NEW PERSPECTIVE ON COMPUTATIONAL CONTACT HOMOGENISATION BASED ON THE METHOD OF MULTISCALE VIRTUAL POWER

António Carneiro[*1], Rodrigo Carvalho[2], Eduardo Souza Neto[3] and Francisco Andrade Pires[1]*

[1]*University of Porto*
[2]*Institute of Science and Innovation in Mechanical and Industrial Engineering*
[3]*Swansea University*

ABSTRACT

Multiscale contact modelling is currently an active research topic which lives in the intersection of the contact mechanics and multiscale analysis spheres. At their core, the so-called contact homogenisation frameworks aim at enriching the macroscopic contact behaviour with information emerging from the highly complex contact interaction at the microscale, underpinned by surface roughness, complex material behaviour, and adhesion, to name a few. While there have been significant efforts to formulate and realise numerical tools that manage multiscale contact, it is still not well-established in the field.

The present work enters the scene with the goal of deriving a contact homogenisation framework bridging microscopic contact and a homogenisation-based constitutive response of the macroscopic interface. Namely, true contact occurs at the roughness level, based on the KKT non-penetration and Coulomb's frictional constraints, and the macroscale does not explicitly enforce contact conditions, yet experiences a contact traction response computed from the microscopic solution. All the theoretical development revolves around the recently proposed Method of Multiscale Virtual Power (MMVP), which provides a systematic approach to developing multiscale theories [1]. The new model is fundamentally characterised by a Minimal Kinematical Restriction based on the carefully selected kinematical postulates. The traction homogenisation formula and the microscopic equilibrium problem are not presumed beforehand, instead coming as consequences of a fundamental multiscale virtual power balance principle. Due to the particular characteristics of the contact problem, novel specialisations of the method to ensure the admissibility of the traction field are proposed and investigated.

The contact homogenisation models are implemented within a large strain finite element program with a dual mortar contact implementation. The formulation is assessed in a series of numerical examples that showcase the overall behaviour of the model, convergence with the dimensions of the microscopic domain and benchmarks with alternatives present in the literature [2,3].

INCREASING THE EFFECTIVITY OF OIL AND GAS WELLS' CEMENTING IN CANADA THROUGH MODELLING AND SIMULATION

Mariana Carrasco-Teja[*1] and Ian Frigaard*[1]

[1]*University of British Columbia*

ABSTRACT

Primary cementing of oil and gas wells is fundamental to achieve well integrity and prevent leakages, and the thin cement sheath is part of the overall well barrier also used at end of life of the well. Oil leakage, gas migration away from the well, leakage into aquifers are all ecologically damaging occurrences, affecting health and safety, subsurface ecosystems, and local communities. Canada is the world's fifth largest oil producer, has the 3rd largest proven oil reserves and has drilled over 550,000 oil and gas wells. Many wells leak some form of hydrocarbon. Reported leakage rates vary widely according to well type, regulatory jurisdiction, data availability and method of assessment. Dusseault et al. [1] summarize various studies, suggesting ~10% of leaking wells. Since curbing leakage and emissions is beneficial to all and since we are able effectively seal wells, why are we not doing a better job? In other industries, where uncertainty is high and measurement or evaluation difficult, physically-based models and simulations are routinely employed, to fill gaps in understanding, allow exploration of design questions, to use as part of control strategies and guide evaluation. In the oil well industry, two-dimensional (2D) operational simulations provide a level of physical complexity vs computational cost that allows widespread (desktop) computational design usage, yet the tools are not widely available. Our group at UBC has been at the forefront of developing models for primary cementing for over the past 20 years. Our current goal is to bring our models from research codes and laboratory experiments, directly into the hands of Canadian stakeholders, in the form of useable predictive software.

In this talk we will describe our primary cementing models, and our predictive software development project. We model the process as the displacement of viscoplastic fluids in an inclined, non-concentric, narrow annulus. Our 2D model uses a Hele-Shaw approach to describe the displacement, and the Herschel-Bulkley model to describe the fluids. We will overview the evolution of our 2D model, including as a purely laminar, immiscible displacement, the addition of transitional and turbulent regimes, and adding dispersion to the interface to better match our 3D simulations and laboratory experiments results.

MULTIFIELD MICROMECHANICS ANALYSIS OF COMPOSITES WITH DEFECTS USING CUF

Erasmo Carrera[*1], Alfonso Pagani[1], Marco Petrolo[1], Rebecca Masia[1] and Mattia Trombini[1]*

[1]*Politecnico di Torino*

ABSTRACT

This work presents the latest developments concerning the micromechanics models built using the Carrera Unified Formulation. CUF is a formulation to obtain any structural theory using a compact notation to define the unknown fields and governing equations. 1D and 2D finite elements based on CUF have proved to be numerically efficient and accurate and may serve as alternatives to 3D elements. For instance, CUF can generate Representative Volume Elements of composite structures and detect the 3D stress field with a fraction of the computational cost required by 3D elements [1]. Micromechanics models from CUF can incorporate defects stemming from manufacturing, e.g., voids, to capture the effect on the local stress and strain fields, including plasticity over the matrix [2].

CUF can be used for multifield analyses [3] as the compact form of the governing equations can be extended to include various fields, e.g., thermal, electrical, magnetical, and combinations thereof. Coupled and uncoupled analyses are possible, and multifield variables can be modeled a priori.
This work focuses on merging the micromechanics and multifield capabilities of CUF for composites. Various numerical examples are considered, e.g., thermo-mechanical analysis of RVE with voids and electromechanical cases. Comparisons with results from the literature are carried out to verify the formulation and assess its numerical efficiency. 3D fields are obtained for different RVE architectures. Perspectives on multiscale analyses are then outlined.

IDENTIFYING WAVE POLARIZATION AND BANDGAPS IN PERIODIC ARCHITECTED MATERIALS

Maria Carrillo-Munoz[*1] and Bhisham Sharma*[1]

[1]*Michigan Technological University*

ABSTRACT

We present a new computational method to accurately identify the elastic wave propagation modes and polarizations in periodic solid structures and metamaterials. The method uses the eigenvectors associated with each propagating wave solution to calculate the contribution of each translational and rotational component of the total mass-in-motion. We use this information to identify the dominant wave propagation mode by defining a relative effective modal mass vector. Then, we associate each wave solution with its correct polarization by defining a polarization factor that quantifies the relative orientation between the wave propagation and lattice motion directions and provides a positive numerical value between 0 (pure S-wave) and 1 (pure P-wave). Further, we suggest a graphical representational scheme for easier visualization of the wave polarization within traditional dispersion plots. To validate the method, we compare our predictions against previously published results for various elastodynamic problems. Finally, we use the proposed method to analyze the effect of various lattice and structural parameter perturbations on the elastic wave propagation and polarized bandgap behavior of a square planar beam lattice. Our analysis reveals the emergence of previously unobserved dynamic characteristics, including various polarized bandgaps, fluid-like behavior, and ultralow-frequency SH- and SV-bandgaps that extend to 0 Hz. Our proposed method provides an alternative computational approach to the typically employed visual mode inspection technique and provides a robust method for analyzing the elastic wave response of periodic solid media.

ABSTRACT

Carbonate petroleum reservoirs are commonly found around the world such as the Brazilian Pre-salt. Due to the nature of the carbonate rocks, diagenetic processes can originate geological features such as vugs, cavities and caves that can be interconnected. These features appear in multiple scales, each influencing the fluid flow inside the reservoir. The presence of these geological features represents a challenge to numerical modeling and simulation of fluid flow in these reservoirs due to the highly heterogeneous rock properties suggesting the use of general unstructured and flexible computacional meshes. Besides, the coexistence of two different flow regimes, a Darcian flow region in the porous media and a free flow region in the vugs, cavities and caves introduces further complexity into the modeling process. In this context, the present work, we propose a cell-centered, collocated, finite volume scheme for the numerical simulation of fluid flow in carbonate petroleum reservoirs. The governing equations are solved using a monolithic approach, where a full pressure support Multipoint Flux Approximation method based on harmonic points (MPFA-H) is extended to discretize Stokes-Brinkman's equations. In our formulation, the pressure gradients are computed via a Global Least-Squares (GLS) approach. Moreover, to guarantee the proper coupling between the pressure and velocity unknowns, a momentum-weighted interpolation method is devised to avoid the odd-even decoupling and non-physical oscillations, typical of collocated approaches. To evaluate the accuracy and robustness o our approach, we have solved some interesting problems found in literature.

TOPOLOGY OPTIMIZATION OF UNSTEADY COMPRESSIBLE FLUID FLOWS

Icaro Amorim Carvalho[*1], Diego Hayashi Alonso[1], Luis Fernando Garcia Rodriguez[1] and Emilio Carlos Nelli Silva[1]*

[1]*University of São Paulo*

ABSTRACT

Unsteadiness is closely related with the vortex dynamics that leads to surge and stall. These phenomena and their adverse effects are rooted in vortex shedding – in common with that found in cylinder wakes in laminar and turbulent regimes. Despite previous efforts, the literature still lacks a formulation in topology optimization to evaluate compressible fluid flows that are unsteady, and thus motivates this study. Finite volume simulations are carried out in OpenFOAM to resolve the fluid flow problem efficiently, while a finite element implementation provided by FEniCS computes the sensitivities through automatic differentiation. A combination of the two is found in the FEniCS TopOpt Foam framework which is employed here. Sensitivites obtained through automatic differentiation and finite differences allow to evaluate changes in the vorticity of the domain with respect to the design variable associated with each cell of the domain, that will vary between 0 (solid) and 1 (fluid). The topology optimization method is conducted in this work to address the typical phenomenon of vortex shedding past a circular cylinder in laminar regimes of a Reynolds number of 100: One in incompressible flow; and another in compressible, subsonic regime for a Mach number of 0.5. We specifically envision to attain a final design to minimize the vorticity in the fluid domain and thus attenuate the formation of vortices, present in a multitude of practical applications.

A NUMERICAL APPROACH TO MODEL THE ROLE OF MECHANICAL STRAIN IN TUMOR GROWTH

Mariana Carvalho[*123], Marco Parente[1] and João Ferreira[1]*

[1]*University of Porto*
[2]*Institute of Science and Innovation in Mechanical and Industrial Engineering (INEGI)*
[3]*Portuguese Oncology Institute of Porto*

ABSTRACT

Despite significant advances in early diagnosis and treatment solutions, cancer remains the leading cause of death worldwide. Cancer is a malignant pathology characterized by accelerated and uncontrolled cellular proliferation. Several experimental and theoretical efforts have been taken to unravel the mechanism of primary tumor development distant metastasis establishment. Constitutive mechanics models are one of these approaches as they can characterize changes in mass and stress development during tumor growth. From a biomechanical standpoint, solid tumors are hyperelastic, compressible, anisotropic materials with a mechanical behavior both space and time-dependent, whose mass varies over time. Tumor mass increase is a complex phenomenon, influenced by molecular and genetic factors, cell interactions, vascularization, and mechanical cues. The purpose of this work is to provide a numerical framework that incorporates the effect of mechanical strain in tumor growth.
Based on experimental evidence that proliferation is improved in post-stretched cells [1], a constitutive model to describe the strain-driven growth of a mass is developed and implemented into Abaqus® (using a user-defined subroutine) by considering the multiplicative decomposition of the deformation gradient into an elastic and a growth contribution.
The model is initially tested in a simple numerical example (using different deformation modes applied to a single unitary hexahedral finite element) to validate the numerical solution, as well as quadratic convergence and model objectivity. Afterwards, a rectangular specimen, comprised by a solid tumor (with a given preferential growth direction) surrounded by softer tissue, is subjected to cyclic uniaxial and biaxial stretch scenarios. Finally, a case study of the development of a ductal carcinoma in situ (DCIS), a pre-invasive form of breast cancer restricted to the mammary glands' ducts, is performed. Assuming homogeneous nutrient supply, the tumor growth occurs in an anisotropic manner (in the direction of least resistance) influenced by mechanical stimulation (introduced by the contractile myoepithelial cell layer surrounding the duct).
The provided examples demonstrate the potential of the developed model which with a growth evolution law derived by experimental evidence can be a very important tool to better understand tumor growth as mechano-chemo-biological process.

ON THE MODELING OF DAMAGE IN RUBBER-TOUGHENED AMORPHOUS POLYMERS ACCOUNTING FOR CAVITATION AND SHEAR YIELDING

A. Francisca Carvalho Alves[*1], Bernardo P. Ferreira[2] and Francisco Andrade Pires[1]*

[1]*University of Porto*
[2]*Brown University*

ABSTRACT

Amorphous polymers have been widely used by the scientific and technological communities due to their excellent and versatile performance in several applications, encompassing aeronautics, automotive, structural and electronic industries. Besides their excellent thermal, optical, chemical and mechanical properties, these materials can be easily blended to fulfil specific applications. A well-known and successful example of this blending technique is the inclusion of rubber particles to improve their toughness, such as the acrylonitrile-butadiene-styrene (ABS) binary blend, which combines the amorphous polymer styrene-acrylonitrile (SAN) with rubber-particles.

The rubber particles are responsible for providing the dissipation of energy through different deformation mechanisms, such as cavitation and growth of voids, multiple crazing and shear yielding, and hence promoting the transition from brittle-to-ductile fracture. As a result of the complex synergistic effect associated with these mechanisms, the prediction of their thermomechanical response is not straightforward.

In this context, a novel finite strain visco-elastic visco-plastic constitutive model is proposed to predict the nonlinear response of rubber-toughened amorphous polymers [1], accounting for the nucleation, interaction and growth of voids. A nucleation law is established to predict cavitation under volumetric strains based on a well-established nucleation criterion [2]. A modified version of the well-known Gurson's potential is adopted to capture the void's growth, ensuring the coherence in the energy dissipation between the macro and microscales. A fully implicit integration algorithm is established, and an optimization-based calibration strategy is designed to identify the model's material parameters efficiently. The response of the model is assessed under different triaxial states and is further compared with the homogenized response of a Representative Volume Element of the voided-amorphous polymer microstructure. The results highlight that the model can capture the typical behavior of amorphous polymers, as well as the decrease of stress associated with the increase of the void volume fraction. The efficiency of the calibration procedure and the overall numerical strategy are also demonstrated.

ANALYSIS OF DENSITY-BASED CELL-SORTING MICROFLUIDIC DEVICES USING A STABILIZED FINITE ELEMENT METHOD

Guillermo Casas[*1], Aniol Sala[1] and Eugenio Oñate[1]*

[1]CIMNE

ABSTRACT

In this work, we use numerical simulations to analyze a class of density-based cell-sorting microfluidic devices. The sorting mechanism exploits (small) density variations among the various particle types using a stratified flow with layers of different densities. This system causes the particles to move toward their equilibrium position under the buoyancy force as they move along the circuit. Previous work on the numerical analysis of such systems has ignored the effect of diffusion, which leads to a blurring of the interfaces between different strata, ultimately affecting the device's precision. We include this effect by numerically solving the convection-diffusion equations to track the evolution of the concentration of the additive used to control the various densities. Other factors, such as the impact of turns in the circuit, are also taken into account. A stabilized finite element formulation is employed to predict the fluid field and the concentration of the additive. We evaluate our numerical results by comparing them to empirical data from the cell separation efficiency of real devices.

A COMPARATIVE STUDY OF ASSUMED-STRAIN LOCKING TREATMENTS FOR NURBS-BASED DISCRETIZATIONS

*Hugo Casquero**[1]

[1]*University of Michigan - Dearborn*

ABSTRACT

NURBS-based discretizations suffer from the same types of locking as conventional FEA discretizations based on Lagrange polynomials. Locking results not only in smaller displacements and rotations than expected, but also large-amplitude spurious oscillations of the stresses. The large-amplitude spurious oscillations of the stresses can persist for meshes for which the displacements and rotations are already accurate. A direct deployment of the numerical schemes used to overcome locking when using Lagrange polynomials is not an effective strategy to vanquish locking when using NURBS since the levels of continuity across element boundaries of Lagrange polynomials and NURBS are different. Thus, the higher inter-element continuity of NURBS requires the development of new numerical schemes to overcome locking. In this talk, I will compare the performance of different assumed-strain locking treatments for NURBS-based discretizations taking into account both accuracy and computational cost. Specifically, I will consider continuous-assumed-strain (CAS) elements [1, 2], lumped-assumed-strain (LAS) elements [3], Bbar elements, and reconstructed Bbar elements. Second-order and fourth-order structural theories for rods and shells will be studied as well as nearly-incompressible solids. Both linear and nonlinear regimes will be analyzed.

AN EFFICIENT, HEREDITARY INTEGRAL APPROACH TO MODELING THERMAL AND AGE-INDUCED PERMANENT SET IN POLYMERS

Stephen Castonguay[*1], Joshua Fernandes[21], Michael Puso[1] and Sylvie Aubry[1]*

[1]Lawrence Livermore National Laboratory
[2]University of California, Berkeley

ABSTRACT

Polymers often undergo permanent deformation when held under states of strain for extended periods of time, a process that is known as permanent set. The resulting residual strain is a function of both temperature and the amount of time the material spends in a particular strain state. Here, we propose an efficient, hereditary integral method to model this phenomenon. The approach utilizes the transient network framework [1], in which polymer chains can detach from a network and reform in a state of zero stress at the time of re-attachment. Under linear kinetics assumptions, certain simple functional forms for the free energy permit a decomposition of the kernel that allows for a recurrence relationship to be established, bypassing the need to integrate over all time history. Its implementation in a finite element framework is demonstrated for both highly compressible and nearly incompressible material models. Multiple examples are presented which illustrate the effect of varying thermal environments and complex loading histories, as well as the model's ability to handle visco-elasticity at shorter time scales.

This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

MULTI-FIDELITY ANALYSIS FOR SITE-SPECIFIC AERODYNAMIC DESIGN OF WIND TURBINE BLADES

Alessio Castorrini[*1] and Alessandro Corsini*[1]

[1]*Sapienza University of Rome*

ABSTRACT

The aerodynamic design of wind turbine blades relies on the optimization of blade shapes and profiles, often starting from scaled-up versions of state-of-the-art machines to achieve larger dimensions. The current trend in wind energy development is shifting towards the installation of new plants in deep waters using floating technology. For these novel configurations, the performance requirements for turbines become significantly more stringent, necessitating a considerable increase in specific and rated power while avoiding excessive loads, weights, and hub-heights. Thus, the conventional approach of scaling up machines designed for fixed foundations may no longer be optimal.
In the preliminary design of new blades, aerodynamic calculations are typically entrusted to reduced-order models, often based on the blade element momentum theory (BEMT). These models, developed and refined over the years, are highly performant, offering quick and reliable aerodynamic insights suitable for integration into the aero-servo-elastic analysis of turbines. However, the BEMT-based model has known limitations, especially in determining correct inductions and loads where significant radial flows and viscous effects are present, such as at the blade tip and root regions.
This study proposes a combined approach of high-fidelity and low fidelity modelling to aid in the design of new wind rotor blades for offshore floating applications. The components of the methodology will include 3D computational fluid dynamics analysis based on the Reynolds Averaged Navier Stokes equations solved for the resolved blade shape, a parametric surface definition tool, and adaptive mesh morphing techniques. This system will be interfaced with a design framework that checks performance against characteristic wind conditions at specific target sites using aero-servo-elastic engineering tools.
The goal of this presentation is to describe the new aerodynamic design strategy, its performance, and results, toward the definition of a new optimized blade concepts for specific deepwater sites.

HIGH-ORDER FORMULATIONS, A POSTERIORI ERROR ESTIMATORS, AND ADAPTIVE PROCEDURES FOR THE G/XFEM

Murilo H. C. Bento[*1], Sergio P. B. Proença[1] and Armando Duarte[2]*

[1]*University of São Paulo*
[2]*University of Illinois Urbana-Champaign*

ABSTRACT

The Generalized/eXtended FEM is able to accurately and efficiently solve problems in which a priori knowledge about their solutions is available. Typical classes of problems in this category are those containing, for instance, weak or strong discontinuities, in the context of either elasticity or heat conduction. The method has proven to deliver well-conditioned and optimally convergent solutions, especially when first-order approximations are considered. Nevertheless, the development of higher-order approximations is ongoing and is of interest due to their higher convergence rates, which give more accurate solutions at a lower cost, and because first-order G/XFEM may be not competitive with second-order FEM for some classes of problems [1], such as those of LEFM. In addition, when it comes to assessing the accuracy of G/XFEM approximations, special tools are needed when exact solutions are not known and a posteriori error estimators play an important role in this. Herein, a newly developed a posteriori error estimator [2], based on a Zienkiewicz-Zhu (ZZ) formulation and tailored to estimate discretization errors of solutions obtained by higher-order G/XFEM [1, 3], is presented. The error estimator is shown to be accurate and computationally efficient through a set of numerical examples. Furthermore, besides being able to estimate well global discretization errors, the estimator is also shown to be locally effective and, therefore, it can be readily applied to drive adaptive simulations. It is known that this type of simulation is important for 3-D LEFM problems since only singular enrichment functions and uniform mesh refinement are not enough to attain optimal convergence [1] and currently, trial and error has been adopted in practical applications to get accurate solutions. Following that, an h-adaptive procedure able to deliver on-the-fly discretizations that meet a pre-specified target on the discretization error and optimal convergence is presented and its advantages are shown.

MULTISCALE FEM AND DPG METHODOLOGY FOR UPSCALING IN SOLID MECHANICS - RECENT ADVANCES

Witold Cecot[1], Marta Oleksy[1] and Marek Klimczak[1]*

[1]*Cracow University of Technology*

ABSTRACT

The work concerns the development of the Multiscale Finite Element Method (MsFEM) [3] for solid mechanics problems with highly oscillating material coefficients and multifield, high-order FEM approximation stabilized by the DPG methodology.

Our enhancement utilizes static condensation in the domains of coarse elements, previously positively tested for two-dimensional problems [2], which transfers the construction of special (optimal) shape functions (i.e. construction of prolongation operator for heterogeneous materials) exclusively to the interfaces of macro-scale elements. This way, our original interface prolongation reduces both the approximation error and computational costs. Higher-order shape functions enhance the efficiency of calculations, and the DPG methodology [1] ensures discrete stability for the mixed formulation due to on-the-fly constructed optimal test functions. The good accuracy and convergence of the improved method will be illustrated by solutions to selected linear and nonlinear problems in three dimensions. Additional reduction of modeling error may be achieved through several iterations on a fine grid, similar to the multi-grid approach.

In the presentation, we will refer to the statistical approach to upscaling developed by J. T. Oden for modeling contact and friction [4].

NUMERICAL TREATMENT OF THE COUPLED GEOMECHANICS AND FLUID-FLOW PROBLEM IN CARBONATE ROCKS WITH VUGS

[1]*Federal University of Santa Catarina (UFSC)*
[2]*TU Delft*

ABSTRACT

Carbonate are sedimentary rocks that generate significant interest in reservoir engineering, as a substantial amount of the world's hydrocarbon reserves are found in this type of rock. They may be constituted by a porous medium (formed by a liquid/solid phases), as well as vugs (macropores filled with fluid that are relatively larger compared to the pores in the porous medium). In the porous media one has a Darcy's flow and in the vug a Stokes flow. Numerical simulations used to predict fluid flow production in such a rock must consider the coexistence of the flow in the porous medium, the free flow in the vugs, and the mechanical behavior of the rock. In this problem one has two distinct physical regions, and the solution usually employs the Two-Domain Approach[1], which requires boundary conditions at the interface between these two regions, being the major drawback of the approach. An alternative consists of using the same set of equations for both regions, which is referred to as Single-Domain Approach (SDA). In this case, the challenge consists of defining a set of equations that appropriately describes the fluid flow and the geomechanics in both regions. The innovative aspect of this work is the creation of an equation for the geomechanics of the vug region, recalling that the vug is not a rock, and the use of an equation for the fluid flow representing the Darcy equation in the porous media and the Stokes equation on the free fluid flow region. Although SDA eliminates the necessity of boundary conditions between the different domains, it introduces new challenges related to numerical stability. Numerical oscillations in pressure, displacement and fluid velocity field can appear. To overcome this problem, another innovative aspect of this work is the use of Physical Influence Scheme (PIS) for interpolating the solid and the fluid velocities which appears in the mass conservation equation. Results in a rock sample considering a circular vug show that the SDA model with PIS can capture the involved physics producing stable solutions.

A HYBRIDIZABLE DISCONTINUOUS GALERKIN APPROXIMATION OF THE DUAL-POROSITY-STOKES PROBLEM

Aycil Cesmelioglu[*1], *Jeonghun Lee*[2], *Sander Rhebergen*[3] *and Dorisa Tabaku*[1]

[1]*Oakland University*
[2]*Baylor University*
[3]*University of Waterloo*

ABSTRACT

In this talk, I will present a numerical method for the dual-porosity-Stokes problem that couples free flow in macrofractures/conduits and flow in microfractures/matrix. Our numerical method couples a pressure-robust IP-HDG method for the Stokes problem and a hybridized BDM discretization for the dual-porosity problem resulting in divergence-conforming velocities and pointwise satisfaction of mass conservation equations in the absence of source terms in the porous medium. A priori error estimates and numerical experiments will be provided.

MACHINE LEARNING-BASED MULTISCALE APPROACH TO ANISOTROPIC DAMAGE IN QUASI-BRITTLE HETEROGENEOUS STRUCTURES

Zakaria Chafia[1], Julien Yvonnet[1] and Jérémy Bleyer[2]*

[1]Gustave Eiffel University
[2]Ecole des Ponts ParisTech

ABSTRACT

A machine learning based multi-scale method is proposed for modeling anisotropic damage in quasi-brittle composite structures. This approach uses the results of damage simulations on Representative Volume Elements (RVEs), at the microscopic scale, as data to build a surrogate model describing the behavior law and internal variables evolution at the macroscopic scale. In order to capture all RVE degradation mechanisms, several damage simulations are performed in a preliminary stage (off-line calculations), at the RVE scale, using the phase field method [1]. Each simulation carried out on the RVE, subjected to periodic boundary conditions, corresponds to a macroscopic strain leading the RVE to its complete state of degradation. At each loading increment, a numerical homogenization technique [2] is applied to evaluate the effective elastic tensor of the RVE. A harmonic analysis of the elastic tensor evolution during crack propagation simulations in the RVE (DDHAD method - Data Driven Harmonic Analysis of Damage [3, 4]) is used to define the macroscopic internal variables. Their evolution is modeled by an appropriate machine-learning-based surrogate model. Machine learning is applied to construct the behavior law and the internal variables evolution, as a surrogate model to be used, at the macroscopic scale. Applications to periodic quasi-brittle composite structures with strongly anisotropic microstructures are presented.

ABSTRACT

Forecasting high-dimensional dynamical systems is a fundamental challenge in various fields, such as geosciences and engineering. Neural Ordinary Differential Equations (NODEs), which combine the power of neural networks and numerical solvers, have emerged as promising tools for forecasting complex nonlinear dynamical systems. However, classical techniques used for NODE optimization are inefficient for learning chaotic dynamical systems. To overcome this limitation, we propose an algorithm splitting the time domain into multiple steps based on the physical properties of the system and penalizing intermediate discontinuities. Our method is devised to address the challenges of non-convexity and exploding gradients observed while optimizing objectives with underlying chaotic dynamics. The proposed algorithm, denoted the Multistep Penalty Neural ODE (MP-NODE), is applied to chaotic systems such as the Kuramoto–Sivashinsky equation and the turbulent forced 2D Navier Stokes equations. It is observed that MP-NODE converges to a better approximation of the physical system for the same training time than standard NODEs. Furthermore, MP-NODE provides performance on par with least-squares shadowing with significant reductions in training costs.

BAYESIAN DISCOVERY OF INTERPRETABLE STOCHASTIC PARTIAL DIFFERENTIAL EQUATIONS FROM LIMITED AND NOISY DATA

Tapas Tripura[1] and Souvik Chakraborty[*1]*

[1]Indian Institute of Technology Delhi

ABSTRACT

Data-driven discovery of governing physics of dynamical systems in terms of ordinary and partial differential equations (ODEs/PDEs) has become an exciting area of scientific machine learning [1]. In complex dynamical systems where the complete knowledge of underlying governing laws is not known a priori, the data-driven frameworks provide an effective way of distilling the governing equations of motion. However, all natural dynamical systems are stochastic in nature due to the continuous interaction between the dynamical system and the external stochastic environment. The approaches to discovering ODEs/PDEs completely neglect the stochasticity in the physical dynamical systems. Of late, a few studies have been carried out to discover interpretable stochastic differential equations (SDEs) from data [2]. An effective method for discovering interpretable equations of motion of stochastic continuous systems from data is still missing in the literature. To that end, we propose a novel data-driven framework for discovering Stochastic Partial Differential Equations (SPDEs) in this study. We propose the extended Kramers–Moyal expansion to express the deterministic and stochastic parts of SPDEs using state observations. We introduce a sparse Bayesian learning (SBL) framework for discovering a sparse representation of the deterministic and stochastic components of SPDEs from data. For efficient SBL, we employ the variational Bayes inference with Spike-and-Slab prior. This setup not only promotes sparsity in the discovered SPDE but also helps in avoiding overfitting of the discovered interpretable model. We illustrate the fidelity of the proposed SPDEs discovery framework for rediscovering the governing equation of the (a) stochastic heat equation, (b) stochastic Allen–Cahn equation, and (c) stochastic Nagumo equation from 1-2 seconds of state measurements. The rediscovered SPDEs show an accurate identification of the true governing equations. In the low data limit, the ability of the proposed Bayesian framework to quantify uncertainty in the discovered model is an additional advantage. We illustrated the application of the developed framework in time-dependent reliability analysis of aging structures. Other potential applications of the developed framework include atomistic modeling, mechanical systems, climate modeling, and financial forecasting.

INTREPID MCMC: A NOVEL SAMPLING ALGORITHM FOR BETTER EXPLORATION AND IDENTIFICATION OF DISJOINT FAILURE REGIONS IN SUBSET SIMULATION

Promit Chakroborty[*1] and Michael Shields*[1]

[1]*Johns Hopkins University*

ABSTRACT

Estimating the reliability of real-world infrastructure requires multiple evaluations of computational models that are often highly complex and time-consuming. For such problems, Subset Simulation (SuS, introduced by Au and Beck in 2001) has been an invaluable tool. Traditionally, SuS uses simple random-walk MCMC algorithms such as the Metropolis-Hastings or Component-wise Metropolis-Hastings methods to generate samples from the conditional distributions relevant to the problem. However, various blind spots of the SuS framework have been recognized under this paradigm, leading to non-convergence or false convergence of the target failure probabilities. In this work, we propose a novel random-walk MCMC sampling scheme, called Intrepid MCMC, that is specifically designed to improve the ability of the Markov Chains to explore the parameter space, by randomly sampling in regions of the distribution tails that cannot normally be reached by traditional MCMC methods due to the additional response-function dictated rejection step utilized by Subset Simulation. The underlying intuition is discussed, followed by a case study highlighting the ability of Intrepid MCMC to find failure regions that are missed by traditional Subset Simulation implementations.

ADAPTIVE MODELING AND LEARNING OF MATERIAL LAWS FOR EFFECTIVE DATA ASSIMILATION

Ludovic Chamoin[*1], Antoine Benady[1], Sahar Farahbakhsh[1], Emmanuel Baranger[1] and Martin Poncelet[1]*

[1]ENS Paris-Saclay

ABSTRACT

In the context of data assimilation, selecting a model which is consistent with the richness of data is a fundamental issue. On the one hand, the model should not be too crude, so that it is able to reproduce the physics revealed by data. On the other hand, it should not be too complex as this would lead to useless computational effort faced to limited experimental information and measurement noise. We propose here a methodology that permits automatic model selection and adaptivity when comparing model outputs and observations. It employs the concept of modified Constitutive Relation Error (mCRE) that refers to reliability of information. This concept has been used for model updating in many structural mechanics applications, and it is here advantageously employed to qualify and adapt the model complexity (by means of a natural modeling error indicator provided by mCRE). We will show how this permits to perform adaptive modeling with local higher complexity when localized physical phenomena (such as damage) occur, in order to manage computation and experimental resources at best. This goes with the selection of a suitable model in a hierarchical list, and with the adaptation of the model parameter space (e.g. refinement of the mesh used to describe a parameter field).

We will also show how the mcRE concept can be coupled with data-based enrichment of the model structure using deep learning tools. The idea here is to learn and correct model bias; it refers to hybrid twins and physics-constrained neural networks which have received much attention in recent years. A method using neural networks for learning constitutive laws in the form of thermodynamic potentials is proposed, with an associated loss function built from the mCRE functional.
All developments will be illustrated on various numerical experiments involving synthetic or real experimental data.

ABSTRACT

Damage tracking and monitoring from digital twins and in situ measurements, through the DDDAS framework, has been one of the numerous research topics addressed by J.T. Oden. In his memory, the talk will present some recent developments on this critical issue, which aim to design smart and autonomous mechanical structures able to perform online control of their health and take anticipated actions during service. An innovative cross-disciplinary approach will thus be presented, which performs fast sequential data assimilation from hybrid twins. This approach couples several advanced numerical methods such as model reduction, adaptive modeling, or Kalman filtering, together with a specific cost function which brings robustness faced to highly nonlinear models, various uncertainty sources, and real-time computation constraints. Its capabilities will be shown on several practical engineering applications when inferring real data on-the-fly and performing online health monitoring on large scale structures.

ENFORCING CELL ENTROPY INEQUALITIES USING SUBCELL LIMITING

Jesse Chan[*1] and Yimin Lin*[12]

[1]*Rice University*
[2]*Applied Intuition*

ABSTRACT

Subcell limiting strategies for discontinuous Galerkin spectral element methods do not naturally satisfy a semi-discrete cell entropy inequality. In this work, we introduce a subcell limiting strategy that satisfies a semi-discrete cell entropy inequality by formulating the limiting factors as solutions to an optimization problem whose exact solution can be computed via a greedy algorithm. We also discuss how the proposed subcell limiting strategy can be modified to accommodate general convex constraints. Numerical experiments suggest that the proposed limiting strategy preserves high-order accuracy for smooth solutions and converge to entropic solutions.

SPATIAL AND TEMPORAL COUPLING METHODS FOR THE MODELLING OF WAVE PROPAGATION IN HETEROGENEOUS MEDIA

ABSTRACT

The discretisation of structures in space and time is directly related to the accuracy of the finite element method when modelling wave propagation. However, utilising a very fine mesh, and a single time step across an entire domain may be computationally inefficient. Firstly, this work proposes a technique for the explicit coupling of non-matching meshes, without the use of Lagrange multipliers and solving an additional system of equations. We employ an analytical method of finding the shape functions on any quadrilateral surface, followed by the transfer of nodal masses and internal forces on a coupling interface. Through enforcing the continuity of acceleration between subdomains, stability is ensured. The method obeys the conservation of mass and internal energy between subdomains. Should a subdomain be discretised with too coarse a mesh, we highlight the issue of spurious wave reflection when conventionally modelling high frequency waves. We also present a novel multi time stepping algorithm, in an updated Lagrangian formulation, that allows for subdomains to independently advance through time. Unlike existing algorithms, we do not assume a constant or integer ratio between coarse and fine temporal discretisations. Both algorithms allow for the concurrent coupling of several subdomains, each with their own mesh and respective time step. The algorithms are demonstrated in three dimensions, where subdomains can be meshed independently with their own element formulation. Wave propagation in Metaconcrete is studied numerically, demonstrating a large speed up when simulating metamaterials in comparison to monolithic simulations. We also study polycrystalline materials, where individual grains have their own spatial and temporal discretisation.

ABSTRACT

Concrete materials are inherently heterogeneous and include internal structures and constituents across length scales ranging from nanometers to tens of millimeters. Multiscale structures and constituents of concrete materials include heterogeneities such as aggregates, sand, fibers, voids, and cracks. The properties and responses of concrete under different loading conditions are dependent upon the multiscale structures and the properties of constituents.

In this work, a hierarchical multiscale finite element modeling method was developed to predict the properties of concrete materials based on their mix designs and experimental paste properties. Properties of fine and coarse aggregates were not experimentally tested, and were estimated based on limited geological information. Nonetheless, the predicted concrete properties closely matched the experimental results for various loading conditions, such as unconfined uniaxial compression, triaxial compression under different confining pressures, and hydrostatic and uniaxial strain compression. The method presented provides a virtual platform for predicting concrete material properties and designing concrete materials for structural applications.

[1]*University of California, Berkeley*
[2]*Kyoto University*
[3]*Massachusetts Institute of Technology*

ABSTRACT

The Material Point Method (MPM) has been widely developed in the past decades for simulating large deformation in solids and geomaterials. However, the method still faces significant challenges in simulating incompressible flow due to three major issues: (i) volumetric locking due to the incompressibility constraint, (ii) the accumulation of quadrature errors, and (iii) instabilities induced by the transfer of information between particles and background grids. Aiming to address these issues, the current research develops a novel stabilized mixed MPM [1] for both free-surface and seepage flow [2]. Unlike traditional Eulerian CFD solvers, the proposed mixed MPM employs a monolithic displacement-pressure formulation inspired by the mixed-form updated-Lagrangian Finite Element Method (FEM). By coupling the displacement and pressure fields and solving them concurrently, the developed solver eliminates the need for free-surface pressure detection and imposition, distinguishing it from the typical fractional-step method. This attribute effectively mitigates spurious pressure oscillations that often arise in MPM from switching free-surface nodal pressure imposition on and off as the fluid front moves through the background grid. Furthermore, to ensure numerical stability, the variational multiscale method (VMS) is incorporated to satisfy the discrete inf-sup stability condition. To simplify the balance equations, a unified formulation to integrate the Navier-Stokes equation with the Darcy-Brinkman-Forchheimer equation is proposed. This unified formulation is then integrated with a blurred interface approach, resulting in a seamless transition of flows between free and porous domains, as well as across two distinct porous media. The proposed formulation's efficacy is verified through benchmark cases in 1D, 2D, and 3D scenarios. A comprehensive verification suite, including analytical solutions for 1D gravity-driven flows under various conditions, is derived to verify the accuracy of the method. Further numerical benchmarks and experiments also demonstrate enhanced accuracy and stability compared to analytical, experimental, and other numerical methods.

MULTISCALE MODELING OF ACTIVE BRAZING

Michael Chandross[*1], Ian Winter[1], Eric Rothchild[1], Jaideep Ray[1], Edward Arata[1], Ping Lu[1], Jeffrey Horner[1], Scott Roberts[1], David Kemmenoe[1], Anthony McMaster[1] and Anne Grillet[1]*

[1]*Sandia National Laboratories*

ABSTRACT

Active brazing is a high temperature joining method that is often used to make hermetic joints between dissimilar materials, like metals and ceramics. A common issue in active brazing is run-out that occurs when a wetting instability causes the braze alloy to flow out of the joint. The spreading is controlled by the wetting of the two substrates by the braze alloy, and this is directly related to the thermodynamic properties of the materials and interfaces, namely (a) surface energies of the solids, (b) surface tension of the liquid braze alloy and (c) the interfacial energies between them. If these quantities are known, then the wetting angles can be predicted using Young's equation. Understanding how these energies vary as a function of composition and temperature is crucial for designing a high quality braze process, but these quantities are hard to measure experimentally. Atomistic simulations provide a route for determining these energies, but methods for treating the metals and the ceramics in the same model are difficult to parameterize and computationally expensive. We present results of a newly developed reactive force field able to accurately model brazing of a model steel to alumina with a AgZr alloy. The brazing is essentially a three step process in which (1) Zr migrates to the alumina surface, and scavenges oxygen to form a ZrO2 surface layer (2) liberated Al diffuses through the braze alloy to the steel surface where extensive mixing of the liquid and solid metals form a multicomponent alloy and (3) the (predominantly) Ag braze alloy wets the two surfaces to form the final joint. We present the results of atomistic simulations aimed at accurately representing the full braze process, including reactions and wetting at both the ceramic and metal surfaces. Surface and interfacial energies are computed using thermodynamic integration to avoid the excessive run times (> 150 ns) necessary for direct wetting simulations. We demonstrate that after calculating these energies Young's equation accurately predicts the wetting angle for a variety of materials. Finally, we use the atomistic simulations to develop a data-driven constitutive model that is implemented in a finite element code to simulate the full brazing process at the manufacturing scale. Results from the simulations are compared to experiments, and the conditions that lead to run-out will be discussed.

PRELIMINARY STUDY OF VEHICLE-BRIDGE INTERACTION USING INSTANTANEOUS FREQUENCY RESPONSE FUNCTIONS

Chia-Ming Chang[*1] and Chi Cheng*[1]

[1]*National Taiwan University*

ABSTRACT

When a vehicle travels on a bridge, the interaction generated between the vehicle and the bridge is the main source of dynamic response in the system. If the frequencies and energy of the bridge, vehicle, and external forces fall within a specific range, excessive deformation of the bridge can be found, leading to damage or other safety issues. In previous studies, the vehicle scanning method was mainly used to indirectly estimate the natural frequencies of the bridge and yielded corresponding structural monitoring methods. However, this method cannot determine the impact of the parameters of the vehicle-bridge interaction from both energy and frequency relationships. Therefore, to understand the characteristics and behavior of the vehicle-bridge interaction system, this study derives the instantaneous frequency response function of the system. In this research, a single sprung mass or multiple sprung masses are used to simulate the moving train. The assumed mode method is applied to simulate the bridge response in the form of the first mode or the superposition of multiple modes. Subsequently, the equation of motion of the vehicle-bridge interaction is established and converted into the frequency domain by the Fourier transform. Eventually, the instantaneous frequency response function of the vehicle-bridge interaction is obtained. In this research, a parametric study is carried out to investigate multiple variables (i.e., mass ratios between the vehicle and bridge, vehicle stiffness, bridge lengths, vehicle speeds, and number of modes and sprung masses), and these results are compared to the finite element analysis and a previous study in literature. As a result, the analytically instantaneous frequency response function is validated to be consistent with numerical results, and this instantaneous frequency response function has the potential to be employed in the structural monitoring of bridges in the future.

RANDOM SOLUTE DISTRIBUTION EFFECT ON MECHANICAL BEHAVIOR IN HIGH-ENTROPY ALLOYS: A CRYSTAL PLASTICITY FINITE ELEMENT STUDY

Hsuan-Wu Chang[*1], Wei-Chih Huang[1], Chang-Wei Huang[2] and Yu-Chieh Lo[1]*

[1]*National Yang Ming Chiao Tung University*
[2]*Chung Yuan Christian University*

ABSTRACT

High-entropy alloys, a new type of alloy composed of multiple primary elements, present interesting mechanical properties due to the random distribution of solutes. This randomness leads to varying energy barriers for dislocation movement, making the process less predictable and causing fluctuations in the overall plastic deformation behavior. This study combines the theory of dislocation density crystal plasticity with the characteristic randomness of solutes. Through a high-entropy alloy finite element model, we introduce a random factor into the parameters of statistically stored dislocations. Utilizing the fine-division capabilities of the finite element method, we establish multiple sets of models for tension testing. By analyzing the resulting stress-strain curves, we aim to simulate and investigate the mechanical properties of high-entropy alloys with solute randomness. This approach allows us to observe mesoscale behavior and explore the influence of solute randomness range on the overall model.

A TWO-DIMENSIONAL SHOCK WAVE PATTERN RECOGNITION ALGORITHM BASED ON CLUSTER ANALYSIS

Siyuan Chang[*1] and Kai Cui*[1]

[1]*Chinese Academy of Sciences*

ABSTRACT

A new technique for detecting and recognizing two-dimensional shock wave interaction patterns in compressible, inviscid flow solutions computed by shock-capturing solvers is proposed. The implementation process of this algorithm is illustrated from three aspects in detail. First, using a traditional shock wave detection approach based on local flow parameters, a series of grid-cells near the shock waves are identified. Next, the shock cells are divided into various clusters by means of a classical K-means clustering algorithm, and the category of each cluster will be defined according to its adjacent information. Finally, a criterion is introduced to merge related adjacent clusters and further determine the locations of shock interaction points; the clusters contained in each shock wave are recorded, and then all the fitting shock lines can be obtained by the Bézier curve fit algorithm. Numerical experiments show that this newly developed technique can be used under different types of meshes, and the fitted shock lines have high quality and positional accuracy; meanwhile, the multiple shock wave interaction patterns are clearly recognized, which can also provide a good visualization method for analyzing the motion and evolution of shock waves in complex, unsteady flow.

[4]*National Taiwan University*

ABSTRACT

Infrasonic signals of large fumarole fields imply important information related to volcanic activities, which directly reflects the changes in the state of the magma or hydrothermal system underground. Variations in the number, type, location, and magnitude of fumarole activities may indicate volcanic anomalies. However, infrasonic signals can be caused by other events, such as earthquakes, gusts, extreme weather, and even human activities, which are difficult to process and identify. This research studied the records of 11 infrasonic sites around the Tatun Volcano Group (TVG) in Taiwan. The signals were transformed into the frequency domain via the Fast Fourier Transform (FFT) to understand its characters. To overcome the uncertainty of infrasonic signals in both time and frequency ranges, the records were then transformed into the Power Spectral Density (PSD) as the basis for analysis. This is due to the PSD representing the power content in a specific time and frequency range. This makes it easier to be superposed with any other PSD in small segments of time and frequency ranges. Two clustering methods, the k-means clustering and the Density-Based Spatial Clustering of Applications with Noise (DBSCAN), were used to achieve unsupervised machine learning of the critical feature of PSD to identify the special events of the volcano. The research results will be transformed into an automatic TVG platform for real-time monitoring, simplifying the significant data for geoscience experts.

INTEGRATING MECHANICS INTO MACHINE LEARNING FOR ELASTOPLASTIC BEHAVIOR MODELING IN FIBER-REINFORCED COMPOSITES

Zhang Chao[*1], Ziqi Li[1] and Yang Chen[1]*

[1]Northwestern Polytechnical University

ABSTRACT

The fiber-reinforced composites are widely used in aerospace, automotive industries and medical area due to its distinguished properties, and its complex three-dimensional elastoplastic behavior can be modeled by machine learning (ML). However, the significantly reliance on substantial training databases hinders progress in ML modeling.To overcome this challenge, our research introduces an innovative mechanics-informed ML approach, aiming to advance the predictive accuracy of the elastoplastic behaviors of unidirectional FRC with a limited database. Incorporating a stress and strain decomposition method rooted in mechanical invariant theory, we establish two parallel Artificial Neural Networks (ANNs) to articulate deviatoric behaviors and the coupling of volumetric and fiber-directional behaviors respectively.The mechanics-informed approach streamlines the architecture of the ANNs, requiring only two inputs and two outputs for each ANN, in contrast to the conventional six-dimensional strain and stress tensors. This reduction in input dimensions significantly enhances predictive accuracy, even with a limited database. Additionally, a tensor transformation link for the output stress of ANNs is incorporated, ultimately deriving tensor-valued stress. Furthermore, our ML approach is refined to predict the impact of the loading path, ensuring a more comprehensive elastoplastic behavior modeling. To validate our proposed ML-based constitutive model, we conduct direct numerical simulations (DNSs) based on a representative volume element, generating datasets for model training and validation. Comparative analysis of results obtained through DNS and ML showcases the exceptional predictive accuracy of our proposed model, even with a small training database.

DATA-DRIVEN-MULTISCALE MODELING OF ANISOTROPIC DAMAGE FROM RVE FRACTURE SIMULATIONS

Julien Yvonnet[1], Qi-Chang He[1], Pengfei Li[1] and Souhail Chaouch[1]*

[1]Gustave Eiffel University

ABSTRACT

A data-driven approach is proposed to construct anisotropic damage models with a minimal number of internal variables from phase field - crack propagation simulations on Representative Volume Elements (RVEs) of quasi-brittle materials. The approach resorts in particular to a harmonic analysis of damage. The orientation distribution functions of two elastic moduli are numerically determined while accounting for the effects of the nucleation and propagation of microcracks by the phase field method. Given these two functions, the effective elastic tensor of a material without or with microcracks is uniquely determined. The expansions into two Fourier series of the relative variations of these two functions related to an undamaged reference state and to a damage state make appear damage internal variables naturally. The number and natures of these variables can be optimized by truncating the Fourier series according to the degree of approximation desired and using POD (Proper Orthogonal Decomposition). Thus, 2D and 3D anisotropic damage models can be constructed without resorting to usual assumptions made in damage mechanics. This construction holds for complex microstructures including image-based ones and for arbitrary loading history. 2D and 3D applications are provided to evaluate the accuracy of the damage models constructed and to show the potential of the approach proposed.

MACRO CLUSTERING FOR ACCELERATING FE2 MULTISCALE SIMULATIONS OF NONLINEAR COMPOSITES CONSIDERING ELASTOPLASTICITY, VISCOELASTICITY AND DAMAGE

Souhail Chaouch[*1] and Julien Yvonnet*[1]

[1]*Gustave Eiffel University, MSME*

ABSTRACT

FE2 method [1] is one of the most accurate widespread approaches for multi-scale modeling of nonlinear heterogeneous materials. In this technique, a macroscopic problem is discretized into a number of finite elements, the constitutive law of each element is assumed to be unknown, and is obtained numerically by solving a nonlinear representative elementary volume (RVE) problem at each macroscopic Gauss point. On the microscopic scale, an RVE is defined and discretized into finite elements too. The main inconvenient of this approach is the involvement of high computational cost, which limits its feasibility for industrial applications.

A method based on unsupervised machine learning is developed to overcome this problem [2]. The idea is to cluster macroscopic integration points in the macro mesh having close mechanical states. Then, instead of solving one nonlinear RVE problem for each Gauss point, only one nonlinear problem is solved for each group of integration points. This procedure significantly reduces the number of RVEs problems to be solved in each Newton iteration at the macro scale.

Several important improvements are made to this method labeled KMFE2 in [3]. First, the definition of macroscopic stress within each cluster is extended using linear interpolation in stress-strain space. Then, the number of clusters is considerably reduced in the case of the presence of internal variables as compared to the previous technique developed in [2]. Finally, some convergence issues associated with the use of clusters are addressed.

This technique has been successfully applied to two-dimensional applications using different loading behaviors and boundary conditions. It is applied to different composite materials with 1) hyperelastic properties, 2) viscoelastic properties, and 3) elastoplastic properties. Finally, extensions of the method to damage are discussed. Typical speed-up factors of around 20 compared to the classic FE2 method were observed, even though no learning step, data base construction or off-line calculations are required.

BUILDING TRUST IN CANCER-PATIENT DIGITAL TWINS FOR PERSONALIZED TREATMENT PLANS

Anirban Chaudhuri[*1], Michael Kapteyn[2] and Karen Willcox[2]*

[1]The University of Texas at Austin
[2]Oden Institute for Computational Engineering and Sciences

ABSTRACT

This talk focuses on the mathematical and computational ingredients needed to grow trust in patient-specific digital twins. We build on the work in Refs. [1,2] that developed the mathematical foundations of a predictive digital twin as a probabilistic graphical model, encoding uncertainty as a core part of the digital twin model and using Bayesian methods to execute the digital twin's calibration, prediction, and decision tasks. In this work, we consider a digital twin supporting a human decision-maker for risk-aware clinical decision-making in brain cancer. To achieve appropriate level of trust, the patient-specific digital twin should be able to (i) provide interpretable decisions with explainability of underlying models being key, (ii) quantify the effects of multiple sources of uncertainty and account for underlying risk in safety critical decisions, and (iii) be computable on actionable (possibly real-time) time scales. We achieve explainability and interpretability through a model-centric view of the digital twin that places physics-based models at the core. This leads the digital twin parameters to have interpretable physical meanings, and the sensitivities that drive the digital twin predictions/decisions to be related to some physical phenomena. The predictive digital twins are made patient-specific through continuous calibration using the patient's data and are deployed for forecasting with quantified uncertainty under different control actions. As shown in Ref. [2], we then solve the optimal control under uncertainty problem balancing treatment efficacy and toxicity that leads to a suite of risk-informed decisions for the particular patient. In order for these decisions to be useful for the clinicians, the digital twin needs to be executed within acceptable time-scales. We achieve fast computations through the use of explainable surrogate models and integration of multiple information sources of varying fidelity and cost in a multifidelity setting.

EFFICIENCY AND ACCURACY IN LARGE-SCALE CARDIAC SIMULATIONS WITH COMPRESSED COMMUNICATION AND ALGEBRAIC ADAPTIVITY IN BDDC PRECONDITIONERS

Fatemeh Chegini[1] and Martin Weiser*[1]

[1]*Zuse-Institute Berlin(ZIB)*

ABSTRACT

Cardiac electrophysiology simulations are essential for understanding arrhythmia mechanisms and designing effective treatments. Large-scale problems in this domain, characterized by elliptic and parabolic equations, necessitate efficient parallel preconditioners, particularly in the context of domain decomposition. Additionally, the locality of solution features in cardiac electrophysiology simulations calls for adaptive methods. However, traditional mesh refinement and coarsening approaches incur significant overhead. This study contributes novel solutions to address these challenges in distributed computation for cardiac simulations with cellular resolution.

The cardiac extracellular-membrane-intracellular (EMI) model enables the precise geometrical representation and resolution of aggregates of individual myocytes. Achieving efficient higher-order time stepping becomes imperative due to large problem sizes. We consider algebraic adaptivity, i.e. nested subset selection for degrees of freedom in spectral deferred correction methods (SDC)~\cite{CheginiSteinkeWesier}. Shrinking the effective support of SDC corrections allows for a reduction of the spatial domains on which Euler subproblems need to be solved, instead of computing on the whole domain. Improved speedups are obtained by the ladder method, using coarser collocation grids on the first sweeps in the SDC computations, method~\cite{CheginiSteinkeWesier}. However, the Balancing Domain Decomposition by Constraints (BDDC) preconditioner~\cite{Mai} requires expensive reconstruction if the basic time step or degree of freedom set changes. We propose a novel combination of BDDC and algebraic adaptivity, demonstrating computational efficiency in numerical examples. The approach involves a subdomain-wise subset selection, enabling an efficient combination with BDDC and incurring negligible overhead.

Distributed solvers such as the BDDC preconditioner, need to exchange data between compute nodes, which can become a bottleneck in massively parallel computations. We explore lossy compression~\cite{wesierCompress}, such as transform coding, quantization, and optional entropy coding, to reduce data exchanged between adjacent subdomains. While providing effective solutions, this approach introduces computational overhead, latency, and errors, dependent on quantization. We present accuracy models and identify scenarios where lossy compression proves beneficial, supported by practical numerical experiments.

PLANAR FAULT TRANSFORMATION AND UNFAULTING OF INTERSTITIAL DISLOCATION LOOPS IN IRRADIATED CHEMICALLY COMPLEX INTERMETALLIC ALLOYS

Cheng Chen[*1] and Jun Song[2]*

[1]Northwestern Polytechnical University
[2]McGill Universtiy

ABSTRACT

The present study has systematically investigated unfaulting mechanism of single-layer interstitial dislocation Loops (IDLs) in irradiated FCC-(Ni,Al), L12-(Ni3Al,Ni3Fe) to extend the existing unfaulting theory from pristine FCC lattice to the L12 ordered lattice, employing atomistic simulations combining continuum theory. Two types of variants for the IDLs have been determined with different superlattice planar faults enclosed in the Frank loop. The unfaulting routes of IDLs by Shockley partial loops have been unveiled through examining the energy barriers of superlattice planar fault transformation. The symmetry breaking occurring in the unfaulting processes were further elucidated and summarized. A continuum model has been formulated to enable quantitative theoretical analysis of the energetics of IDLs and prediction of the unfaulting threshold. These findings clarify the effects of complex faults and symmetry breaking on unfaulting behaviors of IDLs in irradiated L12-(Ni3Al, Ni3Fe), and could be transferable to other L12 systems, and more generally, other chemically complex intermetallic alloys.

BIOMECHANICS ANALYSIS BASED ON HIGH-RESOLUTION LIVE MICRO-CT IMAGES IN THE RAT TEMPOROMANDIBULAR JOINT

Chia Chun Chen[*1], Nien-Ti Tsou[1] and Ding-Han Wang[1]*

[1]*National Yang Ming Chiao Tung University*

ABSTRACT

The mandible bones feature complex trabecular bone structures and various muscles, resulting in complicated hinge and sliding motions, playing an important role in both humans and rats. Existing numerical models in the literature typically simplify loading conditions and adopt uniform bone properties. In this study, a finite element model of a rat's mandible using micro-CT images at three resolutions (20, 40, and 80 μm) is constructed. Where material properties for each element in the model were mapped based on the brightness of the corresponding pixel in the micro-CT image, revealing a detailed trabecular bone structure. Bio-realistic loads, accounting for the surrounding muscles and biting force on the teeth, which aligns with the anatomical and experimental data, were applied as the boundary conditions, simulating the rat chewing process. The resulting stress distribution in the mandible and temporomandibular joint is in good agreement with experimental observations. Furthermore, it is worth noting that the models generated at different resolutions yielded varying numerical results. This also suggests the most suitable image resolution for the rat’s mandible, considering that higher resolution also entails higher radiation exposure. This work establishes a comprehensive workflow for generating a bio-realistic numerical model with enhanced validity, contributing to the refinement of mandible biomechanics studies.

TOPOLOGY OPTIMIZATION FOR PARTICLE FLOW USING EULERIAN-EULERIAN MODEL WITH A FINITE DIFFERENCE SCHEME

Chih-Hsiang Chen[*1] and Kentaro Yaji*[1]

[1]*Osaka University*

ABSTRACT

Topology optimization is a powerful tool to generate an optimal configuration for various engineering problems. For particle flow problems, some studies on topology optimization for single-particle behavior using an Eulerian-Lagrange model have been presented [1]. In this study, we propose a topology optimization method for dispersed particle flow based on an Eulerian-Eulerian model using an implicit finite difference flow solver [2]. In the optimization procedure, we employ automatic differentiation [3] to compute sensitivities without analytical adjoint formulations and a checkpointing algorithm to reduce the memory requirements for storing information from implicit iterations. We formulate an optimization problem in terms of the drag force of dispersed particle flow and demonstrate the efficacy of the proposed method through some numerical examples.

THE C-N FATIGUE LAW FOR EVALUATING THE CYCLE-LIFE OF LITHIUM-ION BATTERIES

ABSTRACT

Fatigue in LIBs is process-sensitive: variation in (dis)charging profiles and operating temperatures are known to be responsible for differences in cycle-life. Furthermore, when the same batch of batteries is tested under the same environmental conditions, their cycle-life scatters. Scattering cycle-life of LIBs further complicates lifetime prediction for LIBs, which is pivotal to engineering practice since batteries are often used in packs and modules. The dependence of critical fatigue parameters on ambient temperature and charging or discharging rate, along with the scattering nature of LIBs' cycle-life remains unknown, which desires novel theoretical innovations.

Through large-scale experimental investigations and systematic data mining, we demonstrated that the charging rate C and the resulted cycle-life N of batteries obey C= c_0*N^b, named as C-N fatigue depedence. In this equation, c_0 is a limiting charging rate that is the minimum charging rate causing battery failure during the first cycle, and b is battery-type related constant. In the log-log coordinate, the C-N curve exhibit a linear dependence, in which c_0 is the intercept and b is the slope. By investigating the C-N fatigue dependence at various discharging rates and fixed temperature, it is further indicated that b is a function of the discharging rate (D) and c_0 is irrelevant to D. In parallel, the authors decipher the effect of temperature upon cycle-life properties of batteries. It is found that the power b of the C-N curve is insensitive to variation in temperature. The limiting charging rate c_0, in contrast, shows strong dependence on ambient temperature. In combination, the C-N fatigue depedence may be further refined as C=c_0(T)*N^b(D). Based on different statistical investigations, the group reveals that the lognormal distribution is the appropriate model for cycle-life scattering analyses of LIBs. For the first time, a probabilistic C-N (P-CN) model is derived for quantifying the fatigue failure probability in LIBs. The above achievements offer novel mechanical insights to analyzing the cycle-life performance, performing health management, and optimizing module designs for LIBs.

ADVANCING STABILITY IN DEEP LEARNING: EXPLORING THE SUPERIORITY OF SQRRESNET IN FUNCTION INTERPOLATION, COMPUTER GRAPHICS, AND PDE PROBLEM-SOLVING

C-S David Chen[*1], Amir Noorizadegan[1], Kenji Kawaguchi[2] and Der-Liang Young[1]*

[2]Harvard University

ABSTRACT

This study introduces an innovative strategy to enhance the stability of adaptive feedforward architectures in deep learning, specifically focusing on function interpolation, computer graphics, and partial differential equations (PDEs). The proposed approach leverages a distinctive Residual Network (ResNet) variant, the squared residual network (SqrResNet). While ResNet is commonly associated with convolutional neural networks, SqrResNet stands out as an excellent algorithm for integration into feedforward networks, substantially improving computational stability. The investigation thoroughly explores back-propagated gradients to loss values, underscoring SqrResNet's exceptional ability to balance different loss terms during model training. This represents a clear improvement over plain neural networks and ResNet. In the domain of function interpolation, we evaluate both smooth and non-smooth functions in both 2D and 3D settings. Furthermore, SqrResNet is tested in computer graphics scenarios involving intricate models such as the Stanford Bunny and in medical imaging applications. The method extends to solving forward and inverse PDE problems, with a detailed comparison to the DeepXDE package using a plain neural network in its feedforward algorithm. The following observations have been made across various examples in these diverse fields:

- SqrResNet consistently outperforms both ResNet and plain neural networks, demonstrating superior accuracy, stability, and convergence.
- SqrResNet stands out for its impressive performance, especially when plain neural networks struggle to train or face divergence shortly after some epochs.
- SqrResNet exhibits exceptional stability, even with over 50 hidden layers, aiming for enhanced accuracy.
- The study underscores the problem-dependent nature of the number of hidden layers, revealing that deeper networks (exceeding ten hidden layers) often yield better accuracy. In contrast, plain neural networks opt for fewer hidden layers to address instability with larger layer counts.

These findings underscore the substantial advantages of SqrResNet over conventional ResNet and plain neural network architectures.

SINGLE-PARTICLE DYNAMICS IN A LOW-REYNOLDS-NUMBER FLUID UNDER SPHERICAL CONFINEMENT

Gaofeng Chen[*1]*

[1]*Chinese Academy of Sciences*

ABSTRACT

Non-colloidal dynamics of a single particle suspended in a low-Reynolds-number fluid under spherical confinement was studied numerically. We calculated hydrodynamic mobilities of a sphere, a prolate spheroid and an oblate spheroid parallel and transverse to the particle-cavity line of centres. The mobilities show maximum in the cavity centre and decay as the particle moves towards the no-slip wall. For prolate and oblate spheroids, their mobilities are also affected by the angle between the particle's axis of revolution and the particle-cavity line of centres due to particle anisotropy. It was observed that the effect of particle anisotropy becomes stronger as the confinement level increases. When the external force on the particle is not parallel or transverse to the particle-cavity line of centres, a drift velocity perpendicular to the force occurs because of the confinement-induced anisotropy of the mobility in the cavity. The normalized drift velocity depends on the particle location, size, shape and orientation of the non-spherical particle. We also studied the motion of a non-neutrally buoyant particle under external forces in a rotating flow inside the cavity. Cooperation between the external force, rotation-induced centrifugal or centripetal force and the force from particle–wall interactions leads to multiple modes of particle motion. A fundamental understanding of single-particle dynamics in this work forms the basis for studying more complex particle dynamics in intracellular transport, and can guide particle manipulation in microfluidic applications ranging from droplet-based microreactors to microfluidic encapsulation.

A PARTITIONED COUPLING ALGORITHM FOR HIGH-FIDELITY HYDRODYNAMIC INDUCED STRUCTURAL FRACTURE ANALYSIS

Gong Chen[*12] and Shunhua Chen[12]*

[1]*Sun Yat-sen University*
[2]*Southern Marine Science and Engineering Guangdong (Zhuhai) Laboratory*

ABSTRACT

The main focus of this work is to develop a partitioned coupling algorithm for high-fidelity structural fracture simulations subjected to hydrodynamic impacts. This is achieved by combining the finite volume method (FVM) with an intrinsic cohesive zone model (CZM). Fluid flows are simulated with the aid of the FVM in conjunction with the volume of fluid method to resolve the two-phase interface. Moving meshes are effectively managed using the arbitrary Lagrangian-Eulerian method. Our algorithm describes crack onset and propagation using the CZM in the context of finite element modeling. The partitioned strategy to couple the fluid and structure domains is implemented by recourse to a multi-physics open-source coupling library, i.e., preCICE. Mesh types and connectivity of both fluid and structure parts are incorporated into solver adapters, facilitating data exchange and mapping between non-matching meshes. We introduce a parallel implicit scheme to enhance coupling convergence, complemented by a Quasi-Newton scheme to stabilize and accelerate the fixed-point iteration at the coupling interface. Additionally, a second-order precision nearest-projection mapping method is employed for data mapping between non-matching meshes on the coupling interface. The coupling algorithm facilitates efficient parallel computation in High-Performance Computing clusters. The communication channel is established through TCP/IP sockets, and the infiniband system serves as the network interface for data communication among multiple computational hosts. Several representative numerical examples are performed to demonstrate the accuracy, efficiency, and effectiveness of our presented coupling algorithm.

[3]*University of Arizona*

ABSTRACT

Originally developed by F.H. Harlow at LANL for hydrodynamic simulations, Particle-in-Cell (PIC) methods are now widely employed in simulating fluid and kinetic plasmas across diverse application domains, including fusion studies, plasma-based accelerators, space, and laboratory plasmas. However, addressing multi-scale physics in astrophysical and laboratory plasmas with strong magnetic fields poses challenges for conventional PIC methods. This has important consequences for understanding particle acceleration and emission mechanisms for a wide range of laboratory and astrophysical systems.

In this study, we leverage a known analytical solution for particle motion in arbitrary constant electromagnetic fields [1,2] to develop approximate solutions with non-uniform fields. This novel approach allows for significant improvements in simulation accuracies and achievable scales within the kinetic model when strong magnetic fields are present, which are unattainable with standard methods. We will showcase the advantages of the analytical particle pusher and the resulting PIC algorithm compared to conventional approaches, demonstrating its efficacy through standard test-particle and self-consistent benchmarks.

Furthermore, we will conduct a thorough comparison between the new algorithm and standard PIC methods in more realistic scenarios, such as relativistic shocks, covering regimes from relatively weak to strong magnetizations. This study aims to shed light on the enhanced capabilities of the proposed analytical particle pusher and its potential impact on advancing our understanding of plasma dynamics in multi-scale astrophysical environments.

DIRECT PROBABILITY INTEGRAL METHOD FOR HIGH-DIMENSIONAL STOCHASTIC MECHNICAS ANALYSIS

Guohai Chen[*1] and Dixiong Yang*[1]

[1]*Dalian University of Technology*

ABSTRACT

Engineering structure is a complex system with a large number of degrees of freedom. Due to suffering from various uncertainties during the construction and service life cycle, the randomness involved in structural parameters and environmental loads forms a high-dimensional input probability space, which makes the uncertainty propagation of the structural system from input to output being a challenging issue. The dimension reduction is a conventional approach to solve this issue, but it also makes the essential characteristics of system difficult to be truly reflected. Monte Carlo simulation (MCS) seems to be dimension-independent, but it needs a large number of samplings. To this end, based on the principle of conservation of probability, this study derives the basic equation governing the propagation of probability density from input to output in the time-space domains, named as probability density integral equation (PDIE). By combining structural equilibrium equation and PDIE, the direct probability integral method (DPIM) is proposed to perform stochastic response and reliability analyses of linear/nonlinear, time-independent/time-dependent structures in a unified way. In this framework, the structural equilibrium equation can be solved by analytical or numerical methods, and the partition of probability space and smoothing technique of Dirac delta function are presented to solve PDIE numerically, to achieve the probability density function of the structural responses. From the perspective of PDIE, this study reveals the relationship between DPIM and MCS, and why MCS is dimension-independent but requires a huge amount of computation. Furthermore, a new probability space partitioning strategy is proposed for the high dimensional probability space, and DPIM is extended to high dimensional stochastic mechanics. The new probability space partition strategy does not need to reduce the dimension of structural system, and the computational cost is greatly reduced. Finally, the numerical examples demonstrate the effectiveness and applicability of DPIM in high-dimensional stochastic mechanics.

NUMERICAL SIMULATION ON THE STRESS RUPTURE LIFE OF 2D-C/SIC UNDER HIGH TEMPERATURE AND WET OXYGEN CONDITION

Guoqing Chen[*1], Leijiang Yao[1] and Bin Li[1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

C/SiC composites with high specific strength/stiffness are important candidates for thermal structures of new-generation hypersonic aircraft, and the main failure mode of this material is stress-oxidation failure under high temperature and wet-oxygen service environments. To further understand the performance of this material under high-temperature and wet-oxygen service conditions, this study takes C/SiC composites as the research object and establishes a multi-physical-field coupled high-temperature stress oxidation model in combination with numerical simulation to carry out the stress oxidation life study.

This study first established a diffusion coefficient equation based on the oxidation law of the carbon phase in a wet oxygen environment. It then mapped the relationship between external load, environmental conditions, and oxidation, and established a comprehensive failure criterion for stress oxidation under a high-temperature wet oxygen environment. Next, we introduce the criterion of overall failure due to stress oxidation into the finite element model of C/SiC composite material. We write a VUMAT user subroutine and simulate the progressive failure process of the composite material by adopting the method of element failure, and achieve the simulation of stress oxidation life. Finally, to carry out the numerical simulation study of the stress oxidation life of C/SiC composites, verify the accuracy of the model by testing data, and analyze the effect of temperature and external load on the stress oxidation life.

Research results show that at 1300℃, the stress oxidation life with the increasing of external load shows a decreasing trend, which roughly shows an exponential function trend; at 140MPa external load, the stress oxidation life with the increasing of temperature appears to decrease firstly, and then increase with the increasing of temperature, which shows a generally parabolic trend.
In this study, we established a multi-physics field coupling high-temperature stress oxidation numerical simulation method through the numerical simulation study of high-temperature stress oxidation of C/SiC composites and obtained a more realistic numerical simulation model of high-temperature stress oxidation of C/SiC composites, which provides a technical basis for the assessment of the high-temperature service performance of C/SiC composites structures.

July 21-26, 2024, Vancouver Convention Centre, Vancouver, British Columbia, Canada

A GENERALIZED PERIDYNAMIC MATERIAL CORRESPONDENCE FORMULATION USING NON-SPHERICAL INFLUENCE FUNCTIONS

Hailong Chen[*1] and Xuan Hu[2]*

[1]*University of Kentucky*
[2]*University of California, Berkeley*

ABSTRACT

Peridynamics theory is a nonlocal continuum mechanics theory. The peridynamic material correspondence formulation provides passage for direct incorporation of any constitutive models from the conventional local continuum mechanics theory. However, the conventional material correspondence formulation suffers from the well-known issue of material instability. The material instability in peridynamics can be understood as the existence of non-unique mapping between deformation states and the resultant force state. This instability poses practical difficulties while using the correspondence model in computational modeling. One consequence of this instability is the oscillation in the predicted displacement field, i.e., existence of zero-energy modes.

Research efforts have been devoted to remedy the material instability issue, such as introducing additional stabilizing force term and formulating bond-associated deformation gradient using a subset of the horizon. In this presentation, a new class of influence functions is proposed to inherently remove the material instability in the material correspondence formulation. The currently used influence function in the literature is spherical and depends only on the scalar state of a bond. A new class of bond-associated influence functions that depend on the bond length and angle between bonds will be introduced. New material correspondence formulation is developed based on the bond-associated influence function. Numerical examples including influence function analysis, wave dispersion analysis, and deformation prediction are studied to test the validity and effectiveness of the developed model. Conclusion and future work are discussed.

STOCHASTIC RESPONSE CHARACTERISTIC ANALYSIS OF UNDERWATER STRUCTURE BASED ON HYBRID DPIM–SBM

Hanshu Chen[*1], Guohai Chen[2], Dixiong Yang[2] and Zhuojia Fu[1]*

[1]*Hohai University*
[2]*Dalian University of Technology*

ABSTRACT

The ocean is an abundant source of valuable resources for humanity. As the exploitation of these resources increases, so does the use of underwater vehicles for exploration activities. However, the unpredictable nature of the ocean environment poses significant challenges to the operation and trajectory planning of underwater vehicles. Therefore, accurately predicting the stochastic response characteristics of underwater vehicles in random ocean environments is of utmost importance. This study focuses on a novel type of underwater vehicle equipped with a rudderless paddle. Adopting this vehicle as the research subject, the probability density integration equation (PDIE) of the system is derived based on the principle of probability conservation. Furthermore, a direct probability integration method (DPIM) based on block parallel computing is proposed. This method effectively decouples the control equations of the underwater vehicle system from PDIE and utilizes block-parallel computation techniques, enabling efficient stochastic response analysis of the new underwater vehicle under random wave excitation. The results indicate that the significant height of sea waves and flow velocity are the primary stochastic factors affecting the response of underwater vehicles. Higher significant wave heights and flow velocities increase the probability of deviation from the predetermined trajectory of underwater vehicles and may lead to random jumping phenomena, thereby reducing the navigation safety of underwater vehicles.

TEMPERATURE AND COMPOSITION DEPENDENT CRITICAL RESOLVED SHEAR STRESS OF BASAL SLIP IN MG-Y ALLOY FROM LARGE-SCALE MOLECULAR DYNAMICS

Huicong Chen[*1] and Jun Song[1]*

[1]*McGill University*

ABSTRACT

Magnesium (Mg) has attracted significant interest in the manufacturing and transportation sectors due to its low density, abundance in the earth's crust, high specific strength, and good castability. However, Mg and its alloys typically exhibit poor room temperature ductility and formability, which limits their use as wrought materials. These limitations are directly linked to the underlying hexagonal-close-packed (hcp) crystal structure, which lacks sufficient independent deformation modes for homogeneous deformation at low temperatures. Increased ductility of magnesium is achieved via alloying with certain solutes, which can change activation of different slip systems due to solute strengthening.

This study investigates the impact of solute atoms (Y) on the critical resolved shear stress (CRSS) for basal slip in Mg alloys across a wide range of temperatures and solute contents. Molecular dynamics simulations were extensively employed to determine the influence of Y on CRSS, while kinetic Monte Carlo simulations were used to examine solute segregation at dislocation cores. In random solid solutions, the presence of solute–dislocation and solute–solute interactions led to a monotonic increase in CRSS with increasing Y concentration, even at elevated temperatures. Furthermore, Monte Carlo simulations revealed that Y atoms exhibited segregation tendencies at dislocation cores. Subsequent molecular dynamics simulations demonstrated that such segregation exerted a stronger pinning effect on the motion of dislocation. The current simulation shows a promising pathway of improvement for ductility of Mg alloys by controlling the content of Y at finite temperature.

A FULLY COUPLED CELLULAR AUTOMATON-MATERIAL POINT METHOD FOR SOLIDIFICATION GRAIN STRUCTURE PREDICTION DURING THE METAL ADDITIVE MANUFACTURING PROCESS

Jia-Wei Chen[*1], Yanping Lian[1] and Ming-Jian Li[1]*

[1]*Beijing Institute of Technology*

ABSTRACT

In this study, we proposed a fully coupled three-dimensional cellular automaton-material point method (fc-CAMPM) for simulating the material deposition and microstructure evolution in metal additive manufacturing (AM). In this method, the multi-physics material point method (MPM) is utilized to solve the thermo-fluid-solid coupling problem at the powder scale. The MPM for the temperature field is fully coupled with the 3D cellular automaton (CA) for the solidification microstructures evolution. In the fully coupled framework, the fraction of solid can be timely calculated for each MPM cell based on the solidification front of the microstructure to update the temperature field. with an accurate latent heat release or absorption. In return, the MPM can provide a more realistic solidification path for the CA. Due to significant differences in cell sizes and time steps between MPM and CA, we proposed a dynamic cell activation technique to reduce the computational cost during fully coupled solving. In this technique, only CA cells within the mushy zone are activated for grain nucleation/growth simulation in each step of CA, while the information of other solid cells is stored in memory. Several numerical examples are presented to showcase the effective and efficiency of the proposed method. It is demonstrated that the fc-CAMPM is a powerful tool for revealing the microstructure evolution mechanism and further to advance the understanding of the microstructure-property relationship during the metal AM.

N-ADAPTIVE RITZ METHOD: A NEURAL NETWORK ENHANCED COMPUTATIONAL MECHANICS FRAMEWORK

Jiun-Shyan Chen[*1], Jonghyuk Baek[21] and Yanran Wang[1]*

[1]*University of California, San Diego*
[2]*Coreform, LLC*

ABSTRACT

Conventional finite element methods are known to be tedious in adaptive refinements due to their conformal regularity requirements. Meshfree methods, such as the Reproducing Kernel Particle Method, relaxed the discretization and approximation regularity requirements in finite elements, however the enrichment functions for adaptive refinements are not readily available in general applications. The fast-growing research and development in data science, machine learning and artificial intelligence offer new opportunities for the development of new paradigms in scientific computing. This talk presents a neural network (NN) enhancement of Galerkin solution for weak and strong discontinuities, as well as for solution enhancement with a fixed discretization, called N-adaptivity. The flexibility and adaptivity of the NN function space are utilized to capture complex solution patterns that the conventional Galerkin methods fail to capture. The NN enrichment is constructed by combining pre-trained NN blocks with an additional untrained NN block. The pre-trained NN blocks learn specific complex solution patterns during the offline stage, enabling efficient enrichment of the approximation space during the online stage through the Ritz-type energy minimization. The NN enrichment is introduced under the Partition of Unity (PU) framework, ensuring convergence of the proposed method.

THERMODYNAMICS-BASED DATA-DRIVEN COMPUTING FOR INELASTIC MATERIALS MODELING

Jiun-Shyan Chen[*1] and Jonghyuk Baek*[21]

[1]*University of California, San Diego*
[2]*Coreform, LLC*

ABSTRACT

Characterization and modeling of complex materials by phenomenological models remains challenging due to difficulties in formulating mathematical expressions and internal state variables (ISVs) governing path-dependent behaviors. Data-driven machine learning models, such as deep neural networks and recurrent neural networks (RNNs), have become viable alternatives. However, pure black-box data-driven models mapping inputs to outputs without considering the underlying physics suffer from unstable and inaccurate generalization performance. This study introduces a machine-learned physics-informed data-driven constitutive modeling approach for path-dependent materials based on the measurable material states. The proposed data-driven constitutive model is designed with the consideration of universal thermodynamics principles, where the ISVs essential to the material path-dependency are inferred automatically from the hidden state of RNNs [1]. For materials subjected to fracturing or strain localization, a neural network enriched Galerkin solution for weak and strong discontinuities and for adaptive refinement without re-meshing is introduced [2, 3]. Applications to plasticity, localization and fracture modeling using the proposed methods will be presented.

SPEED UP THE MULTI-SCALE SIMULATIONS WITH PRECICE AND MICROMANAGER: RESULTS PRESENTED FOR A POROUS-MEDIA FLOW

Jun Chen[*1], Ishaan Desai[1], Mathis Kelm[1], Miriam Schulte[1] and Benjamin Uekermann[1]*

[1]*University of Stuttgart*

ABSTRACT

We aim to increase the computational efficiency of the multi-scale simulation of a flow-field in porous media. There, the macro-scale solver is provided with real-time local properties up-scaled from the outcome of micro-scale simulations. This up-scaling is proven to be superior to resorting to standard empirical equations for the local field description, especially in more complex scenarios like multi-phase flow, with the cost of much more computing time. A general framework to lower the cost is needed.

We partition the simulation into unit solvers for different scales and use the preCICE library to couple them together. Thus, we can focus on improving the general coupling method without touching the case-specific unit solvers.

We also employ the Micro Manager extension in preCICE as a wrapper for all micro simulations and to use its adaptivity features, with which Micro Manager completes the large amount of micro-scale simulations efficiently by solving a couple of representative points and reusing these results to all the other points with adequate similarity.

We contribute to Micro Manager by enabling the adjustment of the strictness of the similarity evaluation based on the current convergence status. It helps to get rid of unnecessarily accurate results at the early stage of the simulation but also brings in the challenge of balancing between solving fewer micro-scale points and retaining the convergence property of the coupled simulation.
We are also working on improving the existing Quasi-Newton(QN) methods in preCICE, which expedites convergence, to handle physical values within specific ranges, e.g. to avoid negative density or phase concentration etc. This would benefit all the simulations, where bounded values are involved in the QN methods.

The performance of the dynamic similarity condition and the QN methods for bounded values will be shown with the results of the two-scale simulation of a multi-phase porous media flow, in which the unit solvers in both scales are implemented in DuMuX. While we treat the unit solvers as black-box in preCICE and MicroManager, the same method would be helpful for other multi-scale simulations coupled with them.

METASTRUCTURES WITH SHUNTED PIEZOELECTRIC PATCHES

Jung-San Chen[1], Yu-Siang Huang[1] and You-Kuan Su[1]*

[1]National Cheng Kung University

ABSTRACT

Low-frequency noise and vibration suppression have long been research sujects over decades. Phononic crystals (PCs) poessessing Bragg scattering mechanism can create bandgaps over certain frequency range. Due to the structure size limit, those crystals are ineffective in the low frequency regime. The emergence of locally resonant (LR) acoustic/elastic metamaterials has provided an additional avenue for eliminating unwanted noise/vibration. Those structures exhibits the phenomenon of LR bandgaps, which is useful for manipulating wave propagation. The local resonating units include spring-mass, cut-out, beam-like, force-moment, cantilever-mass, pillar-type structures, and etc. The bandgap properties can be determined by the geometry of the resonating unit cell. Membrane-type metamaterials have also been considered as potential LR systems. Changing their physical properties, such as membrane tension and mass weight, can tailor bandgap location. However, the the durability issue of membrane tension still remains challenging. Recently, the use of piezoelectric materials has demonstrated their effectiveness in enriching the dynamic characteristics of LR bandgaps. By adjusting the parameters of shuting circuit, the bandgap frequencies can be easily tuned. In this study, two metastructures integrated with shunted piezoelectric circuits are proposed. One is comprised of an elastic base beam with array-type sub-beam structtures; the other is an ealstic plate with shunted piezoelctric films. Theoretical models and finite element analysis are used to predict the vibration transmission. The effects of circuital parameters on attenuation constants are investigated. Multi-frequency wave attenuation can be achieved by adding extra shunted patches. The proposed tunable metastructures might boost the development of vibration control devices.

RE-ORIENTATION OVER RE-ALIGNMENT: ULTRASTRUCTURAL RESPONSES OF CARTILAGE COLLAGEN FIBRILS TO MECHANICAL LOADING

Jingrui Hu[1], Xiaoyuan Gu[1], Keke Zheng[2], Benjamin E. Sherlock[1], Jessica Mansfield[1], C. Peter Winlove[1] and Junning Chen[1]*

[1]University of Exeter
[2]Heriot-Watt University

ABSTRACT

Articular cartilage is renowned for its crucial mechanical roles in load bearing and shock absorption, effectively distributing load and safeguarding the subchondral bone. Its biomechanical properties arise from its extracellular matrix (ECM), comprising a collagenous network interacting with proteoglycan-rich interstitial fluid. The collagen fibrils in the cartilage exhibit depth-dependent organisation, forming three distinct zones—superficial, transitional, and deep—each responding uniquely to external loads. Maintaining these depth-dependent characteristics is essential for the cartilage's biomechanical functionality. The deterioration of these structural traits is linked to cartilage lesions and degenerative disorders like osteoarthritis (OA). Significant research endeavours aim to quantitatively correlate cartilage structure with its biomechanical efficacy, a challenge compounded by collagen's complex hierarchical organisation and the collective responses of the zonal structures to mechanical loading.

Recent advancements in polarisation-resolved second harmonic generation (pSHG) microscopy [1] have enabled probing of collagen organisation beyond optical resolution in a label-free, depth-sectioning manner. This technique has unveiled the hierarchical complexity of fibrillar organisation at nanometre scales and intrafibrillar organisation at the molecular level in cartilage [2]. These findings are critical in understanding local ECM behaviours and their role in mechanotransduction to embedded chondrocytes, thus influencing cartilage synthesis and homeostasis. The rapid scanning capability of pSHG facilitates visualisation of dynamic structural responses to mechanical or chemical stimuli, with collagen organisation at both length scales showing marked sensitivity.

Our study primarily aims to visualise and quantify the spatial gradient and heterogeneity of collagen organisation in bone-cartilage explants, focusing on the principal orientation and degree of alignment at the ultrastructural level. We examine the mechanical responses of this gradient ultrastructure to external loads at various strain intervals. This involves assessing the re-orientation and re-alignment of collagen fibrils to understand the collective role of cartilage zonal organisation in dictating the tissue's overall mechanical behaviour. Utilising pSHG, we captured collagen organisation across the longitudinal plane of cartilage-bone explants with high spatial resolution. A customised loading rig, integrated with our multiphoton platform, enabled loading to the tissue during imaging acquisition. Our findings indicate that the transitional zone undergoes the most significant changes in response to mechanical loading, primarily through collagen fibre re-orientation rather than re-alignment.

PSEUDO-DIFFERENTIAL INTEGRAL AUTOENCODER NETWORK FOR INVERSE PDE OPERATORS

Ke Chen[*1], Jasen Lai[2] and Chunmei Wang[3]*

[1]*University of Maryland, College Park*
[2]*Purdue University*
[3]*University of Florida*

ABSTRACT

Partial differential equations (PDEs) play a foundational role in modeling physical phenomena. This study addresses the challenging task of determining variable coefficients within PDEs from measurement data. We introduce a novel neural network, "pseudo-differential IAEnet" (pd-IAEnet), which draws inspiration from pseudo-differential operators. pd-IAEnet achieves significantly enhanced computational speed and accuracy with fewer parameters compared to conventional models. Extensive benchmark evaluations are conducted across a range of inverse problems, including Electrical Impedance Tomography (EIT), optical tomography, and seismic imaging, consistently demonstrating pd-IAEnet's superior accuracy. Notably, pd-IAEnet exhibits robustness in the presence of measurement noise, a critical characteristic for real-world applications. An exceptional feature is its discretization invariance, enabling effective training on data from diverse discretization schemes while maintaining accuracy on different meshes. In summary, pd-IAEnet offers a potent and efficient solution for addressing inverse PDE problems, contributing to improved computational efficiency, robustness, and adaptability to a wide array of data sources.

MIXED-MODE CRACK OPENING COMPUTATION IN THE PHASE FIELD METHOD

Lin Chen[*1]*

[1]*University of Dundee*

ABSTRACT

The phase field modelling of cracks gains popularity in the fracturing analysis recently, due to its smeared representation of cracks, avoiding the introduction of geometric discontinuities and remeshing around crack tips. The method has been cast in both brittle and cohesive format. In the analysis, the crack opening displacement is an essential variable for the cohesive fracture model, due to the dependence of the fracture energy on it. For the brittle fracture model, the crack opening displacement is also crucial in certain applications, e.g., hydraulic fracturing or fracturing in the oil and gas exploration. In the current study, the full form of the mixed-mode crack opening is derived for the first time in the framework of phase field modelling. The formulations are given separately for the brittle and cohesive fracture model. The crack opening displacement is associated with a line integral normal to the crack. Different factors and matrices apply in the integration for both fracture models and crack directions. The derivations are validated analytically by an edge cracked problem and numerically by curved crack issues.

DERIVATIVE-INFORMED DEEPONETS FOR HIGH-DIMENSIONAL PARAMETRIC PDES

Yuan Qiu[1], *Nolan Bridges*[1] *and Peng Chen**[1]

[1]*Georgia Institute of Technology*

ABSTRACT

Deep operator networks (DeepONets), a class of neural operators that learn mappings between function spaces, have recently been developed as surrogate models for high-dimensional parametric partial differential equations (PDEs). In this talk, we introduce a derivative-informed deep operator network (DI-DeepONet), which leverages the derivative information of the solution operator of parametric PDEs to enhance the accuracy and efficiency of DeepONet. DI-DeepONet uses DeepONet as its backbone and incorporates two derivatives in the loss function for training, including the directional derivatives of the output function with respect to the input function and the gradient of the output function with respect to the physical domain variables. This feature enhances generalization accuracy, especially in scenarios with limited training data, and provides a more accurate approximation of derivatives. Additionally, we propose to use a reduced representation of the input functions (e.g., through projection into the Karhunen–Loève expansion subspace or the active subspace) rather than the full representation. The model-based dimension reduction of input functions allows us to train a much smaller neural network, thereby significantly reducing the computational cost for training and the required volume of training data. We present the results of several numerical experiments to demonstrate the effectiveness of DI-DeepONet compared to DeepONet.

[4]*University of Washington*

ABSTRACT

The long runtime of high-fidelity partial differential equation (PDE) solvers makes them unsuitable for time-critical applications. We propose to accelerate PDE solvers using reduced-order modeling (ROM). Whereas prior ROM approaches reduce the dimensionality of discretized vector fields, our continuous reduced-order modeling (CROM) approach builds a low-dimensional embedding of the continuous vector fields themselves, not their discretization. We represent this reduced manifold using continuously differentiable neural fields, which may train on any and all available numerical solutions of the continuous system, even when they are obtained using diverse methods or discretizations. We validate our approach on an extensive range of PDEs with training data from voxel grids, meshes, and point clouds. Compared to prior discretization-dependent ROM methods, such as linear subspace proper orthogonal decomposition (POD) and nonlinear manifold neural-network-based autoencoders, CROM features higher accuracy, lower memory consumption, dynamically adaptive resolutions, and applicability to any discretization. For equal latent space dimension, CROM exhibits 79X and 49X better accuracy, and 39X and 132X smaller memory footprint, than POD and autoencoder methods, respectively. Experiments demonstrate 109X and 89X wall-clock speedups over unreduced models on CPUs and GPUs, respectively. Videos and codes are available on the project page: https://crom-pde.github.io.

LEARNING NEURAL CONSTITUTIVE LAWS FROM MOTION OBSERVATIONS FOR GENERALIZABLE PDE DYNAMICS

Pingchuan Ma[1], Peter Yichen Chen[1], Bolei Deng[2] and Wojciech Matusik[1]*

[1]MIT

[2]Georgia Institute of Technology

ABSTRACT

We propose a hybrid neural network (NN) and PDE approach for learning generalizable PDE dynamics from motion observations. Many NN approaches learn an end-to-end model that implicitly models both the governing PDE and constitutive models (or material models). Without explicit PDE knowledge, these approaches cannot guarantee physical correctness and have limited generalizability. We argue that the governing PDEs are often well-known and should be explicitly enforced rather than learned. Instead, constitutive models are particularly suitable for learning due to their data-fitting nature. To this end, we introduce a new framework termed “Neural Constitutive Laws” (NCLaw), which utilizes a network architecture that strictly guarantees standard constitutive priors, including rotation equivariance and undeformed state equilibrium. We embed this network inside a differentiable simulation and train the model by minimizing a loss function based on the difference between the simulation and the motion observation. We validate NCLaw on various large-deformation dynamical systems, ranging from solids to fluids. After training on a single motion trajectory, our method generalizes to new geometries, initial/boundary conditions, temporal ranges, and even multi-physics systems. On these extremely out-of-distribution generalization tasks, NCLaw is orders-of-magnitude more accurate than previous NN approaches. Real-world experiments demonstrate our method’s ability to learn constitutive laws from videos.

A SET OF HYSTERETIC NONLINEAR CONTACT MODELS FOR DEM AND APPLICATION FOR DEFORMABLE GRANULAR PARTICLE FLOW

Qiushi Chen[*1]

[1]*Clemson University*

ABSTRACT

In the discrete element method (DEM), contact models describe how particles interact with each other and with boundaries, and are a key element to capture the bulk behavior of a granular system. In this work, we propose a set of hysteretic nonlinear contact models for approximating the bulk strain-hardening phenomena of relatively soft granular materials. These contact models comprise simple polynomial and/or exponential functions to allow for easy calibration. To ensure numerical stability, we have derived unconditionally stabilized viscous damping force models. The resultant DEM model is implemented in LIGGGHTS-INL and applied to simulate an axial compressibility test and hopper flow for deformable granular materials. Results show that the DEM model can reproduce the bulk stress–strain profiles of the physical samples and that the predicted responses agree reasonably with the experimental data.

THE STEADY STATE OF THE OSCILLATORY ADHESIVE CONTACT BETWEEN A RIGID CONE AND A VISCOELASTIC HALF-SPACE

Shiwen Chen[*1], Xuan-Ming Liang[1] and Gangfeng Wang[1]*

[1]*Xi'an Jiaotong University*

ABSTRACT

The steady-state responses in the oscillatory indentation test are widely adopted to evaluate the viscoelastic behavior of cells and tissues. In such tests, the strong adhesion of biomaterials is, however, commonly neglected due to the difficulty in solving the coupled adhesive viscoelastic contact problems. In our research, by introducing the interfacial interaction described by Lennard-Jones potential using connector elements, we develop a finite element method to simulate the oscillatory adhesive contact between a rigid cone and a viscoelastic half-space. It is shown that with a sinusoidal displacement excitation, the reaction force evolves sinusoidally at the same frequency but they are not perfectly in phase. The interfacial adhesion will magnify the amplitude of force vibration while weaken the average strength. For weak adhesion, the mean contact force shows little dependence on the excitation frequency, whereas for strong adhesion, the dependence becomes apparent. The phase difference between the reaction force and the displacement excitation could be either aggravated or eased depending on the strength of adhesion. It is observed that the phase difference attains its maximum at an intermediate strength of adhesion, and approaches the argument of the complex modulus of the viscoelastic substrate as the strength of adhesion increases. The present study can provide guidance for the development of the oscillatory indentation test on viscoelastic materials.

Recent advances in computational fracture mechanics and failure analysis

LAGRANGE MULTIPLIER/COHESIVE ZONE (LM/CZ) METHODS FOR MULTIPLE CRACK SIMULATIONS

Yifang Qin[1], Shunhua Chen[2] and Mitsuteru Asai[1]*

[1]Kyushu University
[2]Sun Yat-sen University

ABSTRACT

Currently, accurate simulations of cracks remain a challenging task in computational mechanics community. In light of this, we have developed a series of nodal-based Lagrange multiplier/cohesive zone (LM/CZ) methods for accurate crack simulations. We consider two different crack patterns, i.e., those crack paths are known and unknown in prior. Special focus is given to the interactions between different crack patterns. The developed methods are capable of dealing interface cracks with matching and non-matching meshes. The main idea of the presented methods is to fulfil the displacement compatibility condition at finite element nodes before crack onset via LMs. The LM forces at each nodal pair are calculated in a predictor-corrector form with a limited number of iterations. The nodal constraints are smoothly switched to cohesive forces after a defined criterion is satisfied. Compared with the conventional intrinsic CZMs, our developed methods can effectively address the so-called artificial compliance numerical issue, thereby yielding more accurate numerical results. Several benchmark numerical examples are performed to demonstrate the numerical accuracy and effectiveness of our developed methods.

REAL-TIME OPTIMISATION OF COMPOSITES FORMING PROCESS

Siyuan Chen[*1], Adam Thompson[1], Tim Dodwell[2], Stephen Hallett[1] and Jonathan Belnoue[1]*

[1]*University of Bristol*
[2]*University of Exeter*

ABSTRACT

In the context of Industry 4.0, the aerospace and composites sectors are increasingly focusing on digitalised manufacturing techniques. With advancements in precise physically based computer modelling and machine learning algorithms, engineers are striving to actualise real-time optimisation and digital twin technologies. This framework promises the capability to adjust system parameters dynamically to achieve optimal or near-optimal performance based on virtual replicas of the physical manufacturing process, even under fluctuating conditions. These technologies significantly reduce trial-and-error costs, mitigating risks to the actual system, curtailing waste of expensive materials and energy, and saving the labour cost.

In liquid composites moulding, forming dry fibrous precursor materials into the mould's 3D shape before resin injection poses challenges, notably the high level of variability. This can lead to significant fabric defects such as out-of-plane wrinkles and folds that result is design tolerances not being met. Traditionally, composites weight saving advantages are not used to their full as “overdesign” is required to compensate for defect occurrence and a lack of process robustness. Finite element (FE) simulation tools, specifically developed for dry textile forming, can predict wrinkle formation under ideal conditions with good accuracy. However, uncertainties inherent to the process make the use of deterministic simulations almost useless and the extensive computational requirements of FE limit the number of simulations that can be run. This introduces difficulties for process parameter optimisation using traditional approaches.

This study introduces a real-time optimisation framework for dry fabric forming process. The framework is underpinned by a Gaussian process (GP) emulator trained on a small dataset built from FE simulations. Utilising dimension reduction and active learning algorithms, the GP emulator can explore a vast design space of control parameters without prior expert knowledge. The parameter range is then refined and an approximate optimal condition is found from running only a few hundred FE simulations. The trained emulator can predict real-time optimum conditions, given the measured fiber-direction variability as an input parameter. To validate the capability of the algorithms on a real-world system, a forming cell equipped with a multi-camera digital image correlation (DIC) system is built. This allows to measure the necessary preform variabilities, adjusts control parameters, and reconstructs the 3D mesh of the formed fabric's surface that can be compared with the simulation predictions. This research highlights the potential of data-driven digital twins in composite manufacturing, showcasing how the GP emulator can drive a digital twin with strong efficiency and accuracy.

DIFFERENTIABLE INVERSE DESIGN OF ACTIVE MORPHING MATERIAL SYSTEMS WITH MULTI-STIMULI RESPONSIVENESS

Liwei Wang[1], Alexander L. Evenchik[1], Jared Mi Yang[1], Ryan Truby[1] and Wei Chen[1]*

[1]Northwestern University

ABSTRACT

Morphing material systems can alter shapes in response to stimuli, such as heat, light, or pH. This responsive morphing behavior provides exceptional controllability and adaptability to the system's functionality, enabling it to perform diverse tasks in varying environments. While this emerging materials paradigm holds significant promise in fields like soft robotics, minimally invasive surgery, and flexible electronics, existing studies predominantly concentrate on the manufacturing and modeling of responsive materials. There is a notable lack of an inverse design framework that can program a material system to achieve specific target shapes. While there are a few design-centric studies, they often focus on simple or periodic architectures, rely on heuristic optimizers, suffer from the computational burden of nested finite element analysis (FEA), overlook manufacturability, and are constrained to isotropic material responses and single stimuli.

In this study, we establish a proficient inverse design framework to tackle these challenges. This framework integrates differentiable simulation and extended topology optimization to program multi-stimuli shape morphing by co-designing the structure, stimuli, and manufacturing parameters. While the framework can accommodate various responsive materials, we focus on network systems made by 3D-printed liquid crystal elastomers (LCEs), which display anisotropic responsive behaviors, primarily contracting along the printing path when exposed to light or heat.

We first conduct experimental investigations into the constitutive and responsive behaviors of LCEs under varied printing speeds and pressures. Based on the results, we develop a differentiable simulation model that enables efficient GPU-backend simulations with auto-differentiation capability. We then extend topology optimization to accommodate mixed-variable design, concurrently optimizing the network system's nodal locations, connectivity, manufacturing parameters, and stimuli selection for each edge. This includes factors such as printing speed, pressure, and the number of layers, generating print-ready designs. We also incorporate manufacturing constraints into the design process to ensure printability. Built upon the automatic differentiation capability of our modeling, we can obtain the gradients of every design variable for all objectives, facilitating effective optimization without manual sensitivity derivation. Our method seamlessly integrates with a neural network-based objective function, allowing adaptation to arbitrary shape-morphing targets. The proposed methodology swiftly generates optimized network designs within minutes to program shape-morphing behaviors. It exhibits unparalleled flexibility in accommodating different network topologies, various initial and active shapes, and multiple stimuli, validated by both experiment and simulation. This inverse design framework can be generalized for use with other responsive materials, making it applicable to a range of robotic and surgical applications.

POTENTIAL THEORY METHOD FOR CONTACT PROBLEMS OF MATERIALS WITH MULTI-FIELD COUPLINGS

Weiqiu Chen[*1]

[1]*Zhejiang University*

ABSTRACT

We report a generalized potential theory method for the boundary-value problems of some advanced materials characterized by both anisotropy and multi-field coupling. The method is based on the original one proposed by Dr. Fabrikant, which is for transversely isotropic elastic materials. The generalization relies on the general solution established in the multi-field coupling cases. Different combinations of boundary conditions for multiple physical fields are considered. Exact, closed-form three-dimensional solutions are derived in terms of elementary functions are presented. Exact indentation relations are then established, which can be used in modern indentation techniques for characterizing material properties of advanced materials.

[3]*Northwestern University*

ABSTRACT

Metamaterials with functional responses, such as wave-based responses or deformation-induced property variation under external stimuli, can exhibit varying properties or functionalities under different conditions. Herein, we aim at rapid inverse design of these metamaterials to meet target qualitative functional behaviors. This inverse problem is challenging due to its intractability and the existence of non-unique solutions. Past works mainly focus on deep-learning-based methods that are data-demanding, require time-consuming training and hyperparameter tuning, and are non-interpretable. To overcome these limitations, we propose the Random-forest-based Interpretable Generative Inverse Design (RIGID), a single-shot inverse design method to achieve the fast generation of metamaterial designs with on-demand functional behaviors. Unlike most existing methods, by exploiting the interpretability of the random forest, we eliminate the need to train an inverse model mapping responses to designs. Based on the likelihood of target satisfaction derived from the trained forward model, one can sample design solutions using Markov chain Monte Carlo methods. The RIGID method therefore functions as a generative model that captures the conditional distribution of satisfying solutions given a design target. We demonstrate the effectiveness and efficiency of RIGID on both acoustic and optical metamaterial design problems where only small datasets (less than 250 training samples) are available. Synthetic design problems are created to further illustrate and validate the mechanism of likelihood estimation in RIGID. This work offers a new perspective on solving on-demand inverse design problems, showcasing the potential for incorporating interpretable machine learning into generative design and eliminating its large data requirement.

ABSTRACT

Bubbles trapped in the woven structures lead to the performance defects of composite materials. It is important to study the bubbles behaviors and regulation mechanism on the complex geometry and surface characteristics. A three-dimensional phase-field lattice Boltzmann method (PFLBM) for immiscible two-phase flow with large density and viscosity ratios was built, which takes into account surface tension, pressure force, viscous force and body force[1]. The three-phase wetting characteristics were successfully introduced on the plane and spherical surface by a geometrical way. The 3D two-phase model was validated by Laplace's law, and the wettability condition on the spherical surface was verified beacause the relative error between the measured and the specified contact angle is less than 2%. Then the complex geometric surfaces were constructed which consists of plane and spherical surface with complex wetting characteristics. An interpolation scheme was imposed at the junction lattices of two suface with differnet curvature. Basing on our built mathematical model, we systemly simulated a bubble motion on 3D complex geometric surfaces with complex wettability distribution. The geometrical shape, changable wettability, physical properties of fluids and driving force were investigated. By analyzing the force, flow field and shape evolution of the bubble in different moving stages, the bubble motion characteristics were got and the movement mechanism of the bubble on the complex geometric surfaces was revealed. Then we grasped how to control the bubble's behvaior on the complex surface shape with complex wettability distribution by surface tension, viscosity, driving force, wettability distribution, surface combined ways, surface curvature. The work would provide theoretical guidance and data support to improve the production quality of carbon fiber composites.
Key words: three-dimensional; phase-field lattice Boltzmann method; performance defects; complex geometric surfaces; wettability distribution

A COMPUTATIONAL FRAMEWORK FOR FRACTIONAL CONTRIBUTIONS FROM EXTERNAL LOADS TO THE FATIGUE OF LARGE-SCALE STRUCTURES

Xianjia Chen[*1]

[1]*Chinese Academy of Sciences*

ABSTRACT

Understanding the fractional contributions from external loads to the damage of complex engineering structures such as high-speed trains (HSTs) precisely is critical for their fatigue reliability design. We demonstrate in this paper a computational framework for identifying fractional contributions from wheel-rail excitations and aerodynamics to the fatigue of HST bogie frame based on multidisciplinary modeling. To this end, we first determine the stress at the vulnerable site for fatigue on the bogie frame of an HST subjected to aerodynamics and wheel-rail excitations under various conditions—single-train operation or two-train intersections in the open air or in the tunnel—using coupled aerodynamics, grid multi-body dynamics and structural finite element calculations. Then, we adopt the rainflow counting method to calculate the stress cycles and evaluate the structural fatigue life at the crucial site with the linear cumulative damage theory. Further, we develop metrics to quantify the individual and coupled contributions of each external load to the structural fatigue life. Moreover, in order to improve the efficiency of multidisciplinary calculations, we rely on machine learning models trained from very limited computational results to produce long-duration load data required for fatigue analysis. This paper clarifies the influence of different external loads on the fatigue of HST bogie frames under various working conditions. The findings may provide a foundation for designing fatigue-resistant critical structures of HSTs, and the developed framework may then supply a unified scheme for evaluating fractional contributions from external loads to the fatigue in many other large-scale structures.

A NOVEL HIGH-ORDER SANDWICH PLATE THEORY-BASED ISOGEOMETRIC ANALYSIS FOR FREE VIBRATION OF VARIABLE ANGLE TOW COMPOSITE SANDWICH PLATES WITH COMPLEX-SHAPED CUTOUTS

Xiaodong Chen[*1]*

[1]*Henan University of Urban Construction*

ABSTRACT

Advanced automated fibre placement technologies enable variable angle tow sandwich constructions possible, which provides an extended flexibility in stiffness tailoring to design lightweight sandwich plates with superior performance. However, complex-shaped openings within this new type of sandwich constructions bring great challenges when dealing with vibration problems. In this paper, an isogeometric analysis formulation based on a novel high-order sandwich plate theory is developed for the first time to the study of free vibration of variable stiffness sandwich plates with complex-shaped cutouts. The proposed new high-order sandwich plate model is formulated based on the idea of layerwise modeling, that is, the first-order shear deformation theory is applied to characterize the kinematics of the two skins, while the high-order theory based on hierarchic Legendre polynomials is utilized to describe the kinematics of the core. The weak-form governing equations associated with the vibration problem of the perforated sandwich plates is firstly derived from the virtual work principle, and then the IGA formulation based on the non-uniform rational B-splines (NURBS) is applied to obtain the eigenfrequencies and the corresponding vibration modes. The novelty of the current work lies in that the introduction of hierarchic Legendre polynomials enables the kinematics of the core to be enriched to any desired expansion order, and also brings some other merits such as the conciseness in derivation process and the easiness in program implementation, which shows great superiority over its traditional counterpart such as EHSAPT. On the other hand, the developed IGA procedure based on the novel high-order sandwich plate theory is applicable to a general sandwich plate even with complex-shaped cutouts. The accuracy and effectiveness of the developed IGA procedure are validated by comparing against the results available in literature and those obtained using ABAQUS. Effects of cutout size, boundary condition, and fiber angle on the vibration characteristics of the perforated sandwich plates are discussed in numerical examples. The results presented herein may be beneficial for the design of variable stiffness sandwich plates with complex-shaped cutouts.

DYNAMIC FRACTURE SIMULATION OF QUASI-BRITTLE MATERIALS USING A GENERALIZED MICROPOLAR PERIDYNAMIC MODEL

Xizhuo Chen[*1] and Haitao Yu*[1]

[1]*Tongji University*

ABSTRACT

A generalized micropolar micropolar peridynamic model is proposed to simulate the dynamic fracture behaviors of quasi-brittle materials. The governing equations of bonds connecting particles are reformulated from the definition of bond deformation rates, leading to a rate-based expression of mechanical behavior of solid particles. The peridynamic parameters are derived as time-dependent functions with the consistence of the strain energy obtained from the proposed peridynamic model and the continuum mechanics. The damage evolution functions are introduced in the model to capture the loading-rate dependence of rock. Moreover, a new failure criterion is proposed to describe the dynamic fracture progress of rock materials. The proposed model is verified by comparing its results with those from experimental observations. Numerical examples demonstrate that the dynamic fracture behaviors of rock materials under loads with different loading rates are well captured by the proposed model.

RESEARCH ON FIBER FRACTURE DAMAGE PATTERN RECOGNITION OF CMCS BASED ON DEEP FEATURES OF ACOUSTIC EMISSION SIGNAL

Xuejiao Chen[*1], Leijiang Yao[1], Xiaoyan Tong[1], Bin Li[1] and Shuaiqi Li[1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

Ceramic matrix composites (CMCs) are widely used in hypersonic vehicles and engines due to their excellent high-temperature mechanical properties. There are many types of microscopic damage mechanisms in the service process of CMCs, such as matrix cracking and fiber breakage, etc. Acoustic emission (AE) technology can monitor damage events online recognize the corresponding damage mechanism based on the AE signal characteristics. However, due to the attenuation and variation of AE signals during their propagation in structures, it is difficult to recognize them according to those commonly used AE parameters, such as energy, average frequency, peak frequency, amplitude, and count. Therefore, constructing the deep features of AE signal that do not vary with propagation is of great value for damage identification. As fiber breakage is the most important damage mechanism affecting the load-bearing capacity of CMCs, it's exact identification is much helpful for structural health monitoring of CMC structures. In this paper,the deep features of AE signal generated from A series of experiments were conducted, focusing on the propagation and attenuation of AE signals originating from a singular source of damage. Tensile tests were performed on individual C fibers and SiC fibers to generate AE signals. These signals were collected at various positions along their propagation paths on a C/SIC plate. The collected AE signals were then transformed into 24-dimensional deep features utilizing Mel-cepstral coefficients (MFCCs), enabling the identification of the "timbre" of original AE signal. These deep features remain consistent throughout the entire propagation process. The results are concluded as follows: (1) During the propagation of AE signals from the fracture of C fibers and SiC fibers in CMCs, most of the frequency responses are concentrated in the range of 0-50kHz. (2) The MFCC curves of the AE signals collected at different locations from the same source demonstrate that the extracted deep features exhibit good consistency. (3) The variation trends of the 24-dimensional deep features extracted from the AE signals collected at different positions are similar, demonstrating that the MFCCs can extract the invariant features in the AE signals.

MICROMECHANICAL MODELING OF THE VISCOELASTIC–VISCOPLASTIC RESPONSE OF FIBER-REINFORCED COMPOSITES

Yang Chen[1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

The demand for fiber-reinforced composites in aircraft components has been steadily increasing due to their improved mechanical properties. However, designing the mechanical properties of composite structures involves time-consuming multiscale computation. As a result, there is ongoing research focused on improving the computational efficiency of multiscale simulations for fiber-reinforced composites. Micromechanical models have shown good predictability with high efficiency when it comes to determining the effective mechanical behaviors based on the mechanical properties of the constituents and the microstructures of the composites. Therefore, these models can be used to replace the simulation of representative volume elements (RVE) in microscopy, leading to improved efficiency in multiscale computation. However, composites with a polymer matrix often exhibit strong nonlinear viscoelastic-viscoplastic responses in the transverse plane. This poses theoretical challenges when it comes to establishing micromechanical models for such composites. This work describes a newly proposed viscoelastic–viscoplastic constitutive model that is used to characterize the effective mechanical behaviors of fiber-reinforced composites based on micromechanical modeling. A homogenization approach is developed in which the effective stress of the fiber-reinforced composite is decomposed into an elastoplastic component and a viscous component. For the elastoplastic component, a bridge model is adopted to characterize the elastoplastic behaviors, while for the viscous component, homogenization theory applied to the time domain is utilized to describe the effective viscous responses. The overall stress for the composite can be obtained by superposing the stress contributions of the two components. The proposed micromechanics-based constitutive model has an explicit form, which contributes to the computational efficiency of the multiscale simulations for the composite structures. Unit cubes with 128 randomly distributed cylindrical fibers of equal size are created as the representative volume element models for numerical validation of the proposed constitutive model. The effects of fiber volume fraction, hardening law, loading condition, and strain rate are considered to comprehensively validate the constitutive model. Experimental results for IM7/8552 carbon fiber–reinforced composite were employed to validate the constitutive model. By comparing the model predictions to the experimental results and numerical observations, the constitutive model was found to provide acceptably good predictions of the viscoelastic–viscoplastic behaviors of the fiber-reinforced composites.

GPT-PINN: GENERATIVE PRE-TRAINED PHYSICS-INFORMED NEURAL NETWORKS TOWARD NON-INTRUSIVE META-LEARNING OF PARAMETRIC PDES

Yanlai Chen[1] and Shawn Koohy*[1]

[1]*University of Massachusetts Dartmouth*

ABSTRACT

Physics-Informed Neural Network (PINN) has proven itself a powerful tool to obtain the numerical solutions of nonlinear partial differential equations (PDEs) leveraging the expressivity of deep neural networks and the computing power of modern heterogeneous hardware. However, its training is still time-consuming, especially in the multi-query and real-time simulation settings, and its parameterization often overly excessive.

In this talk, we present the recently proposed Generative Pre-Trained PINN (GPT-PINN). It mitigates both challenges in the setting of parametric PDEs. GPT-PINN represents a brand-new meta-learning paradigm for parametric systems. As a network of networks, its outer-/meta-network is hyper-reduced with only one hidden layer having significantly reduced number of neurons. Moreover, its activation function at each hidden neuron is a (full) PINN pre-trained at a judiciously selected system configuration. The meta-network adaptively “learns” the parametric dependence of the system and “grows” this hidden layer one neuron at a time. In the end, by encompassing a very small number of networks trained at this set of adaptively-selected parameter values, the meta-network is capable of generating surrogate solutions for the parametric system across the entire parameter domain accurately and efficiently.

LETHALITY PREDICTION OF OSTEOGENESIS IMPERFECTA BY A STRUCTURE- AND SEQUENCE-INFORMED GRAPH NEURAL NETWORK

Yen-Lin Chen[*1], Wei-Han Hui[1] and Shu-Wei Chang[1]*

[1]*National Taiwan University*

ABSTRACT

Collagen, one of the most abundant proteins in the human body, plays a huge role in biomechanics, with its health condition greatly influencing biological performances, such as bone strength, skin elasticity, and blood vessel elasticity. Needless to say, any mutation could potentially have profound impact on the subject. Osteogenesis imperfecta (OI) is one of the rare diseases associated with mutation on type I collagen and is characterized by a reduction in bone strength. Its locus of mutation is not a single site, but any of the amino acids along each collagen molecule, which adds to the complexity of the subject. Although recent advances have made possible sequence-based lethality prediction of this disease, its low occurrence rate and large number of possible mutation sites limit the accuracy of these methods. In this work, we merged the structural features of the collagen molecule with its sequential characteristics into a single graph representation of the vicinity of the mutation site, and designed a graph neural network to interpret the lethality point mutations known to induce OI. Our method enhances the accuracy of lethality prediction in the α1 chain and simultaneously extends the prediction to mutations on the α2 chain. A Grad–CAM-based technique is then employed to explain the inferences made by our model. We anticipate the proposed method to pave the way to methods for early on diagnosis and advance our understanding of the pathology at the molecular level.

KINETIC MONTE CARLO SIMULATION OF ATOMIC DIFFUSION BEHAVIORS IN THIN FILM EPITAXY

Yu-an Chen[1], Xin-Yang Zhong[1] and Yu-Chieh Lo[1]*

[1]*National Yang Ming Chiao Tung University*

ABSTRACT

Kinetic Monte Carlo (KMC) is a kind of simulation method widely used to explore the state transitions on a large time scale. In material science, KMC is a valuable tool for studying the diffusion behaviors of atoms on the surface or inside the materials, such as surface growth and vacancy mobility. In this research, we used KMC method to study the formation of nanowires on vicinal surfaces, aiming to gain insight into the diffusion mechanisms under different conditions and to find the optimal experimental parameters for growing nanowires with large aspect ratios. In addition to showing how to write KMC programs that can be applied to epitaxy simulations, we also tried to improve its shortcomings, turning it into a novel KMC framework called “on-the-fly KMC”. Therefore, the final part of this study demonstrates the introduction of an "on-the-fly" algorithm in the classical framework. The first part involves utilizing the Nudged Elastic Band (NEB) method to calculate energy barriers for different events. To enhance program efficiency, the second part involves using these events to train a machine learning model. Ultimately, machine learning methods are employed to complete the simulation results of epitaxial growth of thin films. The study also discusses some obstacles we may encounter in the future and potential directions for future development.

COHESIVE CRACK PROPAGATION MODELING BASED ON THE SELF-STABILIZED VIRTUAL ELEMENT METHOD WITH AN ELEMENT SPLIT STRATEGY

Yujie Chen[1,2], Umberto Perego[2] and Qun Li[1]*

[1]*Xi'an Jiaotong University*
[2]*Polytechnic University of Milan*

ABSTRACT

The Virtual Element Method (VEM) [1] does not require geometry mapping, allowing for arbitrary element shapes, not necessarily convex, free of distortion sensitivity. Thanks to these features, especially the flexibility in element shapes and mesh definition, the VEM is particularly suitable for simulating crack propagation in arbitrary directions through the elements. Following the mixed approach proposed in [2], a linear strain model is adopted to obtain an initially self-stabilized model and a more accurate stress field.

In this work, a 2D mixed-mode fracture evolution model is established based on the mixed-VEM coupled with cohesive interface elements, considering two different linear strain models. The crack propagation direction is determined based on the maximum principal stress direction. The linear stress field around the crack tip is smoothed across adjacent elements by a patch recovery technique. The crack is allowed to propagate through a Virtual Element (VE) by adding to the element at least one node and two edges (element-split strategy, see e.g. [3]) separated by a cohesive interface element. The non-convex mixed-VE which is obtained in this way requires a specific stabilization. Both mode-I and mixed-mode numerical examples are simulated, allowing cracks to propagate through the VEs. The crack paths and the force-displacement curves obtained with the proposed model, based on the element-split strategy, show good agreement with the experimental results. These examples and results validate the accuracy and computational efficiency, especially in terms of mesh management, of the present VEM-based fracture evolution model.

ABSTRACT

Abstract
Composites have been a material of interest in the aerospace industry because of their superior properties such as high strength-weight ratio and exceptional thermal stability. Understanding the nonlinear process of fracture and damage formation is crucial for enhancing the mechanical performance of these materials. The conventional approach, leveraging finite element methods (FEMs) for damage prediction, encounters limitations. These include the necessity for accurately defined constitutive models and extensive mesh refinement, which often result in computational inefficiencies and potential inaccuracies in complex fracture scenarios. Recent advances in scientific machine learning have opened avenues for more efficient fracture pattern prediction methodologies. For example, a recent data-driven model by Sepasdar et al. [1], employing a deep learning framework with two stacked fully convolutional networks, successfully predicts post-failure stress distribution and failure patterns in composites. However, its static nature limits its application in scenarios where understanding the evolution of fracture patterns prior to ultimate failure is crucial. To bridge this gap, we introduce an innovative approach utilizing MeshGraphNets (MGN), developed by Pfaff et al. [2], for progressive fracture analysis. MGN, operating on a graph neural network architecture designed for mesh-based simulations, employs an Encode-Process-Decode framework. This framework begins with an encoding phase, where the input mesh is transformed into a graph representation. The processing phase then involves iterative message-passing algorithms, updating node and edge embeddings to capture the evolving stress-field dynamics. The decoding phase extrapolates these embeddings to update and predict subsequent mesh configurations, reflecting the progressive fracture patterns. The proposed model is applied to a longitudinal carbon fiber-reinforced polymer (CFRP) composite, selected for its relevance in high-performance aerospace applications. We evaluate the model's efficacy in predicting progressive crack patterns and the full-field von Mises stress distribution over time, offering a significant improvement over traditional methods in computational damage mechanics. The results show the potential to advance the predictive modeling of progressive damage processes in advanced composites.

GRAPH OSCILLATORS: PHYSICS-GUIDED GRAPH MODELING OF MASS-SPRING-DAMPER SYSTEMS FOR TRAJECTORY PREDICTION AND DAMAGE LOCALIZATION

Zhao Chen[*1], Nan Wang[2] and Hao Sun[3]*

[1]*Southeast University*
[2]*Northeastern University*
[3]*Renmin University of China*

ABSTRACT

Recognizing that a multiple-degree-of-freedom mass-spring-damper system can be viewed as a group of connected nodes, this work presents a novel computational framework that learns such coupled oscillations by a graph, a mathematical structure describing pairwise connections between objects. Further reinforced by an incomplete equation of motion, distributed neural networks and an anti-symmetric coupling constraint, we can learn unknown coupling mechanisms (or nodal interactions in the language of graph models) using limited data. The proposed physics-data-hybrid method demonstrates a promising predictive capability even for unseen control inputs, outperforming three black-box and grey-box counterparts in synthetic and experimental studies. In addition to its predictive capability, the distributed parameterization of nodal interactions allows us to identify local anomalies by evaluating updates after short transfer learning. While limits of the current method exist, it displays the potential of a generalizable and interpretable meta-model for predicting nonlinear trajectories and identifying the system's status.

ENGINEERING POROUS COMPOSITES AGAINST IMPACT WITH PARTICLE METHODS

Zhen Chen[1]*

[1]*University of Missouri*

ABSTRACT

The responses of porous composites to impact loading play an important role in optimizing blast/impact-resistant design scenarios, which have been investigated with different spatial discretization methods at different scales. Molecular dynamics (MD) and the finite element method (FEM) are representative discrete particle and continuous methods, respectively. The Material Point Method (MPM) is a continuum-based particle method that is formulated based on the weak form of the governing equations in a way like the FEM. A challenging task is how to verify and validate multiscale shock responses because impact experiments are limited in spatial nanoscale while nanoscale experiments are limited in high loading rates. Based on the recent research results [Saffarini et al., 2023; Su and Chen, 2023], we are performing a comparative study of shocked porous composite responses with MD and different versions of MPM [Su et al., 2024]. Essential features of the responses at the same spatial scale as obtained with both discretization procedures will be presented in the conference for representative composite systems under impact loading. It appears from the investigation that the MD and MPM solutions are consistent at the same scale. Thus, it become feasible to compare the MD and MPM solutions for verification in multiscale simulation of impact responses. The verified MPM solutions will then be validated against macroscale impact experiments. Future tasks will be discussed to improve the proposed procedure for engineering porous composites against impact loading with particle methods.

ABSTRACT

With the advancement of Large Language Models (LLM) and the emergence of humanoid robots, there is an increasing demand for robots to perform complex tasks involving objects with diverse characteristics. Anthropomorphic robotic hands with a high degree of freedom have become a prominent solution in addressing this challenge. However, achieving both high dexterity and structural simplicity in hand manipulation remains extremely challenging due to current hardware limitations. To address this inverse design issue, this paper proposes a fully automated design method for anthropomorphic robotic hands that can handle uncertain clamped targets. We employ neural networks to predict the possible positions of objects and their feature points within the workspace, enabling us to generate potential finger trajectories for anthropomorphic robotic hands based on these predictions. Finally, we do optimized structure after generating of anthropomorphic robotic hands structure based on the fitting of this predict trajectory. However, the linkage group in the finger of anthropomorphic robotic hands exhibits distinct nonlinear dynamics due to variations in linkage lengths and combination methods. The conventional dynamics process is intricate and challenging to optimize. In this paper, a genetic algorithm is proposed for determining the optimal length of the connecting rod that aligns with the predicted trajectory, enabling identification of individual rod lengths and the best matching mode of linkage groups. Subsequently, these parameters including length and composite mode are incorporated into 3D software to facilitate automated design of an anthropomorphic robotic hand. Finally, using commonly encountered real-life objects as examples, this method is employed for optimization and anthropomorphic robotic hands design after topology those objects; subsequently comparing it with existing release hand schemes validates its effectiveness and superiority.

Advanced computational modelling of wood, wood-based products, bio-composites, and timber structures

CONSTITUTIVE MODELLING OF WOOD-BASED MATERIALS

Zhiyong Chen[1]*

[1]*FPInnovations*

ABSTRACT

Computer modelling is an essential part in the analysis and design of residential and commercial buildings. It is also a valuable tool in the development and optimisation of wood-based products, connections, and systems. The global interest for use of wood-based products as structural and non-structural components in high-rise and long-span structures is gaining momentum, due to their sustainability and low carbon footprint. A survey shows that practicing engineers are typically unfamiliar with timber structure modelling, and researchers generally lack resources for advanced modelling of timber systems. Recently, a first-of-its-kind modelling guide for timber structures has been developed by more than 100 global experts [1]: web.fpinnovations.ca/modelling, for supporting the application of numerical modelling on analysis and design of timber structures, and development and optimisation of wood-based products and systems.

Wood, unlike steel and concrete, is an anisotropic material. Because of its inherent characteristics, the mechanical behaviour of wood depends on the direction of the grain and the load type. The mechanical properties of wood change as temperature, moisture, and loading time change. Moreover, growth characteristics such as slope of grain and knots significantly affect the mechanical behaviour of wood-based products. Appropriate material models are the fundamental basis of reliable simulations. The constitutive models incorporated in existing general design software packages are often limited, making the software unsuitable for accurately predicting the mechanical behaviour and failure modes of wood-based materials.

In this paper, a comprehensive constitutive model, composed of sub-models for describing the elastic properties, strength criterion, post-peak softening for quasi-brittle failure modes, plastic flow, and hardening rule for yielding failure modes, and densification perpendicular to grain, will be introduced. Modelling considerations on the effects of temperature, moisture content, and loading time will be discussed. Advanced and practical modelling methods and key considerations for wood-based products will be introduced, aiming to support practicing engineers and researchers to become better acquainted with modelling and analysing timber structures.

THERMALLY-INDUCED FRACTURE IN THE OXIDE SCALE OF T91 FERRITIC/MARTENSITIC STEEL AFTER EXPOSURE TO OXYGEN-SATURATED LIQUID LEAD-BISMUTH EUTECTIC

Yunpeng Liu[1], Chenwen Tian[1], Zhikun Zhou[1] and Ziguang Chen[1]*

[1]Huazhong University of Science and Technology

ABSTRACT

Ensuring the continuity and stability of the oxide scale to separate T91 steel from lead-bismuth eutectic (LBE) is an effective method for limiting corrosion in the lead-based fast reactor system. In this study, we specifically investigated the impact of cooling thermal stress on the stability and damage of the oxide scales of T91 steel when exposed to oxygen-saturated liquid lead-bismuth eutectic at high temperatures. A corrosion test was conducted on T91 steels exposed to stagnant oxygen-saturated LBE at 500 °C. Experimental results indicated that oxide damage exists without external force, including interface cracks and through-scale cracks perpendicular to the interface. We developed a three-layer peridynamic model of T91-(Fe,Cr)3O4-Fe3O4 to simulate the deformation and failure of oxides under a cooling process from high temperature to room temperature. The simulation results show that a temperature drop of about 200 °C from 500 °C can cause through-oxide cracks in the oxide scale, and subsequent cooling can lead to the propagation of interfacial cracks. Additional modifications were introduced in the model to account for the porosity of the oxide scale. Parametric investigations illustrate the effects of oxide scale thickness and porosity on the resulting crack patterns.

PARAMETRIC ANALYSIS AND DESIGN FOR IMPACT PROTECTION BASED ON FINITE LOCALLY RESONANT METAMATERIAL ARRAYS

Weidi Wang[1], Willoughby Cheney[1], Erdem Caliskan[2], Reza Abedi[2] and Alireza Amirkhizi[1]*

[1]University of Massachusetts Lowell
[2]University of Tennessee

ABSTRACT

Locally resonant mechanical metamaterials (MM) have long attracted research interest due to their rich dynamical behavior and application potential in controlling stress wave propagation. This study analyzes the dynamic response of locally resonant metamaterials under impact loadings and aims to identify optimal MM systems for impact mitigation, with specific considerations on the effect of loadings and boundaries. Traditional studies focus on the properties of periodic systems through idealized periodic setups such as eigenfrequency study and frequency domain scattering analysis. While these intrinsic properties encode important information such as band gaps and wave speeds, they can only predict the scattering response to a certain extent in real world or experimental cases. The effects of domain size, loading, and boundary conditions are as important for understanding the extrinsic behaviors and are vital factors for designing applications with finite metamaterials. To this end, a parametric study is carried out to analyze the energy transfer characteristics, as well as the effects of projectile geometry and material parameters, boundary environment, and the MM design. A multi-fidelity approach incorporating a reduced order model and finite element method is employed to accelerate the computation. The parametric and sensitivity analysis reveals design principles for maximizing MM performance given a loading condition, and also shed lights on developing proper experimental setups that can best highlight and demonstrate the metamaterial behaviors.

DATA DRIVEN PAM-4 MODELING WITH GENERATIVE NETWORKS

Priyank Kashyap[1], *Chris Cheng**[1] *and Yongjin Choi*[1]

[1]*Hewlett Packard Enterprises*

ABSTRACT

Data-intensive applications such as artificial intelligence and graph processing require fast data rates to enable edge applications. To that extent, PAM-4 aims to alleviate the present binary or NRZ data transmission issues. As the name suggests, PAM-4 contains 4 distinct logic levels whereas NRZ has 2, enabling it to send double the data of NRZ for the same transmission speed. Using 4 distinct logic levels reduces the noise margin available to recover a symbol; thus, there is a need for accurate simulations during the design process. However, simulations for high-speed receivers work assuming the channel is LTI, leading to overly optimistic results. Further, the receivers contain complex filters to counteract channel impairments to recover the data successfully.

This talk/paper presents a measurement-driven approach for modeling a high-speed PAM-4 receiver. The approach uses conditional generative networks (cGANs), enabling us to create a digital twin of the receiver. The digital twin considers random bitstreams, complex filter settings, and channel conditions containing crosstalk. Though model training is a traditional black box model, we integrate domain knowledge as bathtub curves at different time intervals to improve accuracy.

Once trained, we demonstrate that the model takes under 300 ms to perform inference, which is over 40 times faster than the device connected to a scope. To show the advantage of such a digital twin, pass in a random waveform and use the digital twin as a fast-to-evaluate surrogate to optimize the eye openings. Lastly, we show that the latent space of digital twins based on GANs has physical meaning regarding channel loss and enables the identification of previously unseen cases.

ADVANCING ONLINE PREDICTIONS IN LASER POWDER BED FUSION: A SCIENTIFIC DEEP LEARNING APPROACH INTEGRATING IN-SITU MONITORING DATA WITH MELT POOL SIMULATIONS

Lin Cheng[*1] and Yunhao Zhang[1]*

[1]*Worcester Polytechnic Institute*

ABSTRACT

The employment of in-situ monitoring systems in laser powder bed fusion manufacturing has shown potential in tracking and adjusting process parameters. However, existing systems, such as electric sensors and cameras, face significant interference from harsh environmental factors like high temperatures and evaporation plumes, limiting their ability to accurately capture melt pool evolution. While physics-based simulations offer detailed insights into melt pool dynamics, their high computational costs and extensive calibration requirements render them impractical for real-time monitoring and control. This study introduces a scientific deep learning (Sci-DL) model designed to reconstruct 3D melt pool evolution by integrating multi-modal in-situ data with high-fidelity simulations. The model leverages an encoder-decoder architecture, employing convolutional neural networks for image segmentation and feedforward neural networks for universal approximation. To ensure physical accuracy, the model incorporates governing equations of mass and heat transfer, directing the learning process to align with actual physical phenomena. This integration ensures that the prediction is reliable and robust. With extensive offline training, the Sci-DL model allows real-time 3D visualization of the melt pool evolution during the process and potentially enables online control of the manufacturing process. We demonstrate the model's effectiveness in full-field melt pool recovery with several numerical examples, showcasing its ability to efficiently process various combinations of process parameters using limited data.

A SIMPLIFIED ROBUST DIFFUSION INTERFACE MODEL FOR ELASTIC SOLID-FLUID INTERACTION

Yi Cheng[*1], Yiqing Shen[1], Baolin Tian[2] and Li Li[2]*

[1]*Chinese Academy of Sciences*
[2]*Institute of Applied Physics and Computational Mathematics*

ABSTRACT

The Eulerian elastic solid-fluid diffusion interface model has been applied to simulate the interaction between elastic solids and fluids. However, there still exists several challenges, for example, the calculation of deformation gradient tensors for each component is computationally expensive, the robustness for dealing with non-conservative volume fraction equation needs to be improved. In this paper, we propose a novel approach that combines a simplified deformation gradient tensors equation with the pressure non-equilibrium six-equation diffusion interface model. First, a common deformation tensor with deviatoric elastic strain equilibrium is suggested to simplify the calculation. Furthermore, a pressure relaxation process is used to achieve pressure equilibrium. The Mie-Gruneisen equation-of-state is adopted as the constitutive equation, and the HLLD Riemann solver is utilized to compute the numerical fluxes. Interfaces are sharpened by the THINC method with the MUSCL reconstruction. The third-order TVD Runge-Kutta method is employed for the hyperbolic time step. The variables are updated by hyperbolic time steps and pressure relaxation steps. The effectiveness and robustness of the model are validated through a series of numerical examples involving solid-fluid interaction, including solid-solid Riemann problems and high-pressure gas-solid interaction.

Key words: diffusion interface model, solid-fluid interaction, pressure non-equilibrium

INTERFACE LOCALIZATION-BASED EFFICIENCY ENHANCEMENT ON PARAMETRIC VARIATIONS OF LARGE-SCALE DYNAMICAL SYSTEMS WITH MULTIPLE SUBDOMAINS

Seunghee Cheon[*1] and Jaehun Lee*[1]

[1]*Dongguk University*

ABSTRACT

While the computational approach can leverage efforts to solve various scientific and engineering problems, real industrial engineering applications still require substantial computational resources. For this reason, parametric reduced-order modeling (PROM) approaches have been actively developed for several decades. To achieve efficient computation for these complication systems, the conventional PROM adopts ROM adaptation consisting of the offline and online stages. In the offline stage, the reduced systems are constructed with respect to defined operating points for rapid response of parametric variations performed in the online stage. It is inevitable to consume significant computation for this offline stage data construction. As a solution for the efficient sampling stage, component mode synthesis (CMS) [1] has been suggested for real-world applications involving multiple subcomponents. Based on the concept of domain decomposition, the number of constructed samples is considerably reduced by comparison to full system sampling due to subdomain independence. In addition, the reduced sample systems could be considered in much smaller scale.

Despite the aforementioned benefits of CMS, the interface where is for subdomain synthesis is fully retained without reduction. For sufficient model reduction user aiming, interface reduction [2] is an essential consideration for studies related to CMS. The conventional parametric CMS [3] performs secondary eigenvalue analysis in the online stage. This additional computation, requiring greater computational resources than other basic computations, hinders near real-time operation under multi-query systems. To achieve a highly reduced system without concerning the online stage computation, reduced interface sampling is proposed in this study. Based on the conventional parametric CMS, the solution of the new input parameter is derived by interpolating pre-computed reduced subsystems and interface reduction bases. Additionally, an interface discrimination algorithm is also presented to construct interface samples in semi-localized level. As a result, rapid response for parametric variations is allowed with an affordable amount of offline computation.

OPTIMAL DESIGN OF VEHICLE DYNAMICS USING GRADIENT-BASED, MIXED-FIDELITY MULTIDISCIPLINARY OPTIMIZATION

Hyunmin Cheong[*1], Mehran Ebrahimi[1], Hesam Salehipour[1], Adrian Butscher[1] and Alex Tessier[1]*

[1]*Autodesk*

ABSTRACT

In automotive engineering, designing for optimal vehicle dynamics is challenging due to the complexities involved in analyzing the behavior of a multibody system. Typically, a simplified set of dynamics equations for only the key bodies of the vehicle such as the chassis and wheels are formulated based on reduced degrees of freedom [1]. In contrast, one could employ high-fidelity multibody dynamics simulation and include more intricate details such as the individual suspension components while considering full degrees of freedom for all bodies; however, this is more computationally demanding. Also, for gradient-based design optimization, computing adjoints for different objective functions can be more challenging for the latter approach [2], and often not feasible if an existing multibody dynamics solver is used.

We propose a mixed-fidelity multidisciplinary approach, in which a simplified set of equations is used to model the key vehicle dynamics while incorporating a high-fidelity multibody suspension module as an additional coupled discipline. We then employ MAUD (modular analysis and unified derivatives) [3] to combine analytical derivatives based on the dynamics equations and finite differences obtained using an existing multibody solver. Also, we use a direct collocation method for time integration, which solves for both the system trajectory and optimal design variables simultaneously. The benefits of our approach are shown in an experiment conducted to optimize vehicle parameters for both handling and ride comfort. In summary, the current work demonstrates that a gradient-based, mixed-fidelity multidisciplinary design optimization approach provides a scalable solution for tackling a complex vehicle dynamics application.

MODELING TIME-VARYING PORT-HAMILTONIAN SYSTEMS

Karim Cherifi[*1], Hannes Gernandt[2], Dorothea Hinsen[1], Volker Mehrmann[1] and Riccardo Morandin[1]*

[1]*TU Berlin*
[2]*Wuppertal University*

ABSTRACT

As technology advances and engineering challenges become increasingly complex, the need for robust mathematical frameworks to describe and control dynamic systems is more pressing than ever. Port-Hamiltonian modeling, with its emphasis on energy-based formalism [1], provides a powerful paradigm for understanding the inherent structure of physical systems, especially those characterized by nonlinearity and time variability.
Port-Hamiltonian systems are based on the concepts of passivity and nonnegativity in a more structured way. We will explore the relation between those properties and the solution of the Kalman-Yakubovich-Popov (KYP) inequality that is used for the characterization of passivity [2]. In addition, a port-Hamiltonian formulation is presented for time-varying systems.
The main goal of this work is to represent time-varying systems in a structured and psychically meaningful way within the port Hamiltonian framework while achieving good numerical results. In this direction, we present preliminary results on structure-preserving model reduction using Galerkin projection. This results in a more concise representation that can then be used in industrial
applications.
Finally, we show how this formulation is used to model real world applications and how the port-Hamiltonian framework can be used to model nonlinear and time varying systems.

CONSTITUTIVE MODELING OF THE MULLINS EFFECT IN FILLED RUBBER-LIKE MATERIALS

Shawn Chester[*1] and Keven Alkhoury*[1]

[1]*New Jersey Institute of Technology*

ABSTRACT

Filled rubber-like materials are widely used in engineering applications and are known to exhibit a rate-dependent non-linear inelastic behavior and stress-softening, also known as Mullins effect, is frequently encountered. In this work, we characterized and modeled the constitutive response of a handful commercially available filled rubber-like materials. We first perform a set of large-deformation uniaxial experiments at room temperature and at multiple rates. Those experimental findings are used to develop and calibrate a thermodynamically consistent constitutive model, which is then numerically implemented in a finite element package by writing a user material subroutine. The constitutive model is validated by comparing the results of an inhomogeneous experiment and simulation. A key finding of this work is that the mechanisms that cause the Mullins effect appear to be the main drivers of viscoelasticity.

ACCELERATING PHYSICS SIMULATIONS WITH LIBROM

*Siu Wun Cheung**[1]

[1]*Lawrence Livermore National Laboratory*

ABSTRACT

In decision-making applications, such as parameter study, design optimization, optimal control, and inverse problems, we need to repeatedly solve forward problems. However, subject to the model complexity and the discretization fineness, it may take a long time to complete a single forward simulation with even advanced computing capabilities. Reduced order modeling (ROM) has nowadays become a popular and actively researched computational technique to reduce the computational cost of simulations while minimizing the error introduced in the reduction process. In this talk, we will present recent development of various ROM techniques in the open-source software of libROM, including projection-based nonlinear model reduction, non-intrusive system identification, and indicator-based and interpolation-based local reduced order models. We will demonstrate the capability of libROM to enable accelerated prediction of complex dynamical processes, namely Sedov blast wave, triple-point expansion, Rayleigh-Taylor instability, pore collapse, laser ray tracing, and molecular dynamics.

MODELING PHASE-TRANSFORMATION INDUCED STRAIN LOCALIZATION USING A NEURAL NETWORK ENHANCED REPRODUCING KERNEL PARTICLE METHOD

Xuejun Li[1] *and Sheng-Wei Chi**[1]

[1]*University of Illinois at Chicago*

ABSTRACT

Reproducing Kernel Particle Method (RKPM) has demonstrated its proficiency in solving problems with extreme strain rates and severe material distortion, especially with the semi-Lagrangian (SL) formulation [1]. However, introducing the discontinuity in the approximation that captures heterogeneity, fracture, or strain localization remains challenging and lacks computational efficiency. Meanwhile, the application of Machine Learning (ML) has gained much attention in computational mechanics, e.g., solving elasticity problems with Physical-Informed Neural Network (PINN). Nevertheless, solving the equation solely by Neural Network (NN) without the aid of the existing numerical method may suffer from low efficiency and convergence issues. Therefore, incorporating NN to enhance the current numerical method, such as RK, has been proposed. A designated NN has been integrated into the RK approximation to enrich the discontinuity locally [2]. On the other hand, specific weights and biases can be derived to represent the analytical forms of the shape function in some well-known numerical methods, such as the Finite Element Method (FEM) [3]. Optimized relocation of the nodal points can also be accomplished to best produce the localized behavior within the minimum computation cost. In this research, a Neural Network (NN) based algorithm that utilizes specifically designed NN blocks to reproduce desired shape functions for the approximation is proposed and developed to better capture the localized behavior in the vicinity of the discontinuity in elasticity problems. Some additional improvements, such as the adaptive nodal refinement, can be made to augment the local behavior of discontinuity further. A set of benchmarks, including fracture process and strain localization due to phase transformation, is utilized to evaluate the proposed method's effectiveness in handling discontinuity in the solution of elasticity.

UNVEILING GAS-LIQUID METAL REACTIONS IN METAL ADDITIVE MANUFACTURING USING HIGH-FIDELITY MODELING VALIDATED WITH EXPERIMENTS

Hou Yi Chia[*1], Yanming Zhang[1], Lu Wang[1] and Wentao Yan[1]*

[1]*National University of Singapore*

ABSTRACT

Gases in the atmosphere inevitably react with the melt pool during metal additive manufacturing (AM). Oxygen is particularly reactive and excessive uncontrolled oxidation is detrimental, so most machines purge the chamber with inert gases, which can minimize but not eliminate such reactions. Alternatively, some users exploit the gas–liquid metal reactivity as an opportunity to introduce beneficial precipitates into the melt pool (“reactive AM”). However, the gas–liquid metal reaction and mechanisms in both scenarios remain unclear. Experimental works hitherto provide different explanations to the same phenomena. Therefore, this work seeks to clarify the mass transfer process of oxygen during metal AM through high-fidelity modeling by considering the competition between diffusion and chemical reaction, suboxide evaporation, and the influence of the vapor plume. The simulation results, validated with experiments, provide consolidated insights into the oxygen evolution behavior during metal AM. Counterintuitively, higher melt pool temperatures do not necessarily lead to greater oxidation rates during processing. The melt pool has regions of high and low oxygen gains due to temperature-dependent reaction regimes, with concurrent oxygen loss from evaporation of metal suboxides. Thus, the net oxygen flux varies for different materials, and the oxygen content cumulatively changes as multiple tracks are scanned. Overall, this work provides useful guidance to AM community that seek to ameliorate or exploit the inevitable gas–liquid interaction in metal AM. Cost-saving measures may be possible for determining the purity of shielding gas used in AM, and physics-guided measures can be taken to limit or control gas–liquid metal reactions.

MICROSTRUCTURAL DEFECTS AND LENGTH-SCALE PROBLEM INVESTIGATION OF AM ALLOYS

Edwin Chiu[*1], John Emery[1], Kyle Johnson[1], Kyle Karlson[1], Thomas Ivanoff[1] and John Mitchell[1]*

[1]Sandia National Laboratories

ABSTRACT

The gap between the engineering and microstructural length-scales in additive manufactured (AM) alloys is a challenging obstacle to connecting laboratory analysis with qualification of components. Defects in AM engineering alloys have been observed and well documented and include lack of fusion porosity, gas entrapped porosity, irregular grain shapes and textures, entrapped oxides, grain boundary precipitates, etc. This causes part to part variability in ultimate strength and ductility, making it difficult to qualify built parts. There is a growing literature on the impacts of these microstructural defects explicitly or otherwise in engineering-scale calculations to predict performance. However, bridging the studies of large-scale component and parts with these microstructural studies remain a difficult topic not yet sufficiently explored. With the advancement of AM processing techniques leading to repeatability of certain mechanical and microstructural bulk characteristics, the importance and accessibility of research in this field are of interest and necessity.

In this presentation we study these phenomena using synthetic microstructures generated with the Monte Carlo code SPPARKS [1]that include realistic grain morphology and texture. Our effort focuses on an AM aluminum alloy, and it is informed by data from high fidelity experimental characterization of the material and pursuant performance. This data-driven approach is part of a broader effort to connect the microstructural length-scale to the engineering length-scale for component qualification calculations. We will discuss observations regarding mesh-to-microstructure size ratio, data acquisition methods, and modified boundary conditions necessary to form reliable representative volume element (RVE) models in the presence of strong gradients. We will also report on the comparison of prediction accuracy/reliability of said method and influence of microstructural features known to impact AM component performance.

ARTIFICIAL NEURAL NETWORK FOR THE QUALIFICATION OF DIRECT ENERGY DEPOSITION PROCESSES

Michele Chiumenti[*1], Timothy Herzog[2], Carlos Augusto Moreira[1], Andrey Molotnikov[2], Manuel Alejandro Caicedo[1], Runeal Ramma[2] and Miguel Cervera[1]*

[1]*International Center for Numerical Methods in Engineering (CIMNE)*
[2]*RMIT - Centre for Additive Manufacturing*

ABSTRACT

The objective of this work consists of the development and implementation of an Artificial Neural Network (ANN) for the process optimization of metal Additive Manufacturing (AM) by Direct Energy Deposition (DED).

The in-house software Add2Man developed at CIMNE for the numerical simulation of the AM-DED thermomechanical process is used to analyze the temperature evolution, the melt-pool morphology, and the microstructure features during manufacturing and the following cooling phase. The software is prepared for parallel computing in distributed memory (clusters) and makes use of the most advanced techniques of adaptive meshing (AMR) to ensure the best performance and the highest accuracy.

The novelty proposed in this work consists of taking advantage of Machine Learning (ML) to provide artificial intelligence (AI) to the DED manufacturing process, allowing for the optimization of the process parameters such as the power input, the printing speed, or the dwell time among layers. By adopting for the software the same input as for the DED machines (G-code format), it is possible to faithfully reproduce the power delivery of the laser along its path, as well as the cooling during repositioning pauses, waiting times, etc. The melt-pool volume is used to continuously monitor and modulate the process parameters. In this way, it is intended to add an active and automated control to AM manufacturing, qualifying this technology for its adoption and integration in the industrial manufacturing chain.

HYPER-RESOLUTION AND 3D COMPONENT INFERENCE OF FLOW FIELDS IN VENTRICULAR GEOMETRIES USING NEURAL NETWORKS

Marcello Mattei[1], Mackenzie Meni[1], Arianna Issitt[1], Elizabeth Christ[1], Ryan White[1] and Venkat Keshav Chivukula[1]*

[1]Florida Institute of Technology

ABSTRACT

Purpose of Study: Intraventricular blood flow is strongly 3-dimensional, but imaging modalities like ultrasound can only capture one direction, is low-resolution and noisy. We created a pipeline that uses neural networks (NN) to (i) apply hyper resolution to a single component of velocity acquired with simulated ultrasound data, and (ii) predict the remaining two orthogonal velocity components in high resolution to obtain the complete 3D hemodynamic patterns
Methods: A virtual dataset of 47 different intraventricular flow profiles for different anatomical left ventricle (LV) geometries implanted with LVAD was generated by via computational fluid dynamics (CFD) simulations in ANSYS Fluent. These 3D high resolution flow profiles were randomly sampled to 5% of their data density to simulate noisy, low-resolution data (such as from ultrasound). The ground truth high resolution data and the low-resolution data were interpolated and padded into 100x100x100 regular grids. A 3D convolutional U-Net NN was developed to map the sparse flow profile of a single component to a full-resolution detailed profile for the same single component. Two secondary NNs of similar architectures were trained to map the hyper-resolution single component profile to the two remaining flow directions in high resolution. 40 flow profiles were used to rigorously train the networks, reserving the rest for testing. Training was performed using a custom loss function incorporating 3D geometrical features from each model and known fluid flow physics. The resulting high-resolution predictions were interpolated back into their original LV space for prediction evaluation and post processing to visualize the hemodynamic patterns.
Results And Conclusions: Our network pipeline successfully reconstructed ventricular flow profiles from low-resolution single components. The hyper-resolution network expanded low resolution components with good agreement between the flow patterns predicted and the ground truth data. Furthermore, the secondary network predicted the other two velocity components successfully. The 3D profile resulting at the end of our pipeline from hyper resolution and component inference was compared with CFD ground truth, showing good agreement in the predicted patterns of the flow, velocity gradients and as well as in its magnitude. Prediction time for each of our NNs was less than 0.25 seconds for a 3D spatial resolution of up to 1 million datapoints per geometry, allowing for near real-time resolution of 3D vectors from a single component in a high-detailed space. Our methodology introduces a novel approach for rapidly expanding three dimensional velocity fields from low-resolution one-dimensional components for hemodynamic evaluation.

[3]*Hyundai Motor Company*

ABSTRACT

With advancements in eco-friendly electric hydrogen/propulsion and autonomous systems, the field of advanced air mobility, including electric vertical take-off and landing aircraft, drones, vehicles, and other transportation forms, has the potential to transform the aviation industry and future mobility. As technology and research in future mobility progress, there is a growing interest in assessing the environmental impact, particularly the noise from propulsion systems, which significantly affects boarding comfort and human well-being. Therefore, effective noise control is crucial to ensure safety, provide boarding comfort, and integrate these transportation systems sustainably with a quiet interior environment. In this study, we propose a novel approach to the pipeline in the algorithm for active noise control by training a time series neural network for predicting vibroacoustic characteristics using real-world vehicle test data. Then, we investigate the potential application of this approach in active noise control (ANC) techniques aimed at creating an anti-noise signal to cancel out the target noise signal, ensuring a quieter interior environment. The main key of our framework is predicting noise signals using acceleration signal inputs, specifically at the main vibration transmission path in nonlinear road noise environments. Moreover, to address limitations in existing recurrent neural networks, an Inception network is newly introduced, simplifying the architecture to ensure authentic, on-road conditions shape the findings and conclusions. The proposed framework is evaluated using real-world driving test data, reflecting actual conditions such as road surfaces, driving conditions, ambient noise, and vehicle nonlinear structural dynamics characteristics.

NONLINEAR NATURAL ELEMENT METHOD FOR FUNCTIONALLY GRADED GRAPHENE-REINFORCED SHELL-LIKE COMPOSITE STRUCTURES

Jin-Rae Cho[1]*

[1]*Hongik University*

ABSTRACT

Functionally graded (FG) composite structures reinforced with graphene platelets (GPLs) or carbon nanotubes (CNTs) have been spotlighted as a state-of-the-art structural element in variuous engineering fields due to the excellent properties and the functional designability. For the successful use of these FG nanocomposites, the intensive research activities have focused on the investigation of their mechanical behaviors. However, most studies were focused on the analytical investigation of linear responses of beam- and plate-like structures.

In this context, the current study intends to develope an effecitve and reliable nonlinear numerical method for analyzing the FG graphene-reinforced shell-like nanocomposite structures. But, the curved neutral surface of shell-like structures makes the mathematical derivation more painstaking and the numerical accuracy more difficulty to secure against the numerical locking. Moreover, these nanocomposites are heterogeneous such that both carbon particles and pores are mixed up in the matrix with the specific volume fraction (VF) pattern. And, these VF patterns significanlty affect the neutral surface location and the resulting stiffness matrix.

These nanocomposites are modelled by the VF-based homogenization, and their displacements are expressed by the shear deformation shell theory with the von-Kármán nonlinearity. And, the nonlinear numerical method was developed in the framework of 2-D planar natural element method (NEM), a meshfree method characterized by high-smooth interpolation functions. A geometry transformation between the curved shell surface and 2-D planar NEM grid is introduced to relax the painstaking mathematical job and the troublesome grid distorsion problem. The transverse shear strains are stably interpolated at the tying points to suppress the numerical locking. The nonlinear stiffness matrix is derived by introducing a partial differential operator B_NL and solved by the associated nonlinear iterative schemes.

The developed nonlinear NEM is verified by comparing with other existing solutions, and its dependence on the key factor such as the porosity pattern is examined. As well, the nonlinear behaviors of FG nanocomposite structures such as nonlinear vibration are investigated and discussed.

ACKNOWLEDGEMENTS: This presentation is dedicated to the memory of Professor J. Tinsley Oden to celebrate his lifetime contributions to the computational mechanics. This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (RS-2023-00240618).

STOCHASTIC DESIGN SENSITIVITY AND OPTIMIZATION OF THERMAL CONDUCTIVITY OF GRAPHENE USING LINEAR RESPONSE THEORY

Song-Hyun Cha[1], Youmie Park[2] and Seonho Cho[*1]*

[1]Seoul National University
[2]Inje University

ABSTRACT

We obtained the optimal design for the minimal thermal conductivity of graphene by locating isotopes and antidots in the graphene using a gradient-based design optimization method, which requires a stochastic design sensitivity. Due to the divergent characteristics of the design sensitivity analysis in transient dynamics, however, a direct computation of design sensitivity often fails in long time simulations. Thus, the required stochastic design sensitivity is obtained using a linear response theory.

The linear response theory observes the probability variations with small change of Hamiltonian systems near thermodynamic equilibrium. We obtained the stochastic design sensitivity from linear response theory with variation of design parameters. The computed design sensitivity provides reasonable values compared with averaged finite difference results even though long-time simulations. The linear response theory observes the probability variations with small changes of Hamiltonian system near thermodynamic equilibrium.

We obtained the stochastic design sensitivity from the linear response theory with the variation of design parameters. The developed method for stochastic design optimization is employed to reduce the thermal conductivity of graphene. Thermal conductivity is determined via the Green-Kubo expression. The obtained optimal structure is an aperiodic isotope superlattice structure with the antidots located at interfaces. It turns out that the thermal conductivity of the optimal graphene is reduced by 74.5% of the pristine graphene. In general, the acoustic phonons and the low-frequency optical phonons in dispersion curves have a significant impact on the thermal conductivity. Also, the slope of the phonon curves account for the group velocity. We notice that the slopes of the acoustic phonons and the low-frequency optical phonons get decreased as the design optimization progresses. Also, investigating the effects of the stochastic design optimization on the density of states (DOS), the DOS of the optimal model are smaller than that of the pristine one in low-frequency ranges.

SUBSTRUCTURING SCHEME FOR EFFICIENT MULTIVARIABLE DYNAMIC REANALYSIS OF DIGITAL TWINS

Geomji Choi[*1] and Seongmin Chang*[1]

[1]*Chungnam National University*

ABSTRACT

Computational analysis, which has emerged with the development of computers, has become an indispensable element throughout various industries. While past computational analyses were primarily used to obtain straightforward results, such as assessing the failure of designed structures under static loads, recent applications have significantly expanded. This expansion includes dynamic analyses, multi-physics analysis, and other interactions analysis. Optimal design problems, as one of their applications, necessitate numerous adjustments to design parameters within specified constraint to achieve the desired result. In another instance, a digital twin utilizes a computer model that closely replicates the appearance and composition of an actual structure to predict its behavior. To obtain precise dynamic responses, the damping ratio also needs to be considered. Iterative computations are essential for implementing such precise computer models. Consequently, the demand for iterative analysis is increasing in many fields, which results in a significant increase in the computational resources and time costs required for analysis. Hence, the development of analysis techniques is needed to derive results efficiently.

In this study, we propose a dynamic reanalysis technique to efficiently perform iterative analyses. In the proposed approach, the entire analysis model is divided into multiple substructures based on degrees of freedom. This substructuring scheme enables a reduction in the size of the analysis model, facilitating rapid and efficient analysis. Additionally, the analysis process was divided into offline and online stages. During the offline stage, formulas that remain constant throughout the analysis and are unrelated to design variables are calculated in advance. Since the majority of the resource intensive computations occur during the offline stage, this stage accounts for most of the analysis time. In the online stage, formulas that vary based on design variables are computed. At this stage, computations proceed rapidly. This separation of the analysis process leads to efficient performance in reanalysis, as it requires calculations only from the online stage. The efficiency and accuracy of the proposed method were verified through numerical examples. Furthermore, the ongoing research is extending the applicability of the proposed method to dynamic problems involving damping ratios.

ABSTRACT

The residual stress in manufacturing of material itself and post-processing to manufacture the aerostructure component has been a crucial issue for the dimensional accuracy of the manufactured aerostructure component. In this research, the application of artificial intelligence has been introduced for the prediction of residual stress and machining path optimization for the 2xxx series aluminium alloy which is used for aerostructure components. The Bulk Residual Stress (BRS) which is induced by quenching after extrusion was predicted by the ANN model with respect to geometry of material and quenching parameters. The Machining-Induced Residual Stress (MIRS) was predicted by the simple regression model with respect to machining parameters. The data set for each residual stress prediction was prepared by using finite element simulation and experimental results where contour and X-Ray Diffraction (XRD) methods were used for the experiment of the residual stress. Both BRS and MIRS were applied into finite element simulation for the distortion prediction of machining without any fracture model to describe element deletion in machining. In the simulation, the BRS was initially mapped into the extruded material with its geometry and quenching condition. Based on the machining parameters such as tool, feed rate, width of cut, and RPM, the MIRS come to be inserted into the integration points of the element which is located machined surface. Then, through the additional simulation time step to satisfy the force equilibrium which is violated by the BRS and MIRS, the machining-induced distortion could be predicted only by the BRS and MIRS whereby it is possible to perform numerically efficient finite element simulation for the prediction of machining-induced distortion. As far as machining path optimization is concerned, since MIRS includes the machining process parameters, XGBoost regression model was adopted because of its feature which combines several decision tree models to give the best prediction and shows excellent prediction for small datasets.

ABSTRACT

The rapid heating and cooling cycles in metal additive manufacturing (AM) processes induce residual stress that can lead to build failure and dimensional inaccuracies. The experimental measurement of residual stress can be costly and time-consuming. To address this, we present a differentiable thermomechanical simulation for automatic optimization of residual stress by adjusting the input laser power. The code is written on top of Google JAX for its high-performance computing with automatic differentiation capabilities. We employ a finite element method (FEM) to solve the thermal field, combined with an elastroplastic solver for residual stress computation. Examples are demonstrated for the directed energy deposition (DED) AM process, showing reduced residual stress in the final part with the optimized laser input. This work enables the inverse design of process parameters to eliminate distortion and residual-stress induced fracture in AM. Our code is made available to the community to facilitate collaborative research.

ON-THE-FLY DYNAMIC MODE DECOMPOSITION

Seung Won Suh[1], SeungWhan Chung[2], Peer-Timo Bremer[2] and Youngsoo Choi[2]*

[1]University of Illinois Urbana–Champaign
[2]Lawrence Livermore National Laboratory

ABSTRACT

The on-the-fly reduced order model concept becomes particularly appealing when dealing with a high-dimensional parameter space. In the realm of time-dependent simulations, this approach initiates with a full order model and concurrently trains a reduced order model as solutions from the full order model are collected on the fly, serving as dynamic training data. Subsequently, the trained reduced order model can replace the full order model if it proves trustworthy, significantly accelerating the simulation process. To assess the trustworthiness of the reduced order model, an indicator is crucial. One evident indicator involves utilizing the residual norm, computed by applying the reduced order model's prediction field to the corresponding governing equations. A high residual norm signals a potential lack of trustworthiness in the trained reduced order model, while conversely, a low residual norm suggests reliability.

While there have been successful implementations of on-the-fly projection-based reduced order models in design optimization [1,2], relatively few have been directly applied to time- dependent problems. Moreover, there appears to be a scarcity of on-the-fly dynamic mode decomposition (DMD) approaches, if any at all. Extending the on-the-fly reduced order model to the DMD framework holds great promise, given that DMD requires less interaction with the physics solver compared to projection-based reduced order models. Additionally, its compatibility with time-dependent problems makes it a natural choice.

Our contribution to this field involves the development of an on-the-fly DMD approach [3]. Leveraging the efficiency of incremental singular value decomposition, our method has demonstrated a notable speed-up of 4.4x compared to the corresponding low-fidelity full order model. This acceleration is achieved while maintaining a solution accuracy similar to that of the full order model, specifically in the context of Navier–Stokes flow around cylinder simulations.

MAPPED MPM FOR SOIL-STRUCTURE INTERACTIONS: CAPTURING SHARP GRADIENTS WITH UNIFORM BACKGROUND GRIDS

Jinhyun Choo[*1] and Yidong Zhao*[1]

[1]*KAIST*

ABSTRACT

The material point method (MPM) has become a popular means for computational simulation of highly deforming soils interacting with various “structures” such as foundations, penetrometers, and machines. A common and significant challenge in these MPM simulations is how to address sharp gradients in the displacement fields around the soil-structure interfaces with computational efficiency. The existing MPM simulations handled such sharp gradients through the use of locally refined background grids. Unlike meshes in the finite element method, however, local refinement of background grids in MPM are very complicated and restricted to certain types of basis functions or updated schemes. Here, we present a new MPM formulation--the mapped MPM--that can efficiently capture sharp gradients with a uniform background grid. The central idea is to use the method of auxiliary mapping–-a technique that reparameterizes the given problem in a parametric domain where sharp gradients become much smoother. The performance of the mapped MPM is demonstrated through various numerical examples with a focus on soil-structure interaction problems.

AN INVESTIGATION OF THE MECHANICAL BEHAVIOR OF RE-ENTRANT AUXETIC STRUCTURES

Chia-Ching Chou[*1] and Yu-Cheng Lai*[1]

[1]*National Taiwan University*

ABSTRACT

Auxetic structures exhibit exceptional mechanical properties stemming from their negative Poisson's ratio. This provides advantages in fracture resistance, energy absorption, and indentation resistance. Among various auxetic structures, re-entrant structures have attracted much research attention due to their tunable behavior and lightweight structural properties. This makes them promising candidates for wide applications across fields such as civil engineering, military equipment, biomedical design, and sports protection. In exploring the performance of re-entrant designs, previous studies have focused on geometrical variables and stiffness gradients by varying wall thickness or altering aspect ratio throughout the structure's height. In this study, we start with classical re-entrant structures and use Finite Element Method to investigate the effect of geometrical parameters, including thickness, aspect ratio, zig-zag angle, repeat unit, and the stiffness gradient of materials under mechanical testing. Stress-strain curves and specific energy absorption are evaluated, as well as investigating deformation processes. We also examine the material response during the compression test with higher compression speeds and compare the dynamic deformation against the static one. Additive manufacturing and experiments are also conducted to compare simulation findings. Our results reports how geometrical variables and gradient design effects the mechanical properties of re-entrant structures. This demonstrates that for wide applications of auxetic structures, response under specific loading conditions must be thoroughly investigated. Our study provides a comprehensive simulation procedure to expand the analysis of structure deformation from low-speed to high-speed and dropping tests, validated through comparison with experiments. With the inherent mechanical benefits of auxetic structures and the insights from our study, we can potentially expand applications into broader protective equipment domains.

THE DEVELOPMENT OF A CONSTITUTIVE NEURAL NETWORK APPROACH FOR MULTISCALE FRACTURE-TO-DAMAGE MODELLING

Yu-Chun Chou[1], Wen-Yi Hsieh[1], Yu-Zhen Li[1], Tsung-Yeh Hsieh[1], Tsung-Hui Huang[1] and Po-Yu Chen[1]*

[1]*National Tsing Hua University*

ABSTRACT

A multiscale fracture-to-damage model has been developed to establish a connection between micro-scale fracture mechanics and macro-scale damage evolution [1]. While this model effectively assesses material failure across various scales, it requires intricate problem-solving for microcracks, leading to computationally intensive efforts, like direct numerical simulation (DNS), confined by specific microstructures, e.g. microscopic defects, heterogeneities, and micro-pores. The dimension of the problem often compounds the computational cost due to the curse of dimensionality. Recent offline-type homogenization approaches [2], employing neural network training with a pre-trained model on representative volume elements (RVEs) of the microstructure, have proven effective on online macro-scale simulation. However, conventional artificial neural networks (ANN) may lack accuracy during the extrapolation of data from the offline training dataset. To overcome these challenges, our study introduces an enhanced constitutive artificial neural network (CANN) structure [3] for multiscale fracture-to-damage modelling. The proposed methodology can efficiently compute macro-scale damage evolution from micro-scale fracture or crack accumulation via a derived energy bridging equation, effectively mitigating extrapolation issues in online simulations. The resulting homogenized surrogate model is applicable in macroscopic scenarios with coarser mesh resolutions, significantly enhancing computational efficiency. Validation of this approach involves solving benchmark problems and comparing results not only with DNS but also with the conventional NN method, showcasing superior computational efficiency and efficacy. The proposed enhanced constitutive neural network framework offers a robust solution for overcoming challenges in multiscale modelling of damage in engineering materials.

Multi-physics and multi-scale simulations with the coupling library preCICE
July 21-26, 2024, Vancouver Convention Centre, Vancouver, British Columbia, Canada

A QUICK INTRODUCTION TO THE COUPLING LIBRARY PRECICE AND THE MINISYMPOSIUM

*Gerasimos Chourdakis**[1]

[1]*Technical University of Munich*

ABSTRACT

This talk will open the minisymposium and introduce the main concepts of the open-source preCICE coupling library for partitioned, black-box, multi-physics and multiscale simulations. For a longer introduction, join the short course W24-08 on preCICE on July 21.

preCICE enables the efficient, robust, and parallel coupling of separate single-physics solvers. This includes, but is not restricted to fluid-structure interaction. preCICE treats these solvers as black-boxes and, thus, only minimally-invasive changes are necessary to prepare a solver for coupling. Ready-to-use adapters for well known open-source solvers, including OpenFOAM, SU2, CalculiX, FEniCS, and deal.II, are available, while the core library is included in the xSDK ecosystem. The software offers methods for equation coupling, fully parallel communication, data mapping, and time interpolation schemes. The minisymposium brings together users and developers of the software. It enables the exchange of users among themselves, which otherwise would not know much of each other. Furthermore, the developer team can get direct feedback from users, who they sometimes only know from forum conversations. Lastly, the software and its capabilities can be presented to others in a full and broad sense as not only the developers talk about their software, but also users report on experiences. Recent work focuses on extending preCICE towards multi-scale coupling, higher-order mapping, and applications other than fluid-structure interaction. COARSE-GRAINED MOLECULAR DYNAMICS MODEL FOR MULTICOMPONENT ALLOY SYSTEMS USING NEURAL NETWORKS

Faiyaz Bin Naser Chowdhury[*1], André McDonald[1] and Wylie Stroberg[1]*

[1]*University of Alberta*

ABSTRACT

Cold-sprayed deposition of high-entropy alloys (HEAs) offers an exciting avenue for developing new metal coatings with high wear and corrosion resistance. In the cold-spray process, micron-sized HEA particles are deposited on a substrate at high velocities, leading to large plastic deformation and particle-substrate bonding. The ability to tune the composition of the HEA being deposited has the potential to develop optimized and use-case specific coatings. However, the large compositional design space makes optimizing properties an onerous experimental task. Hence, accurate and fast simulations of HEA cold-spray deposition would be highly valuable. Simulating this process poses two major challenges: 1) The molecular composition must be an input to the model to allow for optimization, and 2) the model must reach micrometer and larger scales to capture the deposition process. To address these challenges, we developed a coarse-grained molecular dynamics method (CGMD). Although several CGMD models for single-element alloys have been developed, building coarse-grained models of multicomponent systems like HEAs remains a significant challenge. For multicomponent systems, the structural coarse-graining based on neighboring atoms leads to an exponentially-large number of coarse-grained particle types. To address this issue, we train a neural network to assign a finite set of coarse-grained particle types based on the elemental composition of the local environment. Then, the coarse-grained interaction potential of each particle type is given by training a Behler-Parrinello-like neural network (BPNN) on all-atom simulations. The coarse-grained model thus retains the compositional information of the underlying all-atomic model while allowing larger length and timescales to be reached. This will facilitate further studies of the microstructural mechanisms driving the deformation of cold-spray particles impacting a substrate.

ABSTRACT

Radiotherapy (RT) for high-grade gliomas is currently planned using anatomical MRI data collected either shortly after the maximal safe resection or as a dedicated MR simulation to plan the radiation treatment. This approach fails to capture the biological heterogeneity when defining the target volumes at this baseline timepoint and does not even attempt to measure the spatial-temporal heterogeneity in response to RT until the multi-week treatment course is completed. There have been mounting evidence that target delineation can be improved with multiparametric MRI (mpMRI) and even multimodal imaging; however, taking these just at baseline would not address any spatio-temporal responses to RT. By leveraging biology-based mathematical models, it is possible to personalize the predictions for each patient to describe the intratumoral dynamics of response [1]. In this study, we leverage data from patients enrolled in a prospective study evaluating the changes of the tumor using weekly multi-parametric MRI (mpMRI) that provide anatomical diffusion and perfusion information. We utilize the data collected up to week 3 of RT to personalize a biology-based mathematical model of response for each individual patient to then predict response and progression at the end of therapy. This patient-specific approach was able to achieve accurate predictions of response at both the tumor and voxel levels by the end of radiotherapy and even at 1 month following radiotherapy. By integrating mpMRI data with biology-based mathematical models, we can introduce the concept of predictive adaptive radiotherapy (PART) based on the anticipated change in regional tumor activity in order to better delineate the biologically active regions of tumor and improve outcomes.

NONPARAMETRIC MATERIAL MODEL-BASED FEA WITH GPU FOR FASTER AND ACCURATE NUMERICAL ANALYSIS

Hyunseung Chung[*1] and Hyo-Gyoung Kwak*[1]

[1]*Korea Advanced Institute of Science and Technology*

ABSTRACT

Finite Element Analysis (FEA) has been extensively implemented in numerical analysis methodology for a long time. However, defining the idealized model for newly developed material with a complex stress-strain relationship based on experiments was challenging, many researchers suggested implementing a machine learning algorithm to resolve the issue. Various algorithms can be adopted to define the representative uniaxial stress-strain material model from the test data, but applying the same method to another material, mostly concrete and steel, requires extensive parameter tuning or algorithm modification. As a result, creating a nonparametric model which can be easily applied to various materials should be investigated. This research defines the Gaussian Process Regressor (GPR) model based on the Radial Basis Function (RBF) kernel directly from the experimental dataset on steel and concrete materials. However, with the GPR-based material model, computational load increases drastically especially using the implicit solver approach. To resolve the computational pressure of the numerical procedure, parallel processing should be considered, and hardware acceleration with the Graphics Processing Unit (GPU) should be performed for even further speedup. The GPU acceleration of the implicit FEA was introduced into the in-house code largely based on the layered approach originally suggested by Owen and Hinton(1980). GPUs can act as hardware accelerators with massively parallel processing units and strength over linear algebraic operations with a CUDA interface.

A nonlinear implicit FEA of two Reinforced Concrete (RC) beams under flexural bending was performed on the accelerated FEA to mitigate the high computational load that comes from both the GPR material model and implicit layered FEA procedure, and results were compared to the experimental result and numerical analysis result using the conventional constitutive material models. The load-displacement response of the beams corresponded with the experimental data, especially the load at the yielding point of the rebar showed less than a 2.28% difference, and the ultimate load showed less than a 1.55% difference. The GPR-based material model showed less sensitivity over the load step configuration and typical sensitivity over the mesh size. The suggested procedure exclusively performed a linear algebraic operation on the GPU, scaling up to 210,000 DOFs with 24GB of GPU memory space. The speedup of acceleration with benchmark was up to 6 times in terms of wall clock time and showed a linear trend of time consumption increase along with the increase of DOFs, while the non-accelerated or non-optimized program showed a polynomial increase.

Multiscale computational homogenization for bridging scales in the mechanics and physics of complex materials

INFLUENCE OF AGGREGATE TYPES ON MECHANICAL, THERMAL, AND DURABILITY PROPERTIES OF LIGHTWEIGHT AGGREGATE CONCRETE

Sang-Yeop Chung[*1] and Seo-Eun Oh*[1]

[1]*Yonsei University*

ABSTRACT

Lightweight aggregate concrete (LWAC) is a material widely employed in the building and construction industry due to its advantageous characteristics, including low density and excellent insulation properties. LWAC exhibits significantly higher porosity compared to conventional concrete due to the incorporation of porous lightweight aggregates. The choice of lightweight aggregates profoundly impacts the physical properties of LWAC, emphasizing the necessity of studying their influence on material strength and durability. To address this, the study introduces concrete mix designs within two distinct theoretical density categories. Each category maintains a consistent composition, with the only variable being the type of lightweight aggregates utilized: expanded glass, expanded clay, and foam glass. These expanded lightweight aggregates are lightweight and exhibit lower thermal conductivity and water absorption than normal aggregates. The study assesses the thermal conductivity and compressive strength of lightweight concrete specimens through experimental and numerical evaluations. Additionally, the pore characteristics and durability-related properties, including sorptivity, open water porosity, and water penetration depth, were investigated. To gain deeper insights, a permeable index, tortuosity, is examined through a numerical method employing X-ray micro-computed tomography (micro-CT). The findings conclusively demonstrate that the choice of aggregate types significantly impacts the strength, thermal conductivity, and durability attributes of LWAC and strongly correlates with their pore structures. Among the assessed aggregate types, expanded glass emerges as the most favorable material in terms of mechanical and permeability characteristics. This systematic approach employed in the study provides a valuable framework for assessing LWAC properties. Although controlling the pore structures of aggregates remains a challenge, the tools utilized in this study to investigate material characteristics can effectively be employed for further examination and development of lightweight concretes with advanced material performance.

TRAIN SMALL, MODEL BIG: SCALABLE ROBUST PHYSICS SIMULATOR VIA REDUCED ORDER MODELING AND DOMAIN DECOMPOSITION

SeungWhan Chung[*1], Youngsoo Choi[1], Thomas Roy[1], Pratanu Roy[1], Tiras Lin[1], Du Nguyen[1], Christopher Hahn[1], Eric Duoss[1] and Sarah Baker[1]*

[1]*Lawrence Livermore National Laboratory*

ABSTRACT

Numerous cutting-edge scientific technologies originate at the laboratory scale, but transitioning them to practical industry applications can be a formidable challenge. Traditional pilot projects at intermediate scales are costly and time-consuming. Alternatives such as E-pilots can rely on high-fidelity numerical simulations, but even these simulations can be computationally prohibitive at larger scales. To overcome these limitations, we propose a scalable, component reduced order model (CROM) method. We employ Discontinuous Galerkin Domain Decomposition (DG-DD) to decompose the physics governing equation for a large-scale system into repeated small-scale unit components. Critical physics modes are identified via proper orthogonal decomposition (POD) from small-scale unit component samples. The computationally expensive, high-fidelity discretization of the physics governing equation is then projected onto these modes to create a reduced order model (ROM) that retains essential physics details. The combination of DG-DD and POD enables ROMs to be used as building blocks comprised of unit components and interfaces, which can then be used to construct a global large-scale ROM without data at such large scales. This method is demonstrated on the Poisson and Stokes flow equations, showing that it can solve equations about 15−40 times faster with only $\sim$ 1% relative error, even at scales 1000 times larger than the unit components. In this work, CROM is further extended toward nonlinear physics such as Navier-Stokes equation, where it is demonstrated to be amenable to hyper-reduction methods such as empirical quadrature points.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under contract DE-AC52-07NA27344 and was supported by Laboratory Directed Research and Development funding under project 22-SI-006. LLNL-ABS-858842.

ABSTRACT

Post-welding heat treatment (PWHT) is a crucial procedure in nuclear industries, particularly for large welded components, intended to relax residual stresses and stabilize microstructural effects. Precise control of PWHT parameters is essential to achieve the most relaxed stress zones while minimizing the impact on other parts of the components. Finite element (FE) simulations provide a valuable framework for comprehending the influence of underlying parameters on the mechanical response of components during PWHT. However, the application of Direct Numerical Simulations (DNS) is constrained in this context due to the non-linear nature of elasto-visco-plastic material behavior and the high dimensionality associated with parametric studies in PWHT.
This study proposes a novel approach by integrating FE simulations with a posteriori Reduced Order Model (ROM) to construct a metamodel capable of real-time reproduction of the 4D space-time mechanical fields during the PWHT process, eliminating the need for DNS reruns. The ROM is founded on a sparse High Order Proper Generalized Decomposition (HOPGD) (Lu Y., June 2018). Notably, the ROM modes are constructed with constraints derived from thermodynamic equations and the evolution equations from material modelling. Another distinguishing feature is the sampling strategy, which can be implemented as a random sparse (Ibáñez Pinillo, 2018).

DEVELOPMENT OF A DESIGN METHODOLOGY FOR SLENDER CARBON-REINFORCED CONCRETE COLUMNS IN AXIAL COMPRESSION BASED ON EC3

Yvonne Ciupack[1], Josiane Giese[1], Manfred Curbach[1] and Birgit Beckmann[1]*

[1]*Dresden University of Technology*

ABSTRACT

Continuous advancements in the field of concrete construction have led to innovative technologies, including carbon-reinforced concretes and ultra high-performance concretes. The engineering utilization of these innovations will in future lead to the construction of slender components and structures with high load-bearing capacities and stiffnesses compared to conventional reinforced concrete structures. The resulting lightweight design not only contributes to resource efficiency but also has positive effects on reducing CO2 emissions by reducing the amount of construction materials needed.
Despite the clear advantages of such innovative material composites, challenging load-bearing and deformation behavior emerges in slender carbon-reinforced concrete components, indicating potential stability issues. To address this concern, current research is dedicated to experimental and analytical investigations of the structural behavior and failure of slender components in compression made of carbon-reinforced concrete, aiming to enhance our understanding of stability-related aspects.
Stability phenomena, such as the buckling of columns, are extensively researched and well-known in steel construction. In Eurocode 3, there is a concept integrated for the calculation of the buckling resistance of steel members, which is based on an empirical-analytical approach. This concept is built on numerous experimental studies on various columns, from which the European buckling curves were derived.
This article focuses on a specific approach to derive a practical design procedure for carbon-reinforced concrete columns in compression based on results from the literature. The proposed methodology follows the proven design concept of steel construction, where the (plastic) resistance of the cross-section for uniform compression is reduced by a reduction factor χ. The advantage of this design principle is that the verification of the cross-sectional capacity is expanded by only one factor to consider buckling appropriately. To enable such an approach for slender carbon-reinforced concrete columns, buckling curves are derived, related slenderness limits and adjustment factors are determined. It is suggested to relate the capacity of the column to a slenderness-related strength at $\lambda_{lim} = 25$ instead of the uniaxial concrete compressive strength ($\lambda << 25$). In this way, a general representation of buckling curves is achieved, which can be applied to a broader range of columns. The overarching goal is to contribute to the development of safe and efficient construction methods with carbon-reinforced concrete, promoting the application of these innovative material composites and facilitating their integration into construction practices.

NONLINEAR SPARSE BAYESIAN LEARNING OF SEMI-EMPIRICAL MODELS IN AEROELASTICITY AND INFECTIOUS DISEASE MODELLING

ABSTRACT

The use of the nonlinear sparse Bayesian learning (NSBL) algorithm [1] to alleviate overfitting in physics-based models is considered for two diverse applications. The NSBL methodology presents a nonlinear extension to sparse Bayesian learning/relevance vector machines, which results in a semi-analytical framework for automatic discovery of the data-optimal nested model. NSBL permits the modeller to assign priors to parameters that are known to be relevant a priori, while inducing sparsity among potentially irrelevant parameters through the use of automatic relevance determination priors.

In the first application, we study the use of NSBL in nonlinear aeroelasticity. For a two degree-of-freedom pitch-plunge airfoil undergoing limit cycle oscillations (LCO), a semi-empirical aerodynamic model consisting of a polynomial expansion of its displacements and velocities is proposed. This model is grounded in physics as some of the terms may be interpreted as stiffness-type and damping-type terms. However, not all terms carry such interpretations; they may contribute to the data-fit of the model but conversely, they may also contribute to overfitting. NSBL is leveraged to alleviate overfitting, particularly in the data-driven component of the model. This was previously demonstrated for a single degree-of-freedom
pitching airfoil, showcasing NSBL's ability to recover the optimal model nested inside an over-parameterized model by comparison with the standard Bayesian model selection [2].

In the second application, NSBL is deployed for the calibration of compartmental models in infectious disease modelling. Although compartmental models have a mechanistic interpretation, deterministic models with time-invariant parameters innately lack the ability to capture the disease dynamics observed over the multiple waves of the COVID-19 pandemic. With lockdown measures and restrictions on movement affecting disease transmission, calibrating compartmental models using both public health data and mobility data collected from cell phones [3] within the NSBL framework can lead to improved predictions of disease spread.

[2]*Universitat Ramon Llull*

ABSTRACT

Wave propagation in elastodynamic problems in solids often requires fine computational meshes. In this work we propose to combine stabilized finite element methods (FEM) with an artificial neural network (ANN) correction term to solve such problems on coarse meshes. Irreducible and mixed velocity-stress formulations for the linear elasticity problem in the frequency domain are first presented and discretized using a variational multiscale FEM. A non-linear ANN correction term is then designed to be added to the FEM algebraic matrix system and produce accurate solutions when solving elastodynamics on coarse meshes. As a case study we consider acoustic black holes (ABHs) on beams and plates. ABHs are traps for flexural waves based on reducing the structural thickness according to a power-law profile at the end of a beam, or within a two-dimensional circular indentation in a plate. For the ABH to function properly, the thickness at the termination/center must be very small, which demands very fine computational meshes. The proposed strategy combining the stabilized FEM with the ANN correction allows us to accurately simulate the response of ABHs on coarse meshes for values of the ABH order and residual thickness outside the training test, as well as for different excitation frequencies.

ABSTRACT

In recent decades, composite materials based on a metallic matrix reinforced with ceramic particles have replaced traditional monolithic alloys in many applications in the aerospace, automobile, and nuclear industries. These composites offer the potential of enhanced thermal and mechanical properties and greater durability in service. An attractive method for fabrication of metal-ceramic composites is the use of cold compaction of a metal-ceramic powder mixture followed by sintering at high temperatures. During the compaction stage, the time dependent hydrostatic stress at each material point, governs the final density distribution of the component. Large density gradients can result in defective components with low thermal conductivity and reduced ductility and strength. As a consequence, predicting the density distribution during the compaction stage is critical. Although many analytical models can provide average values of the compact density, due to the complex non-linear nature of the compaction process, numerical methods must be utilized to obtain local values of density.

This research focused on investigating the cold compaction process of Al-TiB2 and Al-SiC powder mixtures (0-15% volume fraction of TiB2 and SiC in the Al were considered) using finite element analysis in conjunction with compaction experiments. The powder mixture was assumed to behave like a porous media and was modeled using the Gurson-Tvergaard-Needleman (GTN) approach. A density dependent elastic response of the powder mixture was also incorporated using a user defined sub-routine in the commercial code ABAQUS. Convergence studies were used for solution verification and compaction experiments were used to both identify the GTN model parameters and to validate to computational models. By comparing the computations to the compaction experiments, it is demonstrated that a density dependent elastic response is required in order for the GTN model to accurately represent the observed initial part of the compaction curve where the relative density is low. The study also reveals that the GTN model parameters q1 and q2 can be correlated to the volume fraction of the ceramic reinforcement particles. From a practical point of view it is also shown that increasing the volume fraction of the ceramic reinforcement, although increasing initial powder density results in greater local density gradients.

APPLICATION OF A TRANSIENT HEAT SOURCE MODEL TO PART-SCALE SIMULATIONS OF AM

John Coleman[*1], Kellis Kincaid[1], Gerry Knapp[1], Benjamin Stump[1], Matt Rolchigo[1] and Alex Plotkowski[1]*

[1]*Oak Ridge National Laboratory*

ABSTRACT

In the field of additive manufacturing (AM), continuum melt pool models play a crucial role in understanding the process-structure-property relationships in AM parts. These models scale simulations to relevant lengths and time scales by employing volumetric source terms to approximate the heat input from a moving laser and its impact on melt pool dimensions. Here, we address inherent limitations of conventional continuum melt pool models, which predominantly rely on static heat source geometries calibrated against single-track experiments. This conventional approach often leads to inaccuracies in predicting dynamic melt pool shapes influenced by varying scan strategies and part geometries, resulting in notable discrepancies in the prediction of local defects (such as lack-of-fusion and keyhole porosity) and microstructural features compared to empirical data.

To overcome these challenges, we introduce a refined two-parameter heat source model that independently controls the distribution of absorbed power and the shape of the heat source, better approximating the effect of vapor cavities on melt pool shape. This parameterization significantly improves the prediction of melt pool geometries across a wide range of transient thermal conditions with negligible additional computational expense compared to existing models. Importantly, the proposed model leverages empirical evidence from previous experimental studies that establish causal links between melt pool dimensions and laser absorptivity in laser powder bed fusion (LPBF), reducing the reliance on abstract mathematical parameters and thus improving the model’s adherence to physical phenomena. The calibration of both model parameters is demonstrated to be straightforward using an automated surrogate-based approach based on Bayesian statistics.
Implemented within the OpenFOAM finite volume framework, the model's adaptive mesh refinement (AMR) and CPU load-balancing facilitate the investigation of melt pool conditions at the LPBF part scale. Its application within the Manufacturing Demonstration Facility (MDF) at Oak Ridge National Laboratory (ORNL) enables the use of in-situ build data collected from actual AM machines to automate the deployment of simulations and the collection of their predictions in a digital twin framework. This streamlined approach is believed to narrow the gap between experimental observations and theoretical predictions of process-structure-property relationships at the part scale.

PATIENT-SPECIFIC BREAST TUMOUR MODEL FOR PREDICTING RESPONSE TO NEOADJUVANT CHEMOTHERAPY

[2]*University of Luxembourg*

ABSTRACT

Neoadjuvant chemotherapy (NACT) is a common treatment option for patients with locally advanced breast cancer. However, only 39% of these patients achieve pathological complete response and up to 12% experience no response at all. Non-responsive patients suffer the side-effects of NACT without reaping the benefits. It is essential to identify non-responsive tumours as early as possible to enable clinicians to discontinue the unsuccessful NACT and proceed with alternative treatment.

To this aim, we propose a light and efficient mathematical model of tumour spatiotemporal evolution in response to NACT, personalised with data from magnetic resonance imaging (MRI). This evolution is described by reaction-diffusion equations parameterised by the spatially varying tumour volume fraction. We have implemented this model in FEniCSx, an open-source platform for solving partial differential equations.

We use diffusion-weighted (DW-) and dynamic contrast-enhanced (DCE-) MRI acquired from patients before, during and after NACT to personalise the model. The DCE data are used to identify the tumour and derive spatially varying maps of the extended Kety-Tofts model parameters volume transfer constant Ktrans, extracellular extravascular volume fraction ve, and plasma volume fraction vp. These are in turn used to estimate the concentration of chemotherapy drug in the tumour. The DW-MRI data return a measure of the apparent diffusion coefficient (ADC) of water in the tumour, used to estimate tumour volume fraction at each voxel. Initial parameters calculated in this manner from pre-treatment data are used to calibrate the model to data after one cycle of NACT. This returns three personalised coefficients (tumour cell proliferation rate, diffusion coefficient in the absence of stress, and drug efficacy) that are used in the model's forward evaluation.

We apply this process to data from patients from the CHERNAC clinical trial to predict their tumour response to NACT according to the model. Model outputs are compared to images acquired after three cycles of NACT.

A NEW APPROACH FOR THE ENFORCEMENT OF NEUMANN BOUNDARY CONDITIONS WITH THE SHIFTED BOUNDARY METHOD

Jason Haydel Collins[*1], Guglielmo Scovazzi[1] and Alexei Lozinski[2]*

[1]*Duke University*
[2]*University of Franche-Comté*

ABSTRACT

Immersed/embedded boundary computational methods offer a useful alternative to traditional boundary conforming approaches, particularly in cases involving high geometric complexity. The trade off with standard embedded boundary methods (cutFEM, Finite Cell Method, etc.) is that they often require tedious cell cutting processes, specialized quadrature operations, and careful management of so called "small cut-cells". The Shifted Boundary Method (SBM) is an alternative approach that addresses the small cut-cell problem by eliminating the need to perform cell cutting altogether.

The SBM employs the use of surrogate domains which contain only fully formed elements by design (no cuts). The true boundary conditions are shifted onto the location of the surrogate boundary by way of field extension operators constructed with Taylor expansions, preserving accuracy. Indeed, if the boundary conditions from the true domain are assigned to the surrogate without proper modification, the resulting convergence will be sub optimal. Optimal convergence rates have been demonstrated for essential boundary conditions, where the solution and its gradient are readily accessible (in the case of piece-wise linear interpolation functions). However, shifting Neumann boundary conditions requires a modified approach since the higher order terms in the Taylor expansion are unavailable (all terms beyond first order derivatives are zero for linear elements).

Neumann boundary conditions are ubiquitous in many applications, particularly in solid mechanics problems with stress-free boundary conditions. The aim of this work is to provide an approach that achieves optimal convergence for shifted Neumann boundary conditions without the use of a mixed formulation, maintaining the same data structure requirements as the Dirichlet SBM boundary conditions. This is accomplished by introducing extension terms to the variational statement evaluated on the Neumann boundary, which account for the distance between the true and surrogate boundary. Additionally, special care is taken to maintain consistency within this formulation. We show how these implemented modifications provide a stable and accurate scheme for embedded Finite Element computation involving Neumann boundary conditions.

A GENERALIZED WEIGHTED SHIFTED BOUNDARY METHOD FOR PROBLEMS WITH EVOLVING DOMAINS

Oriol Colomés[*1], Jan Modderman[1] and Guglielmo Scovazzi[2]*

[1]*Delft University of Technology*
[2]*Duke University*

ABSTRACT

Unfitted/Immersed or Embedded Finite Element methods have gained significant attention in the past decade for their effectiveness in simulating problems in complex geometries. However, many existing methods in the literature necessitate ad-hoc modifications of standard Finite Element data structures. This often involves tessellation of elements intersected by the embedded boundary, the construction of special quadrature rules, or the definition of geometry-dependent surrogate boundaries.

In this work, we propose a novel approach: a generalization of the Weighted Shifted Boundary method [1], which eliminates the need for special data structures or quadrature rules, and enables the solution of unfitted problems with geometry-independent Finite Element spaces. This newly introduced framework holds particular significance for problems involving evolving geometries and potential topological changes. Applications extend to scenarios such as topology optimization or fluid-structure interaction problems where the ability to handle dynamic geometries is crucial.

In this talk, we will present the formulation of the Generalized Weighted Shifted Boundary method and showcase its application to a variety of problems with evolving domains.

ABSTRACT

Introduction
Modern engineering challenges have pushed forward the use of architected materials and called for a new branch of material science to be explored. These special materials exhibit unconventional properties directly linked to their geometry. When composed of slender elements, architected materials can undergo large deformations exhibiting geometric non-linearities through buckling or snapping behaviors of the cell walls. Furthermore, as any conventional material, their constitutive material could enter its non-linear domain. The combination if these two limits define the domain of linear elasticity of the architected material. This presentation will present the domains of linear elasticity of various 2D architected materials and relate the symmetry of the domain to that of the parent material.

Method
The domain of linear elasticity is constructed from the intersection of the non-buckling domain of the architected material and the linear elasticity domain of its constitutive material. It is well-known that buckling in architected materials can happen at different scales, especially when working with periodic architected materials. Bloch-wave analysis is the appropriate tool for predicting buckling in such periodic materials. This presentation will only consider 2D lattice periodic architected materials composed of beam elements that are modelled with Euler-Bernoulli beam theory. Moreover, the method only accounts for isotropic constitutive material and constant cross-section beams but the latter limitation can be lifted. The method could be extended to architected materials composed of plate or shell elements.

Results
The method has been validated on the classical examples of regular square, triangular and hexagonal honeycombs. The observed bifurcated patterns presented in the literature both numerically and experimentally are predicted by our method and results on the shape of the non-buckling domain can be retrieved.
More interestingly, it is possible to correlate the shape of the domain of linear elasticity with the symmetry of the parent architected materials. Based on several examples, it is observed that the symmetry group of the architected material is partially transferred to the symmetry group of the domain of linear elasticity, when observed in the deviatoric space. This can be explained by a tensorial representation of that domain.

ABSTRACT

Although advancements in manufacturing technologies have enabled material design optimization at multiple scales, the microstructure anomalies and uncertainties present at each scale have not been considered comprehensively enough for them to be robust to manufacturing variations. Specifically, the agglomerations, formed due to high surface energy and attractive Van der Waals forces between nanoparticles in the microscale, as well as voids forming due to different processing conditions at the mesoscale, significantly impact the mechanical properties of the composite materials at higher scales [1,2]. Consequently, considering these anomalies at various length scales of the material's structure and understanding their uncertain effects on a part's response are crucial for designing engineered parts that are robust to various sources of uncertainty.

To account for these anomalies, an efficient bottom-up uncertainty quantification and propagation framework bridging the microscale and the mesoscale to establish a design allowable range for the composite material system at the part-scale is presented. At the microscale, the agglomerated material system is characterized and reconstructed from a few (approximately 30) experimental images and reinforced with interphase percolation for property enhancement. At mesoscale, varying bead structures are created to reconstruct interlayer voids. Subsequently, a copula-based sampling strategy that offers significant dimension reduction to preserve key information across multi-scale design space with a mechanistic reduced-order model that enables fast property prediction to create an efficient uncertainty quantification and propagation framework. The framework provides further understanding regarding the influence of anomalies at lower scales on the part-scale performance. Finally, the applicability of the framework is demonstrated for an additively manufactured polymeric material system, highlighting the importance of considering the effects of process-induced microstructure features on the part performance.

ABSTRACT

In recent years, substantial efforts have been made in the development of Topology Optimization (TO) procedures for a more sustainable technological advancement. One of these efforts consists in the design of multi-material structures. In fact, conventional materials used in the past may not be able to fulfil today's design objectives and requirements. This motivates to enlarge the design space to include multi-material solutions in structural design at different length-scales. Multi-material design can lead to more efficient structures in terms of stiffness and/or strength, while also allows for tailored mechanical and thermal behaviours, such as negative indexes on mechanical and thermal properties. Many industrial sectors, ranging from aerospace to biomechanics fields, could benefit from the use of non-conventional materials, although their fabrication still remains a challenge.

This work addresses Multi-Material Topology Optimization (MMTO) applied to specific cases of practical interest. Firstly, one explores the potential of multi-material design to improve the efficiency of structures at different length-scales [1]. Two different problem formulations can be stated: (1) compliance minimization, and (2) stress minimization. Both problems can be solved at the microscale and macroscale, either independently or in a concurrently manner (multi-scale). Regarding the stress minimization problem, two types of design solutions can be considered. On one hand, two solids coexist being bonded together across sharp interfaces. On the other hand, a Functionally Graded Material (FGM) is obtained as an extensive smooth variation of material properties on account of varying composition’s volume fractions of both solids throughout the design domain, such that a more evenly stress distribution is attained. Lastly, Asymptotic Homogenization (AH) techniques, along with MMTO, are used to design optimal porous composite materials consisting of a periodic microstructure, so-called metamaterials. These metamaterials aim for negative indexes on mechanical and thermal properties, such as negative Poisson’s ratio and/or negative Coefficient of Thermal Expansion (CTE). The AH theory assumes periodicity at the microscale, that it is infinitesimally small in comparison to the macroscale. However, in practice the composite material will only encompass a finite number of repetitions. To assess the feasibility of optimal metamaterials in engineering practice, it is crucial to investigate the proximity of the equivalent thermoelastic properties predicted by the AH to those exhibited by real composites.

A MULTIRATE INTEGRATION FRAMEWORK APPLIED TO SOLID-SOLID AND FLUID-FLUID INTERACTION MODELS

Jeffrey Connors[*1]

[1]*University of Connecticut*

ABSTRACT

We discuss a framework for multirate integration of multi-component systems with coupling across interfaces. The problem is to derive algorithms that support different time step sizes for each component. In the context of multirate coupling, there can be problems with accuracy, stability, or preservation of properties such as system invariants. The proposed framework provides a way to derive algorithms with the desired properties. The multirate coupling is based on the recent work (Connors and Sockwell, 2022) that treats the subdomain integrators as piecewise polynomial in time using the mathematics of discontinuous-Galerkin-in-time methods. These piecewise representations are then mapped into a smooth coupling space that spans some predefined interval of time called a "coupling window". Two example applications are discussed: solid-solid interaction and a two-layer air-sea proxy using rotating thermal shallow water equations. We show how to apply the framework and customize the multirate coupling for each application. Numerical examples illustrate the accuracy, stability and preservation of a system invariant with different time step sizes for each component.

ASSESSING ATOLL ISLANDS' VULNERABILITY UNDER CLIMATE CHANGE CONDITIONS

Maria Teresa Contreras-Vargas[*1], Benjamin Moore-Maley[1], LeAnn Marie Conlon[1] and Luke Van Roekel[1]*

[1]Los Alamos National Laboratory

ABSTRACT

Atoll islands are home to tens of thousands of people from the Maldives, Tuvalu, Kiribati, the Marshall Islands, and several other countries. However, it has been established that many of them will become uninhabitable during the 21st century due to climate change (1). Sea level rise (SLR) is expected to be the most significant threat due to their low elevation and limited area, resulting in more frequent and extensive inundations, groundwater salinity intrusions, and chronic coastal erosion.
Up-to-date studies have improved the understanding of long-term sea level variations using sparsely distributed observations and satellite data (2), limiting the applicability to future conditions. Efforts in numerical modeling have focused on combining SLR and waves, but primarily through parametrization and for small sets of islands (3), due to the high computational costs of combining large-scale ocean dynamics with small-scale wave impact on the islands' coastlines.
Thus, our objective is to improve the understanding of the evolution of atoll islands' coastline and their inundation risk in a changing climate. Through numerical simulations, we integrated the effect of the ocean hydrodynamics, weather, waves, and sea level rise to represent past, present, and future conditions. We used ADCIRC+SWAN to represent the hydrodynamics of the Pacific, with the primary interest in the Marshall Islands. For the historical period, we forced the model with atmospheric conditions from ECMWF Reanalysis 5 (ERA5). We used the climate and SLR predictions from the WCRP Coupled Model Intercomparison Project (CMIP) multimodel mean under the SSP245 scenario for future scenarios. We assessed variations in potential inundation over time and shifts in flood frequency, characterizing the magnitude, time frame, and variability of the impact that different islands will experience, as well as wave power and, hence, the erosion risk. All this information is crucial for decision-makers in order to plan adaptation measurements that allow to preserve the habitability of these islands.

VIBROACOUSTIC BANDGAP MAXIMIZATION THROUGH TOPOLOGY OPTIMIZATION

Vanessa Cool[*1], Ole Sigmund[2] and Niels Aage[2]*

[1]*KU Leuven, LMSD*
[2]*Technical University of Denmark*

ABSTRACT

The control of wave propagation through metamaterials is extensively researched in different disciplines. In the field of noise and vibration, metamaterials are mostly designed to obtain bandgaps, i.e. frequency ranges without free wave propagation. The unit cell designs commonly target the attenuation of structural or acoustic waves separately. Only more recently, metamaterial designs have come forward which have extraordinary performance characteristics by obtaining a simultaneous acoustic and structural bandgap, e.g. [1]. To result in this simultaneous bandgap, intricate complex unit cell geometries are required which are difficult to tune and require expert knowledge since both the elastic and acoustic phase is of importance and influence each other. Moreover, commonly one of the bandgaps is narrow banded. In this regard, optimization routines can be an important enabler to automate the design of these novel vibroacoustic metamaterials. In this work, a 2D topology optimization routine is presented with the objective of maximizing the vibroacoustic bandgap of the in-plane wave modes. During optimization, the vibroacoustic coupling in the design and dispersion curves is considered. A volume constraint is included to control the light-weight character of the designs. Additionally, a connectivity constraint is required to avoid material islands and control the stiffness of the obtained designs. With this framework, novel vibroacoustic metamaterial unit cell designs are obtained, which present wide omni-directional simultaneous acoustic and elastic bandgaps. Moreover, the trade-off between stiffness, weight and attenuation performance during the design of vibroacoustic metamaterials is investigated.

ADAPTIVE COVARIANCE ESTIMATION FOR MULTI-FIDELITY OPTIMIZATION

Thomas Coons[1], Aniket Jivani[1] and Xun Huan[1]*

[1]*University of Michigan*

ABSTRACT

Multi-fidelity variance-reduction techniques (e.g., approximate control variates [1] and multilevel BLUEs [2]) have seen considerable attention in recent years, in many cases providing orders-of-magnitude computational savings in accurately estimating statistics of a high-fidelity model. These methods require the covariance matrix across model fidelities, which is usually estimated via pilot sampling or reinforcement-learning techniques [3] in conjunction with the sample covariance formula. Depending on the model ensemble available, this covariance estimation can be costly or inaccurate, leading to suboptimal estimators. Furthermore, most multi-fidelity estimators are not designed with an outer design optimization loop in mind, where covariance information and thus optimal estimator properties may vary substantially from design to design. In this work, we leverage uncertainty information in a parameterization of the covariance matrix to adaptively guide pilot sampling simultaneously as the outer optimization loop converges. In doing so, the overall multi-fidelity optimization process can converge more efficiently. We demonstrate this through applications for multi-fidelity optimal experimental design.

METRIC-BASED CURVED MESH ADAPTATION USING HIGH-ORDER EDGE OPERATIONS

Krzysztof Fidkowski[1], *Alexander Coppeans**[1] *and Joaquim Martins*[1]

[1]*University of Michigan*

ABSTRACT

We present a strategy for adapting high-order curved unstructured meshes using local mesh modification operations to conform to a prescribed metric field. Curved meshes are required for high-order discretizations, but they are difficult to generate and adapt, especially when anisotropic elements are required near curved boundaries. Typically, mesh adaptation is performed by first converting the curved mesh to a linear mesh, adapting the linear mesh, and re-curving the linear mesh around curved boundaries. The re-curving process can be done through solving an optimization problem or an analogous physics based elasticity problem. However, these approaches are computationally expensive and do not guarantee a valid curved mesh. To address this problem, we extend traditional linear edge-based mesh modification to high-order elements. The use of a sequence of individual local operators guarantees that the high-order mesh remains valid and represents the curved geometry throughout the adaptation process as any modification that leads to invalid elements is rejected. Results for two-dimensional adaptive simulation for a variety of mach and Reynolds numbers are presented. Comparisons with global linear re-meshing with re-curving show similar output error convergence, similar computational cost as re-curving, and improved robustness.

ABSTRACT

The industrial energy sector oversees an extensive quantity of pipelines, and their behavior under normal operation or incidental event shall be understood. Recent works have focused on simulating such pipe structures under intense dynamic loading . However, under the context of the utmost safety of nuclear power plants, it is imperative to investigate extreme accidental scenarios. As a consequence, pipe deformations, as well as hypothetical pipe ruptures, have to be examined.

An advanced tube model has been previously developed in [1] as an uniaxial enriched beam model for thin-walled pipes. It combines a beam and a shell behavior to model the pipe cross-section deformation with Euler-Bernoulli and Love-Kirchhoff hypotheses, respectively. The displacement fields are expanded as Fourier series with respect to the angular parameter, and the degrees of freedom of the model correspond to the Fourier coefficients.

This new mechanical pipe behavior model was formulated within a fast transient time-explicit and Lagrangian Finite-Element framework. Comparisons with multi-dimensional FE models were also performed in [1] to validate the static and dynamic behavior of the advanced pipe model.

In this work, the hybrid shell-beam pipe element is completed in order to study the evolution of a progressive crack through the pipeline. For this purpose, new degrees of freedom are added to allow dynamic crack propagation along the pipe. A short presentation of the kinematics required to accurately represent pipe cracking behavior is conducted. The proposed model is then examined through simple examples of straight pipe or elbow under various loadings, such as internal pressure and flexion. The results and quantities of interest, such as crack speed and position, are compared with a 3D erosion model as in [2] in the explicit dynamics framework to assess the physical reliability of the 1D model.

ABSTRACT

A bicuspid aortic valve (BAV) is a common congenital cardiac disorder where the aortic valve only has two cusps instead of the typical three and is linked to aortic valve dysfunction and aortic aneurysm and affects approximately 1.4% of the population [1]. There are three major types of morphologies that BAVs present in, 90% of which are type 1 valves, where two of the three leaflets are fused. Additionally, several studies have shown a significant variation in BAV morphology within type one BAVs. One study defined variations of type one BAVs based on which two leaflet cusps were fused and whether they were completely or partially fused [2]. This study simulated and analyzed six type 1 BAV morphologies using a validated open-source computational fluid-structure interaction framework based on immersogeometric analysis [3]. Immersogeometric analysis is a computational technique that immerses designs geometries in a non-conforming mesh. This method allows the simulation of flow past complex geometries without worrying about how a boundary-fitted mesh will deform, especially for thin structures such as valve leaflets. To more accurately model the diseased BAVs, both the aortic leaflets and wall employ hyperelastic soft tissue materials and population-based geometric models. Using the above methods, we can isolate the impact of the different valve morphologies on hemodynamics in a physiologically realistic blood flow model. Key metrics for each morphology were studied, such as the wall shear stress in the ascending aorta, valve regurgitation, and valve stenosis. Despite the prevalence of BAVs, the hemodynamics due to varied BAV morphologies are understudied, and tools to assess which BAV patients are most at risk are not readily available. Our open-source computational FSI framework provides a practical approach to investigate these valve morphologies which can later be extended to patient-specific models to increase patient health outcomes.

A SYSTEMATIC METAMODELING FRAMEWORK FOR OPTIMIZING ENERGY ABSORPTION STRUCTURES SUBJECTED TO LOCALIZED DAMAGE

Edinilson Costa[*1] and Larissa Driemeier*[1]

[1]*University of São Paulo*

ABSTRACT

The use of optimization algorithms in designing energy absorption structures has become popular due to their ability to determine the optimal size of geometric features, maximizing performance relative to weight. This approach is particularly valuable in industries where weight reduction is crucial, such as aerospace and automotive. With the advent of digital design and advances in 3D printing technology, optimization can now explore configurations that were previously difficult or impossible to manufacture.
In structures such as composite metallic sandwiches damage modeling is essential to accurately represent the penetration and perforation process when subjected to high velocity impact. These structures can also experience delamination effects, where the thin face sheets separate from the cellular core. The adhesive bonding the components is also susceptible to damage. By considering damage for each component and the adhesive, engineers can better understand the behavior of the structure under impact and make informed design decisions to enhance its energy absorption capacity and structural integrity.
However, this process can be computationally intensive. The proposed metamodeling framework aims to mitigate the computational cost impact in the optimization of structures subjected to high velocity impact. By using a parameterized finite element model of a 3D sandwich structure and space filling Design of Experiment (DOE) techniques for defining sampling points, the framework seeks to create an Artificial Neural Networks (ANN) metamodel that can approximate the behavior and performance of the structure. ANN are then used in combination with genetic algorithms to find the optimum set of variables that improve the energy absorption capacity of the structure.
This metamodeling approach offers several benefits. First, it reduces the computational cost associated with explicitly solving highly non-linear finite element models with damage. Second, it allows for efficient exploration of a wide range of design variables, enabling the discovery of novel configurations that maximize energy absorption. Finally, it provides a systematic framework for optimization that can be applied to various types of energy absorption structures, facilitating design innovation and efficiency.

AN IN SILICO APPROACH FOR SAFETY PHARMACOLOGY STUDIES ON VASCULAR TISSUE

[1]*INRIA*
[2]*University of Antwerp*

ABSTRACT

This work is devoted to the development of in silico models aimed at predicting the effects of drugs on vascular vessels. Specifically, a mathematical model is proposed to reproduce the experimental data of the ROTSAC (Rodent Oscillatory Tension Set-Up used for studying Arterial Compliance) setup [1]. Furthermore, the following two hypotheses on the mechanical impact of vasoconstrictors and vasodilators are investigated numerically: (i) the compound exclusively affects the smooth muscle cells (SMCs) of the vessel; (ii) the compound can alter the stiffness of the endothelium. The arterial wall is modelled as a hyperelastic 3D shell (Ogden law) [2] reinforced with active fibers characterized by an affine stress-strain constitutive law with two parameters: the pre-stress and the elastic modulus of the fibers (see [3]). The inputs of the model are the force measured in the experiment and the parameters describing the behaviour of the material (Young modulus, Poisson ratio, active pre-stress and elastic modulus, initial length, width and thickness of the aortic segment). Parameter estimation is performed with a CRS2 optimization algorithm with local mutation. The numerical results indicate that there are not significant variations in the Young modulus for vasoconstrictors or vasodilators compared to the baseline. However, the most substantial impact is observed on the parameters of the smooth muscle cells' fibers, particularly the active pre-stress and elastic modulus.

POROELASTIC MODEL OF FLUID EXCHANGE BETWEEN BRAIN AND SUBARACHNOID SPACE: A FINITE ELEMENT IMPLEMENTATION WITH JUMP CONDITIONS

Beatrice Ghitti[1], Mohammad Jannesari[1], Patrick J. Drew[1] and Francesco Costanzo[1]*

[1]The Pennsylvania State University

ABSTRACT

The brain, which is suspended in cerebrospinal fluid (CSF) but not attached to skeletal muscles, moves within the skull. The origin and physiological impact of this movement are yet to be understood, but we suspect that it may substantially contribute to CSF circulation and clearing of toxic metabolites from the central nervous system (CNS). Here we present an initial investigation of how mechanical stimuli can be transmitted to the CNS and cause fluid exchange between brain and the surrounding subarachnoid space (SAS). We adopt a large-strain poroelasticity model based on mixture theory with incompressible constituents: a hyperelastic solid, and a fluid moving according to a Darcy flow model. This model was implemented via an arbitrary Lagrangian–Eulerian finite element method (FEM). Both brain and SAS were treated as poroelastic (the SAS is trabeculated and has some load-bearing properties), but with different transport and mechanical properties. Both pressure and fluid velocity are discontinuous across the brain/SAS interface. We performed simple simulations of how the CNS moves in response to mechanical stimuli provided by the vertebral venous plexus (VVP), a network of veins that can communicate pressure changes from the thoracic cavity to the dura of the spinal cord. While our geometry is highly simplified, our results are encouragingly in line with experiments. To obtain these results we had to overcome significant numerical challenges arising from (i) the enforcement of the constituents' incompressibility condition (yielding a nontraditional inf-sup condition), and (ii) the enforcement of the jump conditions at the brain/SAS interface. Particularly challenging was the identification of stable FEM spaces. Here, we will review the jump conditions that arise naturally from the mass and momentum balance laws. We will then discuss our implementation by way of integration by parts for the mass balance equation but not the momentum equation. Our implementation is nontraditional and it explores the use of unusual FEM stable spaces in that the pressure field was interpolated by linear and quadratic Lagrange polynomials with a discontinuity at the brain/SAS interface, whereas the fluid velocity field was interpolated via discontinuous Lagrange polynomials within both the brain and SAS domains. These FEM spaces appear to be inherently stable. We found difficulties in identifying stable spaces with globally continuous (except at the interface) interpolations for both pressure and velocity. However, we also found that stabilization following a Virtual Multi-Scale approach yields promising results.

A COSSERAT FINITE ELEMENT MODEL FOR DEFORMATIONAL BEHAVIOUR OF UNCURED FIBROUS COMPOSITES DURING PROCESSING

Hubert Courteau-Godmaire[*1] and Reza Vaziri*[1]

[1]*University of British Columbia*

ABSTRACT

Composite materials, known for their high stiffness and strength-to-weight ratio, are highly sought after in various industries such as aerospace, automotive, and sporting goods. During manufacturing, fibrous layers, known as plies, are precisely aligned and stacked to achieve desired performance characteristics. However, the layered and soft nature of raw composite materials poses significant challenges, including risks of ply shearing, slipping, or wrinkling, as they are transformed into structural parts.
This research addresses the simulation challenges of layered composite materials. Unlike traditional forming software such as Aniform and PAM-FORM, which model each layer separately, this study employs the Cosserat continuum (micropolar) theory to homogenize the layered kinematics. This approach effectively captures asymmetric shear and intrinsic bending behaviors. A special purpose explicit finite element model, developed in MATLAB, employs high-order elements and a co-rotational approach to enable accurate material orientation tracking. The model effectively handles the large deformation and strain typically experienced by the soft and compliant composite material during its pre-curing stages of processing.
The model's effectiveness is validated through comparisons with experimental data and existing computational models based on classical continuum mechanics. This includes deformation simulations of frictionless thick paper stacks [1] and plastic sheets stacks with interlayer friction [2].
For a direct application in composite manufacturing, the model is shown to capture wrinkle formation in composites during corner consolidation [3]. It is found that such factors as ply bending stiffness and the inter-layer friction coefficient play influential roles in determining the frequency and size of wrinkles.
This research is the first to implement a Cosserat continuum model within an explicit framework for composite processing. While others have used the Cosserat continuum, the current computational framework is particularly effective and robust for handling the large deformation of soft, layered, fibrous materials.

A HIGH-FIDELITY THERMAL-FLUID-SOLID MODELING APPROACH TO UNDERSTAND DEFECT FORMATION AND RESIDUAL STRESSES IN ADDITIVE MANUFACTURING BUILDS

Christie Crandall[*1], Stephen Lin[1], Daniel Moser[1], Carl Herriott[1], Lauren Beghini[1] and Michael Stender[1]*

[1]*Sandia National Laboratories*

ABSTRACT

Qualification of additively manufactured (AM) components for high consequence engineering environments requires science-based understanding of AM processes. Computational simulation has been established as an effective means of probing the complex physics that occur during AM. Defects such as voids, or pores, can be formed as a result of changes in direction of the laser path, or incorrect laser parameters resulting in potentially defective builds. This work uses a one-way coupled thermal-fluid-solid analysis workflow to predict residual stresses and post-build material properties in the presence of voids formed during laser melting and AM processing. Initially a thermal-fluid modeling approach is used to predict laser interactions, deposition patterns, temperature distributions, fluid flow in the melt pool, and the formation of a pore. Results from this thermal-model are then pushed forward into a solid mechanics simulation framework to predict solid phase stresses and the resulting material properties. This talk will show several examples of laser scans patterns that result in pore formation in titanium and aluminum alloys. This modeling approach provides a high-fidelity multiphysics solution for AM processes, albeit at a severe computational cost. These results are useful in quantifying the effects of defects in AM components with the inclusion of residual stresses on structural performance for high consequence engineering environments.

REDUCED BASIS STABILIZATION AND POST-PROCESSING FOR THE VIRTUAL ELEMENT METHOD

Fabio Credali[*1], Silvia Bertoluzza[2] and Daniele Prada[2]*

[1]*IMATI CNR, Pavia*
[2]*IMATI-CNR Pavia*

ABSTRACT

Virtual element methods are known to tackle complex geometries without limitations on the degree of the polynomial that partially contributes to the approximate solution. An important aspect of this method is that we are not required to explicitly compute the basis functions of the VEM space since these are solutions of PDEs. Due to this fact, several quantities are not computed exactly. Two of these are the bilinear form, for which the action on the nonpolynomial part is handled by a stabilization term, and the error, where the contribution of the nonpolynomial part is neglected.
We propose a model order reduction technique constructed by means of the reduced basis method (RB) for efficiently solving the equation associated to each virtual basis function. The idea is to replace the stabilization term with an actual approximation of the nonpolynomial contribution. We show that this operation produces good results even if done in a very rough way. This novel approach improves the convergence properties of VEM when applied, for instance, to anisotropic second order diffusion equations, when standard stabilization recipes show poor performance.
In post-processing framework, it is well known that, when a PDE is solved with VEM, the degrees of freedom of the discrete solution allow only the computation of projections onto discontinuous polynomial spaces, so that the solution is not conforming. The RB approximation of the virtual functions can also be exploited for reconstructing conforming solution in the VEM space. This task can be useful to carry out operations such as visualization, reconstruction in subdomains, pointwise evaluation and evaluation of the conforming error when benchmarking the method.

A PARTICLE FINITE ELEMENT METHOD FOR THE SIMULATION OF 3D CONCRETE PRINTING

Giacomo Rizzieri[1], Liberato Ferrara[1] and Massimiliano Cremonesi[1]*

[1]Politecnico di Milano

ABSTRACT

Over the past few decades, 3D concrete printing (3DCP) has led to significant developments in building design and construction. This technology employs a digitally controlled robotic arm to deposit cementitious mortar filaments, aiming to create arbitrary-shaped items and structural elements. The potential benefits of 3DCP are manifold, including the rapid construction of free-form designs without traditional formwork, decreased reliance on human labour, reduced building costs, and shorter construction times.

However, for the widespread adoption of 3DCP, several challenges need to be solved at both practical and numerical levels. Specifically, the development of efficient and accurate computational tools is crucial for enhancing understanding of the printing process and predicting outcomes in terms of material, structural, and process performance. In this contribution, we simulate the printing process of cementitious materials using a single-phase fluid model [1]. The fluid's motion is governed by Lagrangian Navier-Stokes equations with a non-Newtonian rheological law to describe the material behaviour. To handle numerically large displacements and nonlinearities, the Particle Finite Element Method (PFEM) is here employed [2]. The unique capabilities of PFEM address various numerical issues, including precise treatment of inter-layer contact and the imposition of time-dependent moving boundary conditions at the nozzle outlet [3].

The model has been validated using experimental data from different printing scenarios, providing insightful information on the printing process that perfectly aligns with experimental results. The proposed model can be used as a tool for evaluating the extrudability of cementitious mixes based on rheological parameters. It will be a valuable support to experimental campaigns for developing new cementitious inks, optimizing printing parameters, and predicting occurrences of plasticity and buckling failures during the printing of arbitrarily shaped objects.

A HYBRID HIGH-ORDER METHOD FOR PHASE-FIELD MODELING OF FRACTURE PROPAGATION

Julien Coatleven[1], Alessandra Crippa[1], Daniele Di Pietro[2], Nicolas Guy[1] and Soleiman Yousef[1]*

[1]IFP Energies nouvelles
[2]University of Montpellier

ABSTRACT

In this work we develop and investigate a Hybrid High Order method (HHO) for the problem of modeling of fracture propagation. The formulation of the model exploits a phase-field approach for fracture modeling, which has the advantage of being a continuous method that integrates naturally with Continuous Media Mechanics.

HHO methods offer several advantages with respect to traditional numerical schemes; in particular they support general meshes with non-matching interfaces and arbitrary approximation orders. A direct consequence is the ability to support non-conforming adaptivity of the mesh, which makes HHO methods particularly suited to the case of physical phenomena occurring in small areas of the domain such as fractures propagation.

We exploit the open source HArD::Core library which was developed by D. Di Pietro and J. Droniou and implements HHO schemes for 2D and 3D applications. The library has already been applied to physical problems but not yet to fracture propagation. Thus, we propose to extend it to fracture problems with a novel HHO method based on a coupled system for displacement and phase-field variable in two space dimensions.
Numerical validation on model test problems is also provided.

[3]Universidad Tecnológica Nacional
[4]Universidad de Santiago de Chile

ABSTRACT

A methodology for the simulation of many rigid bodies (RBs) colliding between them and with the walls, and interacting with a Newtonian fluid is presented. The RBs are simulated with the "prtclsys" C++ library, which represents RBs as a set of 4 or more particles with restrictions between them, and uses quaternions for internal computations. The bilateral restrictions are considered via iterative penalization, whereas unilateral restrictions (e.g. collisions between the RBs themselves and with the walls) are computed via penalization. Interaction between the RBs and the fluid is computed via an embedded technique. The Approximate Nearest Neighbor Tree algorithm is used to determine if a given fluid cell belongs to an RB or not to compute the penalization terms, and hence the force of the RB. Regarding the structure, the "prtclsys" library allows the simulation of relatively complex arrays of rigid bodies, links, moors, contacts of the bodies with surfaces, and other restrictions. All items in the simulation are represented as particles, including the rigid bodies which are represented as arrays of four or more particles arranged such that they have the same mass and inertia moments as the target body. The distances between the particles in the rigid body are fixed using restrictions, and the whole dynamic of the system is solved as a system of differential-algebraic equations.

SPATIAL NEURAL ODES FOR MODELING BLOOD FLOW IN STENOSED ARTERIES WITH DEFORMABLE WALLS

Hunor Csala[*1], Arvind Mohan[2], Daniel Livescu[2] and Amirhossein Arzani[1]*

[1]The University of Utah
[2]Los Alamos National Laboratory

ABSTRACT

Coupled partial differential equations serve as a fundamental framework for describing a wide range of multi-physics phenomena in the natural world. Notably, cardiovascular flows exemplify the complex interplay of these equations, carrying significant real-world implications. Yet, accurately and efficiently modeling such phenomena poses considerable challenges. Here, we tackle the problem of blood flow in a stenosed artery with deformable walls, where the geometry is idealized but the problem is made reasonably complex by a realistic pulsatile inlet flow rate waveform and fluid-structure interaction (FSI). We create a low-dimensional model based on neural ordinary differential equations (neural ODEs) [1], inspired by the 1D blood flow equations. Neural ODEs have been proven to be a versatile tool for scientific machine learning and fluid flow modeling. Data-driven approaches have shown promising results in the past for cardiovascular applications [2], but neural ODEs have not yet been leveraged for blood flow problems. However, solving a coupled set of PDEs poses further challenges that have rarely been addressed in the literature. The solution of one PDE has to be fed into the other PDE, which requires solution smoothness and stability. We demonstrate that in 1D transport problems with periodic boundary conditions in time, a reformulation of neural ODEs in space instead of the traditional temporal formulation, shows significant improvement in the stability of the trained coupled PDEs and their extrapolation accuracy with respect to different inlet boundary conditions. Casting the neural ODEs in space, rather than time, is shown to overcome two main challenges. First, it makes it easy to use different inlet boundary conditions as they are transformed to initial conditions in the spatial neural ODE model. Second, it provides accurate derivatives in the spatial direction, enabling coupling with the continuity equation. This innovative framework accurately captures flow rate and area variations, even when extrapolating to unseen inlet flow rate waveforms. The promising results from this approach offer a different perspective on deploying neural ODEs to model coupled PDEs with unsteady boundary conditions, and could be applied to other unsteady transport problems far beyond cardiovascular flows.

ON THE ROLE OF THERMODYNAMICS AS INDUCTIVE BIAS FOR LEARNED SIMULATORS

Alicia Tierz[1], Mikel Martinez[1], Pedro Martins[1], Francisco Chinesta[2] and Elías Cueto[1]*

[1]Universidad de Zaragoza
[2]ENSAM Institute of Tehnology

ABSTRACT

We review how thermodynamics can act as a very effective inductive bias when developing learned simulators based on the employ of deep learning.

To impose the fulfillment of the first and second principles of thermodynamics, we assume that the evolution of the system has a metriplectic structure (i.e., a combination of symplectic and metric forms). The symplectic structure ensures the conservation of energy in closed systems, while the metric part imposes a no-negative entropy production.

In combination with geometric biases (through the use of graph neural networks), the resulting approach gives very promising results, showing to be very robust for out-of-distribution situations.

Examples are provided that show the potential of the suggested method.

DATA-PHYSICS DRIVEN THREE-SCALE APPROACH FOR ULTRA-FAST RESIN TRANSFER MOLDING (UF-RTM)

Junhe Cui[*1], Andrea La Spina[1] and Jacob Fish[1]*

[1]Columbia University

ABSTRACT

We introduce an efficient computational framework designed for simulating the mold filling process in ultra-fast resin transfer molding (UF-RTM), a term used to describe the application of ultra-low viscosity resins (50-200 at room temperature) under ultra-high pressure (~200 bars)—a combination of pressure and viscosity not yet explored in practical applications. The primary innovation of this framework is its data-physics driven nonlinear homogenization method. This approach effectively tackles the unique challenges posed by this high-pressure, low-viscosity scenario while circumventing the extensive computational demands usually needed for simulating intricate microstructures at multiple scales. The proposed data-physics driven mold filling model has been verified against the direct numerical solutions of the Navier-Stokes/Brinkman equations. Furthermore, we introduce a cost-effective tow saturation model, which has been trained to a high-fidelity method based on the numerical solution of the Cahn-Hillard phase field model with Stokes equations at the pore level. This framework shows promise for ultra-fast manufacturing processes of composite parts, contributing to improvements in mold design, reduction of void formation, and consequently leading to rapid development time and minimized production waste.

REDUCED ORDER AERODYNAMIC MODELING RESEARCH FOR HIGH-PRESSURE CAPTURING WING CONFIGURATIONS BASED ON PROPER ORTHOGONAL DECOMPOSITION AND SURROGATE METHOD

Kai Cui[1], Siyuan Chang[1], Zhongwei Tian[1], Guangli Li[1] and Yao Xiao[1]*

[1]*Chinese Academy of Sciences*

ABSTRACT

Fast aerodynamic prediction is one of the key technologies for the multi-disciplinary optimization design of hypersonic vehicles. Most of the research focuses on vehicles with a single lift surface, such as blended-wing-body and waverider configurations. However, if there are strong aerodynamic interactions between the various components of a vehicle, the conventional prediction method may be challenging to be effective. Recently, a novel hypersonic aerodynamic configuration, called high-pressure capturing wing (HCW) [1], has been proposed to achieve the goal that a vehicle with a large volumetric ratio can simultaneously have a high lift-to-drag ratio and a high lift coefficient, which has been demonstrated by the hypersonic experimental investigation referred in [2]. For this configuration, a shock wave induced by the fuselage strongly interacts with the HCW. Therefore, the engineering estimation of aerodynamic forces for the HCW encounters difficulties. Aimed at solving the shortcomings of engineering estimation and computational fluid dynamics (CFD) calculation, a reduced order modeling (ROM) framework based on proper orthogonal decomposition (POD) and surrogate method is proposed. First, five parameters (the incoming Mach number, half-cone angle of body head, expansion angle of rear body, setting angle of HCW, and setting height of HCW) were set to the design variables in this study, and the uniform experimental design method was performed to obtain the 81 samples, uniformly distributed throughout the design space. Next, a CFD solver was used to evaluate the flow field characteristics of all the samples by solving the three-dimensional Reynolds-averaged Navier-Stokes (RANS) equations. Subsequently, a POD analysis process was performed for the pressure distributions acting on the HCW lower surfaces, and the Kriging method was used to establish the relationship between the five design variables and each POD basis mode coefficient. Test results indicate that the mean relative errors of pressure for all test samples can be less than 3%. Using more POD basis modes would not obviously improve the estimation accuracy when the basis modes reach 15. In brief, the reduced order modeling for the aerodynamic prediction of HCW configurations has good accuracy and efficiency.

A MULTIPHASE SPH SOLVER FOR IN-FLIGHT SUPERCOOLED LARGE DROPLET IMPINGEMENT AND SOLIDIFICATION

Xiangda Cui[1] and Wagdi Habashi*[1]

[1]*McGill University*

ABSTRACT

Supercooled large droplets (SLD) solidification is a complex multi-physics process of great importance for assessing in-flight icing problems. This work presents a multiphase smoothed particle hydrodynamics (SPH) solver that can conduct “numerical experiments” of SLD impingement and solidification under flight conditions.

In the present multiphase SPH solver, the momentum and energy equations are solved for flow and heat transfer, along with an equation of state linking pressure and density. A multiphase model is used to represent interfacial flows and a fixed ghost particle method to enforce boundary conditions. Artificial viscous and diffusive terms are employed to smooth physical fields and decrease numerical instability, while a particle shifting technique is used to alleviate anisotropic particle distribution. Several numerical techniques are proposed to model the complex physics of SLD impingement such as a contact angle model to represent the non-wetting properties of hydrophobic surfaces, a latent heat model to account for phase change, and a dendritic freezing model to capture dendrites growth in supercooled solidification.

The solver is validated against a series of experimental results, showing good agreement. It is then first applied to droplets impinging at flight speeds on a water film to study the effects on the post-impact water crown of droplet speed and diameter, water film thickness, and impact angle. Droplets impacting cold solid surfaces are then simulated to study freezing time and post-impact ice particle distribution for a range of speeds and impact angles. Following this, an improved contact angle model is used to study the interaction between droplets and hydrophobic/superhydrophobic coatings. Finally, SLD impingement on ice surfaces is studied via a dendritic freezing model, assessing supercooling degree and impact speed effects on residual ice.

This solver is a comprehensive toolset for the parametric study of SLD impingement and paves the way for an SLD icing simulation model more specifically applicable to aircraft flight speeds.

AN ANALYTICAL SENSITIVITY ANALYSIS FOR THE TOPOLOGY OPTIMIZATION OF HYPERELASTIC MATERIALS

Yi Cui[*1], Toru Takahashi[1] and Toshiro Matsumoto[1]*

[1]*Nagoya University*

ABSTRACT

Topology optimization finds diverse applications across aerospace, mechanical, bio-chemical, and civil engineering disciplines. In most previous topology optimization studies, elastic materials (linear materials) were usually assumed when analyzing the displacement field. Hyperelastic materials, exemplified by for example Mooney–Rivlin Material, typically manifest a highly nonlinear stress-strain relationship, often undergoing substantial reversible strains. Addressing the complex topological optimization challenges of Mooney–Rivlin Material greatly expands the applicability of topology optimization. This study employs the open-source software Freefem++ to conduct displacement field analysis of nonlinear materials through the analytical sensitivity analysis. This is achieved by iterating through multiple iteration loops, ultimately obtaining the topological optimization results of Mooney–Rivlin and Neohookean Material by solving the respective adjoint problems.

A MULTISCALE CREEP MODEL CONSIDERING THE CONCURRENT EVOLUTION OF POINT DEFECT, DISLOCATION, GRAIN BOUNDARY, AND VOID

Yinan Cui[1] and Zhun Liang*[1]

[1]*Tsinghua University*

ABSTRACT

Creep poses a significant threat to the integrity and longevity of structural components at high-temperature. The most current understanding of creep mainly focuses on the coupled effect of point defects and dislocation, which may well describe the second stage of creep. However, the behavior of the three stages of creep is jointly contributed by point defect (vacancy) diffusion, dislocation glide, dislocation climb, GB sliding, and void evolution. A critical knowledge gap still exists regarding how these different creep mechanisms are simultaneously coupled during the different stages of creep. In this work, a multi-physical mechanism-based multiscale model is proposed to consider the concurrent evolution of point defect, dislocation, GB, and void based on a unified thermodynamic framework. In-situ scanning electron microscope (SEM) creep experiments and macroscopic creep experiments of Ti-6Al-4V were conducted to validate our model. The proposed model well predicts both the microscopic and macroscopic experimental creep behavior. The contribution of different microstructure evolution is discussed, and a phase diagram of the dominated creep mechanism is obtained This work not only deepens our understanding of the micro creep mechanism but also offers valuable insights for designing materials with specific microstructures to enhance their creep resistance.

MODELING BRITTLE MATERIALS WITH FLIP+MPM

David Culp[*1] and Jiajia Waters*[1]

[1]*Los Alamos National Laboratory*

ABSTRACT

When brittle materials are involved in numerical simulations, the materials modeled will ultimately undergo fragmentation, that is, complete material failure and the opening of new physical crack surfaces. In order to simulate this phenomenal, a viscoelastic brittle material model (VBMM), an isotropic, orientation-independent model, is proposed to predict the initial stages of mechanical response, including material damage and viscoelasticity. However it will be challenging for Eulerian framework to simulate fragments due to failure. Therefore, by implementing this viscoelastic damage model into FLIP+MPM and applying simple failure criteria we can simulate processes where material catastrophically fails.

FLIP-MPM has significant advantages for solving problems that have large material deformations and has also been applied to many areas, such as material fracturing and fragmentation, fluid-structure interactions, and multiphase flows due to its multi-velocity capability.

In order to simulate the constitutive response of brittle materials, a viscoelastic strength and damage model were developed in the framework of Pagosa's FLIP+MPM. The model is calibrated over a variety of strain rates and calculates damage via growth of initial shear cracks to a critical size also taking tensile/spall criteria into account. The model also considers the nonisothermal condition. The temperature will change not only due to the inelastic work, but also the frictional heating (crack work). Here we will show the simulation by the viscoelastic brittle material model in FLIP+MPM/Pagosa and the (macro-damage) failure criteria.

NONRIGID IMAGE REGISTRATION OF LONGITUDINAL SUBJECT DATA TO QUANTIFY AGE-RELATED VENTRICULAR ENLARGEMENT

Lauren Cunniff[*1] and Johannes Weickenmeier*[1]

[1]*Stevens Institute of Technology*

ABSTRACT

One of the most prominent features of the aging brain is cerebral lateral ventricular enlargement caused by neurodegeneration-driven tissue volume loss. As such, ventricular changes are considered a valuable marker to distinguish between healthy aging and neurodegenerative diseases. Therefore, we developed a novel approach to extract lateral ventricular shape changes from longitudinal magnetic resonance images via nonrigid registration and quantify corresponding mechanical loading of the ventricular wall. Our registration approach utilizes rigid, affine, and nonlinear registration to obtain true ventricular deformations between two longitudinal images. Rigid registration facilitates broad global alignment, allowing subsequent affine and nonlinear registrations to capture age-related differences rather than positional disparities. We utilize FSL-based registration algorithms to provide the final deformation field between scans. To enable comparison between subjects, we created a template model of the ventricle based on segmentation of the MNI-152 brain atlas. We deform the template model to fit each subject’s baseline scan using our registration framework and subsequently map the subject’s displacement field onto the mesh. This allows us to compare ventricular deformations among subjects as well as to perform statistical analysis across our subject pool. In a final step, we compute area stretch and thickness changes of the ependymal cell layer forming the ventricular wall as measures of the mechanical loading of the ventricular wall.

We selected 50 healthy subjects from the Alzheimer's Disease Neuroimaging Initiative based on their age at baseline (70-75 years) and a follow up scan 4-5 years later. The ventricular deformations between the initial and follow-up scans revealed mostly uniform expansion during the observation period. Some local features include (i) pronounced wall strains along the ventricle’s edges of the main body and (ii) above-average curvature changes in the anterior and posterior horns. Strikingly, regions of higher mechanical loading coincide with locations commonly associated with periventricular white matter hyperintensities. This suggests that periventricular white matter hyperintensities are possibly caused by increased mechanical loading of the ventricular wall.

TWO-SCALE DATA-DRIVEN DESIGN FOR HEAT MANIPULATION

Daicong Da[*12] and Wei Chen*[2]

[1]*Boise State University*
[2]*Northwestern University*

ABSTRACT

Data-driven methods have gained increasing attention in computational mechanics and design. This study investigates a two-scale data-driven design for thermal metamaterials with various functionalities. To address the complexity of multiscale design, the design variables are chosen as the components of the homogenized thermal conductivity matrix originating from the lower scale unit cells. Multiple macroscopic functionalities including thermal cloak, thermal concentrator, thermal rotator/inverter, and their combinations, are achieved using the developed approach. Sensitivity analysis is performed to determine the effect of each design variable on the desired functionalities, which is then incorporated into topology optimization. Geometric extraction demonstrates an excellent matching between the optimized homogenized conductivity and the extraction from the constructed database containing both architecture and property information. The designed heterostructures exhibit multiple thermal meta-functionalities that can be applied to a wide range of heat transfer fields from personal computers to aerospace engineering.

SPARSE BAYESIAN NEURAL NETWORKS FOR NONLINEAR TIME SERIES PREDICTION: TACKLING OVERFITTING AND UNCERTAINTY QUANTIFICATION

ABSTRACT

Neural networks (NNs) demonstrate impressive expressivity to mimic the dynamics of complex systems, thereby offering a promising predictive model. In pursuit of enhanced predictive accuracy, there has been a trend toward increasing parameters in these networks, which has introduced significant challenges. A primary concern is overfitting, where the model becomes too tailored to the training data and fails to generalize well to unseen data. With the increase in parameters, the computational demand also rises.

While many approaches have been proposed to resolve this issue, they often fail to adequately address the complexity inherent in such models. This leads us to a critical question: how can we effectively choose the complexity of NNs while ensuring robustness and reliability in their predictions? To address this critical question, the focus shifts toward finding a balance between model complexity and data-fit. Leveraging insights from a hierarchical Bayesian setting in which the priors are conditional on hyperparameters, we construct a Bayesian NN (BNN) by applying a semi-analytical framework known as nonlinear sparse Bayesian learning [1]. This network aims to address the practical and computational issues associated with BNNs by imposing a sparsity-inducing prior that encourages the automatic pruning of redundant parameters based on the concept of automatic relevance determination (ARD).

This network is designed to leverage a hybrid prior [1], facilitating the use of a combination of ARD priors and informative priors. This configuration is advantageous for problems in computational mechanics as it permits the incorporation of relevant knowledge of the underlying system. Additionally, a Gaussian mixture model approximation of posterior distribution as a function of hyperparameters enables semi-analytical calculation of Bayesian entities. This reduces computational complexities typically associated with BNNs. The sparse BNN (SBNN) algorithm eliminates redundant parameters by optimally selecting the precision of the ARD priors, identifying the optimal sparse NN, effectively addressing overfitting. To demonstrate the benefits of the SBNN, we introduce an illustrative regression problem and contrast the results with a BNN using standard Bayesian inference and hierarchical Bayesian inference. Sparse Bayesian recurrent neural networks and Long Short-Term Memory will then be applied for the prediction of dynamical systems; a nonlinear oscillator inspired by the aeroelastic dynamics of airfoils in wind tunnel experiments, and compartmental model for COVID-19.

PHYSICS-INFORMED MACHINE LEARNING AND MOLECULAR DYNAMICS OF COMPUTATIONAL DIFFUSION MAGNETIC RESONANCE IMAGING

Michael Dada[1], Bamidele Awojoyogbe*[1] and Nicholas Udeme*[1]

[1]*Federal University of Technology, Minna*

ABSTRACT

In this talk, we present the viability of adding physics-based limitations into neural networks for image processing applications and the ability of Physics-informed neural networks (PINNs) to identify and extract relevant features from medical images, utilising the underlying physical properties of the imaging modality for more accurate feature representation, and evaluating the effectiveness of PINNs in reducing noise and artefact pre-selection.

There is no molecular situation where diffusion may be completely ruled out. The observed molecular dynamics are a product of all conceivable events occurring in the sample. Attempts to derive NMR diffusion from the Bloch NMR flow equations have been made [1]. The magnetic resonance signals detected from molecular dynamical processes derived in term of molecular diffusion is the focus of this presentation.

The goal is to develop physics-informed neural network algorithms for feature extraction, denoising, and segmentation of diffusion magnetic resonance signal (images) based on (i) physics-guided feature extractions (ii) strategies inside neural networks that rely on physics-based models to decrease data noise (iii) segmentation tasks, that include physical limitations in neural networks (iv) model performance in terms of peak signal-to-ratio (PSNR) and structure similarity index (SSIM).
These involve accurately defining boundaries or regions of interest, as well as performing comprehensive quantitative and qualitative studies to compare the performance of the PINNs method to traditional approaches and other deep learning techniques. Metrics including accuracy, sensitivity, specificity, and processing efficiency will be employed.

By incorporating the underlying physical laws driving the data, PINNs may increase segmentation accuracy, particularly in instances where conventional, exclusively data-driven algorithms may fail owing to noise or a lack of annotated data. Since medical imaging data are expensive or complicated, incorporation of physics-based constraints inside neural network topologies has the potential to reduce dependency on vast amounts of labelled training data which could be beneficial.
Combining physics principles with neural networks for feature extraction, denoising, and segmentation may pave the way to new insights and breakthroughs in fundamental medical imaging knowledge, showing relationships and patterns in medical data that would not be evident using traditional methodologies.

ABSTRACT

Abstract:
The temperature jump at the gas-liquid interface existing during the boiling and evaporation process reduces the internal heat transfer[1]. It is a changelling issue to accuratly capture both two-phase interface and the heat transfer at the two-phase interface because of the rapidly changing interface and different thermophysical properties of two phase. The developed phase-field lattice Bolzman method (pf-LBM)could simulate the immisble two-phase flow. Two energy equations for two phase coupling with pf-LBM is applied to the two-phase flow and heat transfer considering little interface that the computationl cost is high. We borrowed the idea of the concentration change method [2] for the mass transfer at two-phase interface and extended it to two-phase flow and heat transfer process. An energy equation was developed to express the heat transfer process for two phase and two-phase interface. Therefore, it can describe the temperature jump of interface, which is significant for non-equilibrium gas-liquid heat transfer. The new energy equation was integrated with pf-LBM. The integrated mathematical model was fully validated using a thermally stratified Poiseuille flow driven by external forces, thermal capillary flow in microchannels, and droplet migration driven by temperature gradients. The results were in good agreement with the analytical solution.

DISCRETE ELEMENT SIMULATION OF POWDER SPREAD AND OPTIMIZATION

Ling Dai[*1]

[1]*Institute of High Performance Computing*

ABSTRACT

Discrete element modelling (DEM) was used to simulate the process of spreading the Inconel718 powders. Firstly, based on experimental observations, we set up individual powder models with different sizes and shapes. Then powder test, including Pouring Heap, Hall Flowmeter, Revolutionary Powder Analyzer, were simulated to extracted the intrinsic properties, such as the friction coefficients and adhesion strengths. Afterwards, the powder spread process was simulated to deposit powders onto a working platform. In order to achieve high packing density, we characterized various conditional parameters, including blade sliding rate, shape effect, etc. Especially, we studied various blade geometries, such as inclined front surface, flexible cantilever beam, cylindrical roller. With carefully tuning parameters and characterizing packing density, we concluded that the optimized powder packing density was attributed to a combination of regular powder shape, slow sliding rate, and thin blade with slight inclined front surface. Our findings predicted an effective means of powder spreading process so as to serve as the benchmark of Additive Manufacturing technology.

A NONLOCAL ELASITICITY MODEL FOR SIMULATING THE STRUCTURE AND STRESS OF CRYSTALLINE DEFECTS

Shuyang Dai[*1] and Xiaoyin Wang*[1]

[1]*Wuhan University*

ABSTRACT

In this work, we present a nonlocal model in order to solve the static and dynamic problems related to crystalline defects such as dislocations, interfaces, etc. In our model, a superposition framework based on nonlocal description is used to solve the stress and displacement field due to defects. The interaction of dislocation with other types of defects such as cracks can be modeled with higher accuracy due to the consideration of nonlocal effects. The model is sovled by optimiaztion based numerical techniques in order to acclerate the simulations. We also apply this model to problems related to crystal interfaces.

RESEARCH ON SPH MODEL FOR PREDICTING DEPOSITION EFFICIENCY OF COLD SPRAY

Zhen Dai[1], Fei Xu[1], Jiayi Wang[1] and Wei Feng[1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

Cold spray is a solid-state material deposition technique widely used in the repair and coating of metallic components, where understanding and optimizing the corresponding deposition efficiency of process parameters is crucial for process improvement and coating performance. The research commenced with the establishment of a GPU SPH model that simulates the high-velocity impact of particles during the cold spray process. This model incorporates the CS interface force that describes dynamic contact to predict the deposition efficiency based on the adhesive strength of the CS interface force. Results from the simulations showed a high correlation with the experimental data in the literature, demonstrating the model's robustness in predicting particle deformation and bonding conditions, which are essential for determining deposition efficiency. The effects of particle characteristics and process parameters on deposition outcomes were systematically analyzed, revealing that particle temperature and velocity are pivotal in achieving optimal deposition efficiency. The conclusions drawn from this study indicate that the SPH model is a viable tool for predicting deposition efficiency in cold spray processes. This predictive capacity not only provides a deeper understanding of the complex interactions during particle impact but also serves as a foundation for optimizing process parameters without extensive experimental testing.

Keywords: Cold spray, SPH model, deposition efficiency, CS interface force, process parameters.

ABSTRACT

The advancement of nanotechnologies has been clearly driven by the discovery of novel nanomaterials and new nanofabrication routes. Research in nanostructured materials is an emerging field in which revolutionary devices can be designed with unique characteristics using nano-engineered structures as building blocks (Mitchell et al., 2020). This emerging field operates within the 1 to 100 nanometer scale, where morphology, shape, and structure determine material properties.

To successfully obtain nanostructures with tailored properties, different approaches need to be considered. Recently, a new topology-based machine learning method was proposed to predict materials' properties. Another approach, namely Nano-Topology Optimization, was presented to manipulate atom-by-atom to maximize elastic constants. Despite previous studies in designing optimized nanostructures, the use of TO methods at the nanoscale is still in its infancy.
This study proposes a formalized topology optimization method for nanomaterial design. Our approach combines molecular modeling using the LAMMPS (Large-scale Atomic/Molecular Massively Parallel Simulator) package (Plimpton, 1995) with the TOBS (Topology Optimization of Binary Structures; (Sivapuram & Picelli, 2018)) method to design nanostructures with unique mechanical properties.

Here, we present optimized metal nanostructures with unique mechanical properties obtained through a coupling of molecular modeling and the topology optimization method. Single and multiple objective functions were employed to design optimized 2D and 3D nanostructures. Our results demonstrate that their elastic properties can be easily tuned by coupling both approaches with proper constraints. Our results confirm that the coupling between molecular modeling and TOBS is promising for finding optimized designs with enhanced properties. This approach can be extended to more complex problems, including maximizing elastic constants with multiple objective functions and constraints and designing nanofluidic channels to minimize energy dissipation.

NEURAL NETWORKS MEET PHASE-FIELD: A HYBRID FRACTURE MODEL

Franz Dammass[*1], Karl Kalina[1] and Markus Kästner[1]*

[1]*TU Dresden*

ABSTRACT

For the mechanical behaviour of elastomers, micromechanically-informed constitutive models that are based on statistical mechanics have proven of high value, for instance the non-affine unit sphere model [1]. However, these approaches are computationally expensive. Likewise, for the prediction of fracture, the phase-field approach has become a well-established tool, although it comes along with a severe computational effort.

Physics-augmented neural networks (NNs) become increasingly popular for constitutive modelling, and have shown to be suitable surrogates for hyperelastic materials, see e.g. [2]. Apart from their flexibility for describing complex experimentally-observed material responses, these approaches may also reduce computational effort compared to classical micromechanically-informed models.

This contribution aims at combining the predictive capability of the phase-field approach to fracture with the advantages of NNs by means of a hybrid model of fracture. To this end, conceptionally similar to [3], a pseudo-energy functional is introduced, and as contributions to this functional, a neural network-based free energy potential and the classical phase-field fracture dissipation potential are considered.

MACHINE LEARNING-AIDED DIGITAL TWINS FOR DAMAGE SENSING: A MULTI-PHYSICS AND MULTI-SCALE COMPUTATIONAL FRAMEWORK USING PIEZOELECTRIC COMPOSITES

Saikat Dan[*1], Preetam Tarafder[1] and Somnath Ghosh[1]*

[1]*Johns Hopkins University*

ABSTRACT

Failure of composite materials is inherently a multiscale phenomenon. It is governed by damage mechanisms at the microstructural length scale of the material. These damage mechanisms determine the initiation and evolution of fracture across length scales, manifesting its effects on the structural response. This necessitates the development of a robust sensor that can quantify the characteristics of material damage. Piezoelectric composites are an obvious choice for this application due to a strong electromechanical coupling. This work attempts to advance our understanding of damage and develop a tool to predict it. A micromechanical model for crack evolution in heterogeneous piezoelectric composite microstructures is developed. Crack propagation and interfacial decohesion in the presence of electro-mechanical fields are modeled by a phase-field model integrated with cohesive traction-separation laws at material interfaces. However, high gradients in the solution fields require a fine discretization of the computational domain leading to increased computational cost. The first part of the work implements an adaptive wavelet-enhanced hierarchical framework to improve the efficiency of the finite element solver. Numerical examples are solved to demonstrate the advantage of this technique over conventional methods.

Simulating damage in structural scale components using a high-fidelity phase field model is computationally intractable. Therefore, a generalized higher-scale continuum damage mechanics model for piezo-composite structures is introduced in the second part of the work. Evolution laws are formulated to model damage growth at the component scale with evolving mechanical and electrical fields. A nonlocal scheme is included in the finite element implementation to alleviate mesh dependency in the simulations. Numerical examples are solved to demonstrate the macroscopic effects of damage on the structural response.

The strong electromechanical coupling in piezoelectric materials leads to the third part of the work which develops the digital twin of a damage sensor. This can quantitatively predict microstructural damage from the measurement of macroscopic electrical signals at predefined locations on the surface of the structure. An advanced machine learning model capable of treating history-dependent nonlocal material data is employed for this purpose. This model can replace current practices of damage sensing techniques by providing a quantitative global damage indicator in near-real time rather than a location-specific qualitative damage measure.

CONTINUOUS-DISCONTINUOUS ANALYSIS OF FATIGUE FAILURE USING THE DISCONTINUITY STRAIN METHOD

Alireza Daneshyar[*1], Leon Herrmann[1] and Stefan Kollmannsberger[1]*

[1]*Technical University of Munich*

ABSTRACT

Fatigue failure analysis involving crack initiation and propagation is numerically challenging as the pre-crack mechanism is governed by continuum mechanics, while the post-failure behavior falls into the category of contact mechanics. Although either continuous or discontinuous models are frequently employed to describe the process, none of them is adequate when considered alone. Discontinuous models use strong discontinuities to resemble sharp cracks, yet they are not well equipped to describe diffuse damage arising from micro-crack nucleation. Ductile damage models, on the other hand, render the deformation of the failed region to be irreversible, leading to unphysical behavior upon unloading. The reason lies in the fact that continuum straining continues after complete failure, which gives rise to the accumulation of plastic strain across the failed region. Thus, neither stress redistribution nor the unloading branch of global responses can be correctly captured. We provide a solution for those issues by augmenting the conventional additive strain decomposition of the infinitesimal strain theory. We introduced a discontinuity strain to the conventional elastic-plastic strain decomposition to absorb the unphysical continuum strains across the failed region [1, 2]. Accordingly, no further plastic straining occurs, leading to more realistic local and global responses. This augmentation neither invokes a major modification of the constitutive model nor increases the computational efforts associated with crack closing and reopening effects. Although the method can be employed in conjunction with any kind of material model, we use simple ductile damage to introduce the idea. We adhere to this strategy to keep the complexity arising from constitutive modeling minimal. After presenting the theoretical and algorithmic aspects of the method, it is validated against established experimental benchmarks from the literature, showing its robustness in fatigue failure analysis and potentially in other phenomena invoking the representation of discontinuities along with ductile damage formulations.

[4]Nanyang Technological University

ABSTRACT

Conventional plasticity theories have long held that hydrostatic pressure merely results in volumetric changes in solids without inducing plastic deformation. However, our studies here reveal a fascinating deviation from this conventional understanding as exemplified by nanotwinned (NT) metals. Using X-ray diffraction (XRD) and transmission electron microscopy (TEM) techniques, we have found detwinning phenomena in Cu-10wt.%Ni NT metals under high quasi-hydrostatic environment (~11.5GPa) applied by using diamond anvil cells. In addition, there exist a significant grain growth and a reduction in the number of twins, which are key indicators for plastic deformation behavior of the NT material under hydrostatic pressure. To comprehensively understand these phenomena, we have conducted large-scale molecular dynamics (MD) simulations to explore the plastic deformation behavior of NT metals under such extreme loading conditions. Remarkably, our MD simulations unveil a compelling insight: the presence of grain boundaries and twin boundaries leads to localized stress concentrations, ultimately resulting in plastic deformation at the nanoscale. Such behavior is quite unconventional according to the conventional plasticity theories under hydrostatic pressure. These results not only corroborate our experimental observations and but also expand our understanding of material behavior under extreme conditions. Furthermore, the present study not only sheds light on the unique plastic deformation mechanisms in NT metals but also challenges the conventional plasticity theories, advocating for the expansion of their boundaries , which may open up new directions for material design and engineering.

PERFORMANCE OF ARBITRARY-ORDER FINITE ELEMENTS IN NONLINEAR LUMPED-MASS EXPLICIT DYNAMIC ANALYSIS

Kent Danielson[*1] and Robert Browning*[2]

[1]*U.S. Army Engineer Research and Development Center*
[2]*Battelle Memorial Institute*

ABSTRACT

For over a decade, higher-order finite elements have proven to be effective for lumped-mass explicit methods in highly nonlinear solid dynamics, including contact/impact applications, and have increasingly become available in popular codes [1-3]. These elements have distinct advantages that can naturally represent curved shapes, model flexure without significant shear locking or artificial spurious hourglass control/special modes (e.g., incompatible, assumed strains, etc.), and can facilitate locking treatments for nearly incompressible materials. Nevertheless, use of lumped-mass higher-order elements generally is still far less than that of the traditional first-order ones. This is especially the case with increasing orders, as the LS-DYNA and IMPETUS AFEA codes have only first-, second-, and third-order solid elements. Hierarchical finite elements can provide improved performances using higher-order enriched basis functions but are not amenable to mass lumping. Similarly, more recent IsoGeometric Analysis (IGA) can exhibit tremendous smoothness benefits but also loses some of its effectiveness in lumped-mass explicit methods. This area is continuing to mature, but smoothness and lumping seem to be opposing mechanisms. Classical Lagrange elements, however, can effectively strike a balance by permitting C0 discontinuity, important in many typical high-rate explicit applications like fragmentation and penetration, while also providing element curvature and increased smoothness via higher-order polynomials. Whereas an effective diagonal lumped-mass central difference time integration is still used, the critical time increment can decrease non-proportionately with increased element order, particularly due to increasingly closer inter-nodal locations used to improve basis accuracy. In this presentation, an examination of the performances of arbitrary-order finite elements in lumped-mass explicit methods is made particularly with regards to basis order and nodal placement. This study uses both single element and other simple analyses as well as common benchmark and practical high-rate applications using various elastic, hyperelastic, and elastic-plastic material models.

EFFECT OF INTERPASS TEMPERATURE ON RESIDUAL STRESS EVOLUTION IN A NICKEL-ALUMINUM BRONZE WIRE-ARC ADDITIVE MANUFACTURING BUILD

Matthew Dantin[*1] and Charles Fisher*[1]

[1]*Naval Surface Warfare Center Carderock Division*

ABSTRACT

Nickel-aluminum bronze (NAB) alloys are commonly used for marine applications such as propellers and valves. Recent interest has shifted to replacing conventionally cast NAB components with those fabricated using large-scale, wire-arc additive manufacturing (WAAM) processes. However, residual stresses and part-level distortion in as-built parts can contribute to build failures and reduced performance in components produced by additive manufacturing (AM) techniques, which hinders process qualification and part certification due to reduced performance. Implementation of higher interpass temperatures are being investigated as a mitigating technique to reduce distortion and residual stresses. This study used commercial AM simulation tools to analyze how differing interpass temperatures can influence the as-built residual stresses in a WAAM-built NAB part. The predicted results were validated using the contour method to quantify the amount of residual stress in the selected component.

TOPOLOGY OF CELLULAR STRUCTURES WITH THE TARGETED NON-LINEAR MECHANICAL RESPONSE

Sushan Nakarmi[1], Nitin Daphalapurkar[1], Kwan-Soo Lee[1] and Jeffery Leiding[1]*

[1]Los Alamos National Laboratory

ABSTRACT

With the advent of advanced additive manufacturing capabilities, it is feasible to create sophisticated cellular structures using diverse materials such as polymers, metals, and ceramics. By altering the topology of the unit cell, a mechanical property can be modulated without changing the material composition. Nevertheless, identifying an optimized topology within an enormous design space that would precisely deliver the targeted non-linear material response is challenging. We have developed a data-driven machine-learning approach capable of reverse-engineering the topology of a cellular structure based on the intended material response in linear as well as non-linear regimes. Our method involves two steps: (a) generating new topology using cellular automata, enabling a database of cellular structures for assessing the structure-property relationship, and (b) reverse-engineering the unit cell topology from the desired non-linear stress-strain data using a generative machine learning framework. This work has potential applications in identifying novel structures with mechanical specifications requiring complex materials response suitable for applications requiring optimized energy absorption, damping attenuation, and impact mitigation.

MULTI-PHASE-FIELD MODELLING FOR AM PROCESSES SIMULATION INCLUDING IN-SITU THERMAL FRACTURING

Roya Darabi[1], Ana Reis[1] and Jose Cesar de Sa[1]*

[1]*Porto University*

ABSTRACT

In the realm of engineering, tackling the intricate challenges associated with thermal fractures in metal additive manufacturing stands as a formidable task. This study harnesses the capabilities of parallel modeling and the Multi-App feature within MOOSE, presenting a comprehensive solution to this multifaceted issue.

Our methodology involves the seamless coordination of both the Main-App and sub-applications to delve into the intricacies of thermal fracture modeling. The Main-App focuses on simulating the underlying physics, encompassing processes such as heating, phase change from powder to liquid state, and solidification. This is achieved through the application of the Allen-Cahn phase field, coupled with an elastoplastic model, all facilitated by the Multi-physics Object-Oriented Simulation Environment (MOOSE). Following this, the data seamlessly transitions to the sub-application for a meticulous analysis of thermal fractures. Specifically tailored to model liquation cracks in Martensitic alloys, the sub-application utilizes diffusive phase field crack modeling, incorporating an additional energy scale of Allen-Cahn to control non-conserved damage evolution.

Efficiency and computational time optimization are realized through the implementation of a staggered method for process synchronization, ensuring the smooth exchange of data between the Main-App and sub-application. Additionally, an adaptive mesh is employed to finely control the interface, guaranteeing precise and accurate modeling of thermal fracture dynamics.

The findings of this study illuminate the impact of process parameters in additive manufacturing and their inherently complex multiscale nature. The ultimate aim is to identify optimal conditions and minimize imperfections in the pursuit of enhancing the overall efficiency and quality of metal additive manufacturing processes.

A PROJECTION-BASED FILTERING STRATEGY FOR QUASI-NEWTON INTERFACE METHODS IN FLUID-STRUCTURE INTERACTION

Nihar Darbhamulla[*1], David Brown[2] and Rajeev Jaiman[1]*

[1]*University of British Columbia*
[2]*ANSYS Canada Inc*

ABSTRACT

Problems involving multiphysical interactions, such as fluid-structure interaction (FSI) require the imposition of interface coupling conditions between the component systems. The extent of interface coupling to be enforced is dependent on the potential instabilities arising as a consequence of the interactions between the systems. A partitioned approach allows for maintaining flexibility and modularity with regard to solving the individual physical systems independently while compromising on the extent of coupling between the systems. In this regard, the coupling is achieved through the formulation of a fixed-point problem. Relaxation strategies have been observed to be slow to converge. The interface Quasi-Newton method (IQN-ILS) [1] based on Anderson mixing has succeeded in accelerating convergence of the fixed point problem involving elastically deforming structures at moderate mass ratios. However, in FSI systems involving low-mass ratios, the problem of coupling the fluid-structure systems is accentuated by the added mass instability [2], and demands an efficient convergence acceleration strategy. The proposed non-linear iterative force correction method illustrated excellent performance in the case of elastically mounted structures with low mass ratios.

The IQN-ILS method involves the formation of an inverse Jacobian whose quality is detrimental to the performance of the method. In this regard, it is essential to ensure linear independence of the residual vectors constituting the secant pairs used in the method. In the current work, we present a method of filtering based on the approximate inverse Jacobian which eliminates redundant data from previous iterates. Simultaneously, we construct a projection-based strategy which regulates no redundant data enters into the computation of inverse Jacobian. Furthermore, this ensures the Anderson acceleration method always attempts to update the solution along new vectors at every iteration. We demonstrate the reduced iteration count, and lower cost [3] involved in the Turek-Hron FSI benchmark for a range of mass ratios.

ABSTRACT

In phase-field simulations of phase transformation reactions in material systems, an accurate obtaining of relevant thermodynamic properties has been a matter of interest. Slight deviations in these properties can lead to enormous discrepancies in the finally evolved microstructures. The Gibbs free energies are among the main factors in this context. To achieve Gibbs free energy functions, Calphad thermodynamic databases are widely used which are constructed based on the applicable theoretical and experimental information on phase equilibria for the specific systems. Different coupling approaches are introduced between these databases and the phase-field models in the literature. The direct implementation of the Gibbs energy functions in the simulation model can exemplarily be mentioned. As an alternative method, the necessary thermodynamic data can be achieved from the databases instantly. In the present investigation, it is shown that such methods are not deemed suitable within the framework of the considered grand-potential-based phase-field model. To reduce the computational effort in solving the higher order mathematical expressions of the Gibbs energy formulations, a workflow is presented to approximate the Gibbs energy expressions in the form of second-order polynomials depending on the temperature and composition. It is shown that these functions can represent the Gibbs values and the chemical potentials quite accurately in a range close to thermodynamic equilibriums. As practical utilizations of the introduced method, the eutectic reactions in different binary and ternary material systems are simulated. Eutectic solidification in NiMo, NiAlMo, and BiInSn systems are discussed under Directional and/or Rotating Directional Solidification (DS-RDS) conditions. As an important parameter study, the effects of anisotropic interfacial properties on the formed patterns are studied and convincing correlations with the experimental and theoretical anticipations are achieved. Self-propagating High-temperature Synthesis (SHS) is another process that is investigated in NiAl and RuAl systems. The evolving polycrystalline grain microstructures reveal convincing agreements with the available experimental data. Altogether, the achieved results demonstrate the applicability of the established coupling method between the Calphad databases and Grand-potential-based phase-field approaches.

LARGE-SCALE MATERIALS MODELLING USING DFT-FE

Sambit Das[1], Vikram Gavini[1] and Phani Motamarri[2]*

[1]University of Michigan
[2]Indian Institute of Science

ABSTRACT

Large-scale Kohn-Sham density functional theory (DFT) calculations involving tens of thousands of electrons are critical required in variety of application areas, which include extended defects in metals and semiconductors, low-symmetry layered materials, large-scale bio-molecular simulations, and many others. However, the stringent accuracy requirements in DFT needed to compute meaningful material properties, in conjunction with the asymptotic cubic-scaling computational complexity with number of electrons, demand huge computational resources. Thus, these calculations are routinely limited to material systems with at most few thousands of electrons. In this talk, I will present a massively parallel real-space DFT framework (DFT-FE) [1-3], which is based on a local real-space variational formulation of the Kohn-Sham DFT energy functional discretized with higher-order adaptive spectral finite-elements, and handles pseudopotential and all-electron calculations in the same framework. I will present the efficient and scalable numerical algorithms in conjunction with HPC centric implementation strategies for the solution of Kohn-Sham equations, that has enabled computationally efficient, fast and accurate DFT calculations on generic material systems reaching ~200,000 electrons. DFT-FE demonstrates an order of magnitude performance advantage over widely used plane-wave codes both in CPU-times and wall-times. Finally, I will discuss a successful large-scale application of DFT-FE to modeling of dislocations in crystalline materials, where we computed the core-energetics of pyramidal dislocations in magnesium and dislocation-solute interaction energies in presence of dilute Yttrium solute alloying. These core energetics are critical inputs to phenomenological modelling of ductility in magnesium alloys, but have so far been out of reach using plane-wave DFT codes. I will present accurate cell-size converged computation of these first-principles inputs that required simulation sizes reaching 3000-6,000 atoms (30,000-60,000 electrons), and has provided crucial insights towards predictive modelling of ductility in magnesium.

REGULARISED CONTINUUM DAMAGE MODELS

Sanhita Das[1] and Eran Bouchbinder*[2]

[1]*Indian Institute of Technology Jodhpur*
[2]*Weizmann Institute of Science*

ABSTRACT

Continuum damage models, typically those with an order parameter, are extremely useful in characterizing both 2D and 3D fracture in materials. They eliminate the necessity of ad-hoc criteria for fracture propagation and regularize a discontinuous crack by the use of a physically meaningful lengthscale. In this talk, there will be a discussion on the application of such regularized models to two problems. The first problem is that of pure brittle damage of elastomers. To solve this problem, we use a geometrically inspired approach where the kinematic quantities appearing in the strain energy takes into consideration the damage of the undeformed configuration. The resistive energy is a function of the Riemannian curvature that ensues from the assumption that the manifold is no longer Euclidean after damage commences. Through this approach, we are able to resolve numerically, a rapidly evolving singularity which is a challenge with all commonly available damage models. The second problem is that of a dynamic crack propagation through a 3D solid containing a tougher asperity. In this problem, the encounter with the asperity gives rise to solitonic crack front waves that travel unabated along the crack front. Contrary to earlier approaches that involved linear perturbation based analytical solutions or the cohesive zone approach, we are able to obtain a nonlinear object with both in-plane and out-of-plane components. The fact that a front wave comprises of both in-plane and out-of-plane components is consistent with experiments and analysis of post-mortem fracture surfaces. Complexities in both these problems are manifold, yet the regularized models are able to resolve them elegantly, with reasonable numerical effort.

SIMPLIFIED CONSTITUTIVE TENSOR MODEL FOR THIN-WALLED FERROCEMENT WALL SYSTEM SIMULATION

César Dávalos[*1], Jairo A Paredes[2], Julian A Mosquera[2] and Daniel Bedoya-Ruiz[2]*

[1]*Universidad Autónoma de Ciudad Juárez*
[2]*Universidad Nacional de Colombia, Sede Manizales*

ABSTRACT

The thin-walled ferrocement wall system has been shown to provide earthquake-resistant properties usable in housing structures through experimental tests. Experimental tests, applied to walls built on a full scale, allow structural parameters to be identified and the capacity and performance of walls under static load to be evaluated.
Previously, constitutive models have been proposed based on an isotropic damage model for modeling the mortar and the classical elasto-plasticity theory for modeling the reinforcing bars and mesh. The combination of the models, through mixing theory, allows reflection of their mechanical behavior for implementation in numerical simulation. The models' complexity and interaction lend itself to using code developed expressly for this type of simulation restricting their use to research purpose.
This document establishes a methodology for simulating thin-walled ferrocement walls through commercial programs using a simplified model for their characterization and analysis, whose input will be the constitutive matrix of the composite material assigned to each finite element. The constitutive matrix of the composite material will be computed considering the percentages of volumetric participation of the simple materials that compose it and the working orientation of the fiber-type materials through the serial/parallel mixing theory.

PROJECTION-BASED MODEL ORDER REDUCTION OF ENVIRONMENTAL FLOWS USING FEM-BASED VARIATIONAL MULTISCALE METHOD

Sujal Dave[1] and Artem Korobenko*[1]

[1]*University of Calgary*

ABSTRACT

The simulation of environmental flows presents a formidable challenge due to the inherent complexity of natural phenomena and the high computational cost associated with traditional modeling approaches. In this study, we propose a framework for the efficient and accurate simulation of environmental flows through projection-based reduced order models (ROMs) within the framework of finite-element method (FEM) and variational multiscale (VMS) modeling [1]. The POD-Galerkin approach is used to construct ROMs that capture the dominant flow features while significantly reducing the dimensionality of the problem. By extracting the most informative modes from high-dimensional flow data, the POD-Galerkin ROMs provide a compact representation of the flow dynamics, enabling faster computations while retaining essential physical insights. To assess the efficacy of our approach, we validate the projection-based ROM framework on standard benchmark cases such as lid-driven cavity, vortex shedding behind a 2D cylinder and turbulence generation on a 2D backward-facing step. Additionally, we demonstrate the applicability of the proposed methodology to real-world environmental flow problems, showcasing its versatility and utility in addressing complex flow dynamics scenarios encountered in environmental sciences and engineering. Through rigorous validation and application to diverse flow scenarios, we demonstrate the effectiveness and potential impact of the proposed approach in facilitating computationally affordable yet accurate simulations of environmental flows.

SIMULATION OF PARTICLE-LADEN FLOW ON AN INCLINED PLANE WITH VARYING TOPOGRAPHY

Evan Davis[*1], Lingyun Ding[1] and Andrea Bertozzi[1]*

[1]*University of California, Los Angeles*

ABSTRACT

We develop a dynamic model to investigate mixtures of particles and viscous fluid on an inclined plane with varying topography. Our model accounts for several important factors, including gravity-induced settling of particles, particle resuspension due to shear-induced migration, the liquid surface tension, and the topography profile. In the thin film limit, we derive a reduced model consisting of hyperbolic-type equations for the liquid layer thickness and particle volume fraction. The resulting equation depends only on the direction parallel to the inclined plane, making it easier to solve compared to the governing equation while still capturing its essential features. A noteworthy aspect of our study is the incorporation of additional terms in the reduced model, which consider the influence of the normal component of gravity, surface tension, and variations in the topography. This inclusion allows us to gain a deeper understanding of how these factors influence the dynamics of the system. We analyze several cases of topographical variations, such as sinusoids, Gaussians, and sharp steps, using both theoretical and numerical approaches. These analyses hold significant practical applications, including the study of mudslides, microchip manufacturing, and material processing.

SURROGATE MODELING WITH DEEP RANDOM FOURIER FEATURES RESIDUAL NETWORKS AND MULTIFIDELITY INFORMATION

Owen Davis[1], Gianluca Geraci[2] and Mohammad Motamed[3]*

[1]*Sandia National Laboratories, University of New Mexico*
[2]*Sandia National Laboratories*
[3]*University of New Mexico*

ABSTRACT

In this work, we consider neural network based surrogate construction leveraging multifidelity data. This is an active area of research that has promising applications in uncertainty quantification for high dimensional problems where conventional surrogate construction is computationally prohibitive. While this body of literature has grown markedly in recent years, there remain important deficiencies, two of which we address here. First, many of the current modeling paradigms are designed with bifidelity information in mind, and they do not present clear principled extensions in cases where we have an ensemble of lower fidelity information sources of know hierarchy in terms of their predictive capability of the true quantity of interest. Second, neural network based modeling paradigms rarely come with embedded and/or scalable uncertainty quantification procedures, which severely limits their utility in practical applications.

To address these shortcomings, we propose a multifidelity modeling paradigm capable of leveraging a hierarchical ensemble of lower fidelity information sources and with embedded uncertainty quantification. This paradigm is based on deep random Fourier features residual networks, which have similar approximation capability to ReLU networks[1], and makes fundamental improvements over our previously proposed bifidelity modeling paradigm based on one layer random Fourier features network[2]. In particular, the new method leverages a novel layer-by-layer global-optimization-free neural network training algorithm with error control. This algorithm utilizes and extends an adaptive Markov Chain Monte Carlo (MCMC) method developed for random Fourier features regression[3], and we leverage this MCMC based training to obtain computationally efficient uncertainty estimates updated after each layer of network training. We will illustrate our method's ability to leverage an ensemble of hierarchical lower fidelity information sources on an array of benchmark problems from the literature, and we will demonstrate the quality of our method's embedded uncertainty estimates on a surrogate modeling task related to quantum gate implementation for noisy intermediate scale quantum (NISQ) devices.

QUANTUM COMPUTING FOR FINITE ELEMENT PROBLEMS

Osama Muhammad Raisuddin[1] *and Suvranu De**[23]

[1]*Rensselaer Polytechnic Institute*
[2]*Florida State University*
[3]*Florida A&M University*

ABSTRACT

Quantum computing holds significant promise for revolutionizing computational approaches in various fields, including engineering and science. Its potential to solve finite element problems, which are computationally intensive on classical computers, stems from its ability to perform calculations at exponentially faster rates. This makes quantum computing particularly suitable for tackling large-scale and complex finite element analyses that are currently challenging or impractical with traditional methods.

In this talk, we will introduce solution algorithms for the two primary types of quantum computing architectures: quantum annealers and gate-based quantum computers. Quantum annealers are specialized for solving optimization problems. However, their application is limited to specific types of problems, and they require a large number of qubits for complex tasks. On the other hand, gate-based quantum computers are more versatile and capable of executing a wide range of algorithms. They promise exponential speedups for a broader set of problems, including those involving linear systems and differential equations. Despite these advantages, gate-based systems are currently more challenging to scale and require sophisticated error correction techniques. As these challenges are addressed, quantum computing is expected to unlock new possibilities in solving finite element problems with unprecedented efficiency and precision.

HIGH-ORDER, STRUCTURE-PRESERVING SCHEMES FOR MAGNETOHYDRODYNAMICS ON GPU ARCHITECTURES

*Joseph Dean**[1] *and Garth Wells*[1]

[1]*University of Cambridge*

ABSTRACT

Established codes for magnetohydrodynamics problems often rely on traditional, low-order discretisations of the Navier–Stokes equations and Maxwell's equations. These low-order methods have low arithmetic intensity, which is not well-suited to current and future generations of high-performance computing architectures. Simulation of complex, whole-system problems will require accurate and stable methods with high arithmetic intensity, especially to exploit the coming generation of exascale computers.

We investigate the application of high-order, structure-preserving methods for the magnetohydrodynamics equations on GPU architectures. These discretisations are stable, arbitrarily high-order accurate, conserve mass exactly, and yield exactly solenoidal magnetic fields, but present some challenges on GPU architectures due to the reliance on high-order H(div)- and H(curl)-conforming finite elements. High-order geometry is also required, which can result in both mathematical and computational difficulties. As an example application, we focus on liquid metal breeder blankets, which are used in some nuclear fusion reactor designs, and present results that examine the fraction of peak hardware performance that can be achieved. The solver makes use of recent developments in the FEniCSx finite element library.

ACCELERATING CFD SIMULATIONS WITH ARTIFICIAL INTELLIGENCE (AI) – A PRACTICAL APPROACH

Manas Kumar Deb[*1] and Marcin Rojek*[2]

[1]*Capgemini*
[2]*ByteLAKE*

ABSTRACT

Throughout the past decade, we have been witnessing a strong and steady rise in the interest in applications of Artificial Intelligence (AI) and the associated Machine Learning (ML) techniques to help solve diverse scientific and industrial problems. One such area is computational mechanics where the focus has been to improve the time and cost efficiencies of complex, nonlinear, and multi-scale systems with the help of AI.

In general, Computation Fluid Dynamics (CFD) simulations involve nonlinear equations which require the use of numerical solvers and fine-scale domain discretization. This leads to high computational costs and long waiting times for results for such simulations. This burden is exacerbated even further in design optimization exercises where typically many simulations need to be conducted to find the optimal flow domain shapes and flow parameters/variables. These challenges make CFD a good target for investigation of potential use of AI.

As an active area of research there are now many publications on the topic of “AI in CFD” (see, for example, presentations from Steve Brunton [1] or Michael Bauerheim [2], and the references therein for a quick summary of problem formulation, solution techniques, and their pros and cons). As such, there are two high-level approaches through which AI can be applied to CFD simulation. The first, creating an alternate/surrogate CFD solver using AI that solves a problem equivalent to the original one, and the second, creating an AI-based layer alongside or surrounding the standard CFD solvers to accelerate the speed of the overall simulation, for example, by requiring fewer iterations or gaining faster convergence rates in an iteration.

The current presentation will focus on the use of AI to accelerate CFD simulations. We will present the overall construct of a self-optimizing AI layer which works in tandem with traditional CFD solvers (see [3] for some background information) making this approach easily adaptable to a wide variety of problems and without requiring a deep knowledge of AI/ML techniques. We will report details of the high (10x-40x) performance gains with this approach in benchmarked problems. We will also discuss the impact of the underlaying HPC hardware on the time/cost of the simulation.

MODEL ORDER REDUCTION TECHNIQUES FOR THE PREDICTION OF VIBRATION IN THE BUILT ENVIRONMENT

Amar Pashov[1], Stijn Francois[1] and Geert Degrande[*1]*

[1]KU Leuven

ABSTRACT

Considerable progress has been made regarding the development of numerical models for the prediction of railway induced vibration, including 2.5D and periodic coupled FE-BE or FE-PML models of the track and soil, as well as 3D FE-BE models for buildings accounting for dynamic soil-structure interaction. These models are used to design vibration mitigation measures and to perform environmental impact studies.

Industry experiences a strong need to conduct extended parametric studies, to optimize vibration mitigation measures in a robust manner, and to perform forward stochastic predictions. These applications require prediction models that are fast to run. We therefore investigate the potential of model order reduction techniques such as Proper Generalized Decomposition [1] to tackle the curse of dimensionality.

The PGD formulation is based on the assumption of a separable form of the multi-dimensional field. Each contribution therefore consists of a rank-one tensor and is computed in a greedy manner. To this end, the PGD formalism is introduced into the weak form and the resulting non-linear problem is solved using fixed-point iterations. Damping terms result in non-Hermitian properties of the operator, hindering convergence of the standard Galerkin PGD approach. Therefore, alternative solution strategies, like Petrov-Galerkin based solvers, are considered [2]. We compare the classical greedy rank-one update with a greedy Tucker approximation method [3].

We elaborate the PGD formulation for three problems with different complexity: (P1) a simplified source model of a beam on Winkler foundation; (P2) a 2.5D model of a ballasted track on a heterogenous soil medium, modelled with finite elements in combination with complex frequency-shifted perfectly matched layers; (P3) Green’s functions for in-plane (P-SV) and out-of-plane (SH) wave propagation in a layered halfspace. Apart from the frequency and wavenumber, we take along the foundation stiffness (P1), ballast and soil properties (P2), or source and receiver positions (P3) as coordinates in the PGD formulation. The considered algorithms are compared in terms of convergence, memory requirements, and CPU time.

DEVELOPMENT OF A METHODOLOGY TO QUANTIFY THE DISTRIBUTION OF VIBRATION FREQUENCY AND DAMPING FOR SUBMERGED ELASTIC STRUCTURES

Joris Degroote[*1] and Henri Dolfen*[1]

[1]*Ghent University*

ABSTRACT

It is well-known that the free vibration frequency and damping ratio of elastic structures, like tube bundles or pump rotor blades, can be significantly different when submerged compared to in vacuum, due to the added mass and damping by the fluid. The complexity of the fluid mechanics in play makes purely analytical derivation of these effects difficult, so a numerical methodology has been established to quantify the submerged vibration characteristics in a reasonable time.

This methodology begins with the development of a time-dependent fluid-structure interaction model by coupling a finite volume flow solver to a finite element structural solver using a quasi-Newton coupling algorithm. The turbulence is modelled with an unsteady Reynolds-averaged approach, as a compromise between computational cost and fidelity. In this model, the structure is then deformed according to one of its eigenmodes in vacuum as initial condition. The free vibration resulting from the release of the structure is subsequently calculated, from which the modified vibration frequency and damping ratio can be extracted [1].

It can occur that the geometrical or operational parameters are uncertain, rendering the vibration characteristics uncertain too. To quantify this uncertainty, the approach mentioned above has been combined with polynomial chaos expansion [2]. This approach requires a number of repetitions of the simulation mentioned above, but the computational cost is reasonable for a handful of parameters, yielding a feasible approach to quantify the distribution of vibration frequency and damping. This new methodology has been validated for the first mode of a flexible tube with uncertain bow in a bundle.

ADAPTIVE WEIGHT TUNING OF PHYSICS-INFORMED NEURAL NETWORKS WITH HARD BOUNDARY CONDITION IMPOSITION FOR FAST AND ACCURATE INVERSE ANALYSIS

Shota Deguchi[*1] and Mitsuteru Asai*[1]

[1]*Kyushu University*

ABSTRACT

Data-driven approaches have found widespread applications in various domains, including the field of computational engineering. In recent years, the use and development of machine learning methods have attracted much attention.
While many machine learning models learn only from a large amount of observed data, the recent trend involves the active development of models to exploit well-established expert knowledge. For physics problems, many models have been proposed to integrate limited data and physical laws, with physics-informed neural networks (PINN) [1] attracting particular attention. PINN integrates known physical laws modeled by the governing equations, making it applicable to both forward and inverse analyses, which is particularly advantageous when the available data is scarce.
In the original formulation of PINN, the loss function is composed of several terms: the difference from observed data (observation loss), the error in fitting the boundary condition (boundary condition loss), and the residual of the governing equations (physics loss). In this formulation, the boundary condition is considered only in a “soft manner”, by adding a penalty term to represent the boundary condition error. The accuracy of PINN solutions is strongly dependent on the penalty coefficient, and therefore, it is effective to impose the boundary condition in a “hard manner” [2]. However, when applied to inverse analysis, penalty terms are still needed to define the observation that is sensitive to the penalty coefficient, although it is difficult to estimate the appropriate range before training. To address this, an adaptive weight tuning method [3] has been shown to be effective.
In this study, with a special focus on inverse analysis, we present a hybrid technique that combines hard boundary condition imposition and adaptive weight tuning to quickly reflect the observed data while imposing the prescribed boundary conditions. The high reliability and efficiency of the presented method is verified by numerical examples.

ABOUT THE HUMAN-STRUCTURE INTERACTION THROUGH A SELF-EXCITED SPRING-MASS-DAMPING MODEL ON RECTANGULAR PLATES

Zenon Del Prado[*1] and Phablo Dias*[1]

[1]*Federal University of Goias*

ABSTRACT

In this study, the human-structure interaction during jumping on a thin rectangular plate is examined. The rectangular plate is modeled according to the nonlinear theory of Von Karman, exploring various boundary conditions and geometric imperfections to closely simulate real behavior of building floors structures. To describe the human effect on the plate, initially, a self-excited single-degree-of-freedom Mass-Spring-Damper (SMD) oscillator is used. Subsequently, a second SMD oscillator is introduced to assess the effect of the synchronism of rhythmic jumping by two jumpers on the plate. A detailed parametric analysis is conducted using the theory of smooth contact dynamics to examine the influence of contact loss during the flight phase of jump cycles. The dynamic response of the plate is analyzed for different values of human biodynamic factors, such as human damping ratio, and the frequency and amplitude of jumps. Consequently, the human response to these changes is evaluated.

ANALYSIS OF WAVEGUIDE PROBLEMS WITH IMPEDANCE BOUNDARY CONDITIONS

Leszek Demkowicz[*1], *Norbert Heuer*[2] *and Jay Gopalakrishnan*[3]

[1]*The University of Texas at Austin*
[2]*Catholic University of Chile*
[3]*Portland State University*

ABSTRACT

The presented work is motivated with the well-posedness analysis for bent optical fibers. To our best knowledge, even the simplest 2D model acoustical waveguide problem in polar coordinates with an impedance boundary condition remains an open problem. We will present at least results for the related straight waveguide problem. Similar to the standard problem with hard boundary conditions, the L^2 stability constant for the first order system depends linearly upon the waveguide length L. The proof is based on the classical (but little known) theory for non self-adjoint operators, see [1]. The results are critical for the numerical analysis of bent optical fibers using the Discontinuous Petrov Galerkin (DPG) method.

A NONLINEAR OPTIMAL CONTROL FRAMEWORK FOR THE DPG METHOD

Leszek Demkowicz[*1] and Jiaqi Li*[2]

[1]*The University of Texas at Austin*
[2]*Oden Institute for Computational Engineering and Sciences*

ABSTRACT

The Discontinuous Petrov-Galerkin (DPG) method is a novel technology to solve partial differential equations numerically, and has been developing rapidly and applied to a broad range of problems in the past 15 years. As a minimum-residual method, the DPG method comes with guaranteed discrete stability and a-posteriori error estimator, which can be utilized to drive hp-adaptive refinements. The majority of applications of DPG involve linear problems; to tackle any nonlinear problem, we have to first linearize the problem, then apply the DPG method to the linearized problem. However, there is no easy guarantee that by minimizing the residual successively for every linearized problem, we obtain a residual minimizing solution of the nonlinear problem. Hence we consider the nonlinear optimization problem directly, in an optimal control framework [1]. As a standard technique in optimal control, we can compute the gradient by introducing the Lagrangian and solving the adjoint equation. With the gradient at hand, we can use steepest descent or nonlinear conjugate gradient methods (e.g. Polak-Ribière) to minimize the residual and obtain the final solution in an iterative way.

In contrast to [1], where Hessian-based methods are developed, we focus on gradient based methods, for two reasons. First, the problem we are interested in may involve cost functional which is not second order differentiable (e.g., penalty functional for inequality constraints). Second, apart from the test norm, the trial norm also enters the computation of the gradient. The freedom of choosing a trial norm means that we can get faster convergence by a wise choice. We analyze, in particular, the linear case, where we can get one-step convergence if the trial norm is the energy norm; if we use L2 trial norm and adjoint graph norm as test norm, linear convergence is also guaranteed, and we find explicitly an upper bound of the spectral radius.

Lastly we demonstrate the capability of our method by solving two nonlinear PDEs. The first problem is a manufactured one, and we compare our results with [2]. The second problem is the full-potential equation.

CONVERGENCE ANALYSIS AND ERROR ESTIMATION FOR MIXED FINITE ELEMENT METHOD MODELING FLEXOELECTRICITY

Feng Deng[*1]*

[1]*Xi'an Jiaotong University*

ABSTRACT

Flexoelectricity is the coupling between strain gradient and electric field (or polarization) in dielectric materials under inhomogeneous deformation. The Mathematical framework describing flexoelectricity is a boundary value problem (BVP) governed by 4th-order partial differential equations (PDE). Direct modeling of the problem BVP with the use of the conforming Finite element method (FEM) requires C1-continuous elements that are complicated to construct and difficult to use. Mixed FEM is another practical approach and shows excellent potential in modeling flexoelectricity as it involves only C1-continuous finite elements. However, the convergence theory and error estimation formula for mixed FEM are absent up to now. In this work, we established a mixed variational principle for general flexoelectric problems by introducing displacement gradient as independent variables and confirmed the well-posedness of the variational principle. Following this, we developed several mixed finite elements that satisfy the well-known inf-sup condition.
Further, we estimated the error of numerical results from the exact solutions for primary and extra variables. In addition, numerical tests were conducted for several benchmark problems, and numerical results were performed in excellent agreement with the presented error estimation. This work bridged the gap of numerical analysis for mixed FEM in modeling flexoelectricity.

DATA-DRIVEN DESIGN OF MULTISCALE NONLINEAR SPINODAL MATERIALS

Shiguang Deng[*1], Liwei Wang[1], Stefan Knapik[1], Horacio Espinosa[1] and Wei Chen[1]*

[1]Northwestern University

ABSTRACT

In recent years, there has been significant research interest in bio-inspired spinodal metamaterials. This is attributed to their versatile and nonperiodic structure, which is less sensitive to manufacturing defects, stress concentration, and material failure compared to conventional materials. However, the design and optimization of such spinodoids often face challenges due to the vast design space of microstructural morphology. Existing efforts have primarily focused on quasi-static linear elastic loading scenarios, neglecting the material's significant potential for nonlinearity. This oversight is attributed to the high costs associated with nonlinear analyses and the laborious derivation of nonlinear sensitivities.

In our work, we introduce a data-driven multiscale topology optimization method that combines microscale spinodal optimization with macrostructural topological design in a generic neural network (NN) framework. Specifically, we formulate a controlled anisotropy scheme in the spectrum density function to accurately depict stochastic, non-periodic, and amorphous microstructures using only a handful of design parameters in a low-dimensional design space. In addition, to emulate the material nonlinearity of hyper-elastically behaved spinodoids subject to large deformation, we employ Gaussian Process (GP) models to establish correlations among material geometry, strain, and stress states. Subsequently, we incorporate the GP models into the NN-based multiscale topology optimization where the tedious derivation of nonlinear sensitivity (which is often performed manually) is seamlessly replaced by NN’s automatic differentiation functionality. To demonstrate the proposed method, we present numerous examples that highlight the superiority of our multiscale spinodal design over conventional multiscale truss-like structures, especially in nonlinear applications.

RC-CAN: RANGE-DEPENDENT CONDITIONAL CONVOLUTIONAL AUTOENCODER FOR REAL-TIME FAR-FIELD UNDERWATER NOISE PREDICTION

Indu Kant Deo[*1], Akash Venkateshwaran[1] and Rajeev Jaiman[1]*

[1]*The University of British Columbia*

ABSTRACT

The transmission of underwater noise in the ocean is an intricate and dynamic process influenced by the complex geometry of ocean bathymetry. Developing accurate and general physical models for predicting acoustic transmission loss in diverse oceanic conditions has been a longstanding challenge. In addressing this challenge, we introduce a novel solution called the Range-Dependent Conditional Convolutional Autoencoder Network (RC-CAN), a deep learning model specifically designed for the real-time prediction of far-field underwater acoustic noise in varying bathymetry ocean environments.

Being data-driven, the RC-CAN model offers a unique advantage, relying solely on data irrespective of the method of data acquisition. By learning a latent representation of input ocean geometry, RC-CAN efficiently reconstructs distributions of far-field transmission loss across the provided ocean mesh. We evaluate the RC-CAN model in a two-dimensional ocean environment with varying bathymetry specifically on the benchmark test case of Dickin's Seamount, revealing its exceptional ability to learn fundamental factors influencing acoustic signal transmission loss, such as sound wave spreading, refraction, and reflection from ocean surfaces and floors. RC-CAN's capacity to capture the intricacies of ocean acoustics holds tremendous potential for real-time prediction of far-field underwater noise. The versatility of our framework suggests its potential applicability in predicting large-scale 3D underwater radiated noise. This innovation could revolutionize decision-making for marine vessels and online control strategies, enabling informed and timely interventions in the constantly changing underwater auditory environment.

MOLECULAR DYNAMICS STUDY OF THE HYGRO-MECHANICAL BEHAVIOUR OF NATURAL AND CONSOLIDATED WOOD

Ali Shomali[1], Jan Carmeliet[1] and Dominique Derome[*2]*

[1]ETH Zurich
[2]Université de Sherbrooke

ABSTRACT

To better understand the hygro-mechanical behaviour of wood, Molecular Dynamics combined with Grand Canonical Monte Carlo simulations [1] is used to model sorption and sorption-induced deformation and determine the mechanical properties of wood components and their mixtures. Adsorption or desorption of moisture are modelled with an imposed chemical potential during the GCMC simulation, while deformation, either swelling or shrinkage, are modeled under constant pressure in MD. In our study, GCMC is implemented using Cassandra package and MD is performed using GROMACS. In this study, we analyze the hygromechanical behavior of amorphous cellulose (AC), mimicking a natural wood component, and of the mixture of AC and polyethylene glycol (PEG), where PEG is used to consolidate.

The results show that pure AC is a hygroscopic material, showing a substantial swelling-induced sorption and a mechanical weakening upon sorption. It also shows hysteresis between adsorption and desorption isotherms. Pure PEG shows much higher moisture contents and swelling strains at high relative humidity (RH) compared to AC, what opens the question how PEG can reduce AC's sorption behaviour. Our results confirm that adding PEG reduces the sorption and swelling behaviour of AC. This counterintuitive observation can be explained by: (1) PEG fills a large part of the existing porosity in AC, as such preventing additional sorption; (2) PEG molecules are constrained by the existing AC structure, hindering swelling and additional swelling-induced sorption. PEG is also found to weaken the material structure reducing the mechanical stiffness. A poromechanical model is developed describing the hygromechanical behaviour of AC, PEG and AC+PEG mixtures allowing to optimize the consolidation process, showing an optimal PEG mass fraction of 15%.

This study was inspired by the treatment of waterlogged archaeological wood of shipwrecks, like the Varsa and Mary Rose, with PEG for its consolidation and stabilization, where PEG molecules replace the water making wood at museum conditions less susceptible to changes in humidity and able to sustain mechanical load.

MICRO MANAGER: A TOOL FOR MULTISCALE COUPLING WITH PRECICE

Ishaan Desai[1] and Benjamin Uekermann*[1]

[1]*University of Stuttgart*

ABSTRACT

For many challenging applications in simulation technology, micro-scale phenomena can dominate macro-scale behavior. Examples in this setting are reactive porous-media flow, biomechanical models of the human organs, and composite structures. This talk presents a novel software framework to couple existing micro-scale and macro-scale simulations in an adaptive and flexible way. We present the Micro Manager, a software component which manages a set of micro simulations, and couples them to the macro simulation through preCICE. By design, preCICE is able to couple two or more models on one physical scale. Hence, we develop the Micro Manager, to allow for application-agnostic macro-micro coupling with preCICE. While reusing key coupling implementations of preCICE (e.g., parallel communication and fixed-point acceleration schemes), the Micro Manager calls all micro-scale simulations as libraries in an adaptive manner and is itself coupled to the macro-scale simulation using preCICE. We show several applications which use the Micro Manager. For every case, we investigate running the micro simulations adaptively, and its effect on load balancing for large parallel cases. Lastly, we present a dynamic load balancing strategy to increase efficiency of large cases.

LÉVY'S SOLUTION FOR LAMINATED COMPOSITE PLATES USING HIGHER-ORDER SHEAR AND NORMAL DEFORMATION THEORY

Himanshu Sawhney[1], Sunil Yadav[2], Yogeshkumar Desai[1] and Sandeep Pendhari[2]*

[1]Indian Institute of Technology Bombay
[2]Veermata Jijabai Technological Institute

ABSTRACT

Equivalent single layer theories (ESL) have been extensively used in the analysis of plates. One of the common assumptions that are considered in all the ESL theories is that the thickness is small as compared to the in-plane dimensions. This assumption is the basis for converting a 3D plate problem into a 2D plate problem by assuming a displacement-model along the thickness. Higher-order shear deformation theories (HOSTs) consider more realistic non-linear variation of displacements along the thickness as compared to the other ESL theories i.e., the classical plate theory (CPT) and first-order shear deformation theories (FOSTs), which consider the linear variation. Due to this reason the solutions obtained using HOSTs are closer to the elasticity solutions. In this paper, static solution of the laminated composite plates is provided using 12 degrees of freedom higher-order shear and normal deformation theory (HOSNT). Results are obtained using the state-space approach for Lévy-type plates i.e., two opposite plate edges having simply-supported boundary condition and other two plate edges having combination of simply-supported, clamped and free boundary conditions. Results from the work compare well with the corresponding results available in the literature. Model can be used for accurate and expeditious analyses of laminated composite as well as sandwich plates.

SEMICLASSICAL NUMERICAL MODELING OF GAIN MATERIALS WITH A HIGH ORDER DISCONTINUOUS GALERKIN TIME-DOMAIN SOLVER

Stéphane Descombes[1], Stéphane Lanteri*[2] and Cédric Legrand[2]*

[1]*Université Côte d'Azur*
[2]*INRIA*

ABSTRACT

In this talk we discuss numerical modeling of the interaction between an electromagnetic field and a gain medium in the context of laser physics, with the goal of simulating the gain process that results in an increase in optical power. This phenomenon can be modelled by a four-level atomic differential system that
couples Maxwell’s equations with a set of non-linear Ordinary Differential Equations to describe the electronic density evolution for each energy level. We present a novel numerical modeling leveraging a Discontinuous Galerkin Time-Domain method in 3D, this method is validated in a 3D framework using a model problem with manufactured solution and is used in more realistic problems.

TOWARDS PREDICTING RAFT COALESCENCE AND NUCLEATION INDUCED BY LIGAND-BINDING ACROSS THE CELL MEMBRANE

Chiara Bernard[1], Angelo Rosario Carotenuto[2], Nicola Maria Pugno[1], Massimiliano Fraldi[2] and Luca Deseri[1]*

[1]*University of Trento*
[2]*University of Napoli Federico II*

ABSTRACT

This current paper studies lipid rafts co-localization during ligand-binding triggered by chemically affine transmembrane receptors (e.g. GPCRs-G Protein Coupled receptors). The latter populate the cell membrane and respond to external ligands through signaling producing cAMP-cyclic Adenosine Mono Phosphate. This is known to be the final product of a cascade of events triggered by activated GPCRs through their conformational changes and simultaneous membrane remodeling. Such activation is mediated by evolving raft co-localization as GPCRs find the right environment for their activation precisely on those sites [1]. Homeostatic levels of cAMP are known to be maintained over time thanks to the presence of MRPs-Multidrug Resistant Proteins, which play the role of signaling regulators in such dynamics. Due to the 'confining' work that the active species exert on the surrounding lipid clusters, the interspecific kinetics between GPCRs and MRPs, and their diffusion across the membrane, are coupled with the deformation of the hosting membrane, at is was found in [2]. In such a paper rafts formation was predicted to be triggered by ligand-receptor activity across the membrane.
Unfortunately, that work provided no insights into the experimentally observed raft coalescence. This is analyzed here through a Cahn-Hilliard type energetics and kinetics of the phase transition of both GPCRs and MRPs. The resulting chemical potential for each species is determined by the change in this newly determined energy plus the specific confining work mentioned above. The interplay between the balance of forces and coupled interspecific kinetics shows diffusive-induced membrane remodeling and raft coalescence, enhancing the size of active receptor sites. Sensitivity analysis suggests how such outcomes can predict cell membrane changes and remodeling by keeping track of active species near homeostasis and, also, away from such states [3].
This could help to gain new insights into the remodeling of cell membranes and could suggest mechanically based strategies to control their selectivity, by orienting intracellular functions and mechanotransduction.

BOUNDS ON Q-FACTOR OF QUASI-STATIC METAMATERIALS AND OPTIMAL MICROSTRUCTURE DESIGNS

Kshiteej Deshmukh[1] and Graeme Milton*[1]

[1]*University of Utah*

ABSTRACT

Resonances in materials have led to many exciting properties and applications in nano-photonics and optics.
A famous example of material resonance is the "Lycurgus cup", which is a 4th century Roman drinking cup made of glass with fine particles of gold suspended in it. The resonances of the gold particles at optical wavelengths cause it to appear either red or green depending on where the light shines from. By making the gold particles hollow one can shift the resonant frequency, even into the infrared where nanoshells have proved significant in destroying cancer cells. So, it is of great interest to know what are the limits to which they can be tuned. The bandwidth of the resonances in materials is an important feature which is commonly characterized by using the Q-factor. We present tight bounds correlating the peak absorption with the Q-factor of two-phase quasi-static metamaterials and plasmonic resonators evaluated at a given peak frequency by introducing an alternative definition for the Q-factor in terms of the complex effective permittivity of the composite material. This composite may consist of well-separated clusters of plasmonic particles and thus we obtain bounds on the response of a single cluster as governed by the polarizability. Optimal metamaterial microstructure designs achieving points on the bounds are presented. The most interesting optimal microstructure is a limiting case of doubly coated ellipsoids that attains points on the lower bound. We also obtain bounds on Q for three dimensional, isotropic, and fixed volume fraction two-phase quasi-static metamaterials and particle clusters with an isotropic polarizability. Some almost optimal isotropic microstructure geometries are identified.

STATISTICAL INVESTIGATION OF THE FAILURE MODES OF STRUT BENDING AND COMPRESSION DURING COMPRESSION LOADING OF POLYDISPERSE CERAMIC FOAMS

Vinit Vijay Deshpande[*1] and Romana Piat*[1]

[1]*Darmstadt University of Applied Sciences*

ABSTRACT

The work studies the modes of failure of the struts during uniaxial compression loading of a ceramic foam with polydisperse pores. The foam is made by mechanical stirring of an alumina slurry [1]. Its microstructure resembles interconnecting polydisperse pores. Gibson-Ashby [2] models (GA) correlate the uniaxial compression failure of open-cell foam to the bending failure of its struts. The strut thickness increases with the relative density and beyond a certain density, the failure mode changes to strut compression and the material no longer resembles a foam. This understanding works well in the case of foams with monodisperse pores. However, in foams with polydisperse pores, there is a wide distribution in strut thickness and orientation for a constant value of relative density. This study answers the question of whether this leads to a combination of failure modes in which strut bending and strut compression act together to cause macroscopic failure. For this, a novel image segmentation algorithm is developed to isolate the struts in the foam microstructure obtained by micro-CT scanning [1]. The distribution of strut thickness and orientation is quantified. Next, a finite element-based uniaxial compression simulation is performed on the same microstructure to identify the failure modes of the struts. It is seen that strut failure mode depends on its thickness and orientation with respect to the loading direction. Classifying the type of strut failure at each step of the loading curve shows that the struts oriented normal to the load direction fail in bending at the very early stages of the loading. However, the macroscopic load keeps on increasing as the struts orientated parallel to the loading are in compression and withstand more load since the compression strength of the base material is much higher than the tensile strength. Macroscopic failure occurs when these struts fail in compression. The numerical value of the compression strength agrees well with the experimental value [1]. Since the dominant mode of strut failure is compression, the strength value is higher than the prediction by the GA open-cell model which assumes strut bending as the failure mode. These conclusions necessitate the development of better models to predict compression failure of such foams that will take into account both failure modes of the struts.

ABSTRACT

In order to make accurate predictions of the structural behaviour of FRP reinforced concrete elements, one of the key problems in the development of this type of new material system is the capacity of modelling the load transfer mechanisms between the concrete matrix and the reinforcement elements. To predict the load-deflection response up to ultimate limit state conditions, a wide range of numerical simulation approaches, with capability of modelling the bond behaviour between the different materials have been proposed over the years and compared to experimental results. This research work presents new possibilities for comparing numerical finite elements models (FEM) with laboratory data generated by computed tomography, namely in the context of three point bending tests performed on carbon-reinforced concrete specimens. The aim is to validate numerical simulation results through computed tomography generated data. Examples of possible validation procedures are shown, which focus on generated strain fields and crack patterns.

A COMPARATIVE STUDY OF ADAPTIVE IMPLICIT-EXPLICIT AND EXPLICIT-EXPLICIT TIME-MARCHING PROCEDURES FOR WAVE PROPAGATION ANALYSES

Isabelle de Souza Sales[1], Delfim Soares Jr.[2], Lucas Ruffo Pinto[1] and Webe João Mansur[1]*

[1]*Federal University of Rio de Janeiro*
[2]*Federal University of Juiz de Fora*

ABSTRACT

This paper delves into the effectiveness of two time-integration techniques, namely the adaptive implicit-explicit (imp-exp) and explicit-explicit (exp-exp) methods, which stand as efficient formulations to address complex systems with multiple time scales. The imp-exp technique blends implicit and explicit procedures, automatically applying implicit and explicit elements for the faster and slower components of the considered model, respectively. Interface conditions do not need be considered in this hybrid approach, rendering a very straightforward technique. In addition, it enables to compute the most favorable time-step value for optimal performance considering implicit and explicit sub-domains distribution, providing an entirely automated highly effective formulation. On the other hand, the exp-exp method, a variant of the considered explicit approach incorporating sub-cycling, employs smaller sub-steps to address the faster elements of the model. In this case, different time-step sub-domains are automatically distributed along the model, following the stability conditions of the referred explicit approach and the properties of the discretized model, enabling larger time-step values to be properly locally applied and enhanced analyses provided. Both these multi-domain techniques provide adaptive algorithmic dissipation, allowing for the local application of numerical damping if necessary, according to the properties of the adopted discrete model and its computed responses. Numerical results are presented at the end of this manuscript, illustrating the good performances of these adaptive procedures, as well as discussing the circumstances under which one approach should be favored over the other, providing valuable insights for decision-making in practical implementations. Special emphasis is placed on geophysical applications exhibiting multiscale configurations.

ABSTRACT

In recent years, there has been a growing focus on a new generation of fiber-based strengthening systems, specifically Fabric Reinforced Cementitious Matrix (FRCM). While Fibre Reinforced Polymers (FRP) are widely acknowledged for their effectiveness in retrofitting interventions, the preference for new composite materials with an inorganic matrix is often attributed to their greater reversibility and compatibility with historical architectural heritage.

The potential of FRCM in enhancing the structural performance of reinforced concrete structures has been demonstrated by numerous studies, whereas the literature studies focusing on masonry and historical buildings is inadequate due to the heterogeneity, complexity and aleatory nature of the material. Due to the abovementioned limited applications/studies, numerical models and simulations of masonry structures retrofitted with FRCM remain an open issue, especially with regard to the interactions between the inorganic matrix and reinforcing fibres.

This study implements a 3D Finite Element (FE) analysis of a small-scale masonry column retrofitted by FRCM reinforcement and subjected to tensile (debonding) loading within the reinforcement layer; the analysis is carried out in ABAQUS. The case study is derived from an experimental study [1]. The retrofitted column is modelled using a micro-modeling approach, developed according to the latest literature advances [2]. Each material is individually modelled and assigned its mechanical characteristics, calibrated based on past experimental data; two fictitious surfaces are introduced to simulate the nonlinear interaction between the inorganic matrix layer and the reinforcing fibres and to investigate the global bond behaviour. The numerical results are compared with the reference experimental outcomes both in terms of load-displacement curves and damage evolution, and the comparison shows a good agreement. Accordingly, the modelling approach can be efficiently extended to further case studies not experimentally assessed.

IMMERSED B-SPLINE FOR IMPROVED THE IMPOSITION OF ESSENTIAL BOUNDARY CONDITIONS IN THE MATERIAL POINT METHOD

Alban de Vaucorbeil[*1]*

[1]*Deakin University*

ABSTRACT

The Material Point Method (MPM) is a particle based method in which solids or fluids are discretized into a series of points. These points move freely through a computation background grid that spans the whole physical domain. Through the discretization process, knowledge of where the boundaries lie is lost. This is problematic for the imposition of essential boundary conditions. In some limited cases, the boundaries onto which these conditions need to be applied coincide with the background grid nodes. In these cases, the imposition is directly done via the background grid. However, in most cases, this is not possible.

This problem is not specific to the Material Point Method but to all particle based methods and also to cutFEM. In cutFEM, the finite element mesh can cut through the solid domain, again making the imposition of essential boundary conditions difficult. In this context, Sanchez et al. (10.1016/j.cma.2010.12.008) have developed the Immersed B-splines that are a modification of the standard B-splines shape functions to locally interpolate exactly the Dirichlet boundary conditions.

B-spline shape functions are already commonly used in the MPM to mitigate stress oscillations due to points crossing background grid cells. Immersed B-splines are regular B-splines that are modified such that their support outside of the solid or fluid domain is null, exact on the boundaries and identical to standard B-splines in the bulk. This way, boundaries can be tracked and Dirichlet boundary conditions can be applied to the background grid easily, independently of the position of the solids or fluids with respect to it.

In this work, we adapt the Immersed B-splines to the Material Point Method and demonstrate with 2D and 3D examples the efficiency and robustness of the proposed approach to simulate large deformation problems with imposed non-trivial Dirichlet boundary conditions.

A PRIMAL HYBRID FINITE ELEMENT METHOD TO SOLVE GENERAL COMPRESSIBLE, QUASI-INCOMPRESSIBLE AND INCOMPRESSIBLE ELASTICITY USING STABLE H(DIV)-L2 SPACES

Philippe Devloo[*1], Giovane Avancini[2], Nathan Shauer[2] and Hugo Oliveira[2]*

[1]*ABMEC and USACM*
[2]*UNICAMP*

ABSTRACT

Hybrid methods are usually derived from an extended variational principle, in which the interelement continuity of the functions subspace is removed and weakly enforced by means of a Lagrange multiplier. In this context, a new primal hybrid finite element formulation is presented, which uses H(div) conforming displacement functions and discontinuos L2 approximation for pressure together with shear traction functions to weakly enforce tangential displacement. This combination allows the simulation of compressible, quasi-incompressible and fully incompressible elastic solids, with convergence rates independent of its bulk modulus. The proposed approach benefits from the property that the divergence of the H(div) displacement functions is De Rham compatible with the (dual) pressure functions. The hybridization of the tangential displacements is weakly enforced through a lower order shear stress space. This leads to a saddle-point problem that is stable over the full range of poisson coefficient (large compressibility up to incompressible). Moreover, a boundary stress (normal and shear) can be recovered that satisfies elementwise equilibrium. Hybridizing the tangent stresses and condensing the internal degrees of freedom, a positive-definite matrix with improved spectral properties can be recovered. The stability, consistency and local conservation features are discussed in details. The formulation is tested and verified for different test cases.

ON THE ITERATIVE SOLUTION OF SADDLE POINT PROBLEMS USING A SYMMETRIC POSITIVE DEFINITE PRECONDITIONER

Philippe Devloo[*1], Giovane Avancini[2] and Marina Meneghel[2]*

[1]ABMEC and USACM
[2]UNICAMP

ABSTRACT

Saddle point problems frequently appear in many mathematical and engineering applications. Most systems of partial differential equations with constraints give rise to saddle point linear systems. Typical examples include mixed finite element formulations to solve fluid flows and/or elasticity problems under full incompressibility. The inversion of saddle point problems is challenging due to inherent numerical instability in the direct inversion methods. Many direct and iterative methods have been proposed to overcome this challenges, such as the Schur complement and the Uzawa's method. In the context of mixed finite element for incompressible flows using stable H(div)-L2 spaces for velocity and pressure, we propose an iterative method that can effectively solve a saddle point problem iteratively by summing a small compressibility to the original matrix. The preconditioning matrix is symmetric positive-definite, which allows the usage of Cholesky decomposition and/or CG-like iterative solvers to compute the incremental solution for the velocities unknowns. A procedure to compute the average pressure of each element of the incompressible problem is developed using the unbalanced fluxes caused by the compressibility perturbation. The average is updated during the iterative process as a function of the velocity increment at each iteration.

REAL-TIME ESTIMATION OF THERMOMECHANICAL STATE DURING ADDITIVE MANUFACTURING BY ASSIMILATING INFRARED IMAGING DATA INTO SIMULATIONS

Stephen DeWitt[1], Bruno Turcksin[1] and James Haley[1]*

[1]*Oak Ridge National Laboratory*

ABSTRACT

Additive manufacturing techniques for metal alloys are revolutionizing product design and manufacturing. However, suboptimal process parameters and stochastic aspects of printing can lead to significant variability in component quality, making qualification and deployment difficult. The ability to comprehensively monitor the printing process is vital to ensure that a particular component is usable and can provide valuable clues as to how the process can be modified to limit adverse results.

Many modes of in-situ monitoring have been demonstrated, with thermocouples and imaging at visible and infrared (IR) wavelengths being most widely used [1]. However, these methods have a significant drawback – they cannot create a full 3D reconstruction of the thermomechanical state. Instead, they give a limited view of quantities along non-blocked exterior surfaces (imaging) or at individual points (thermocouples). 3D characterization is possible with x-ray and neutron diffraction, but these require large facilities that are not tractable for practical manufacturing settings. An estimate of the full 3D thermomechanical state is important because thermal gradients that lead to residual stress and other quantities of interest usually vary dramatically throughout the interior of the part being printed.

We demonstrate a method to estimate the full 3D state in real-time by incorporating in-situ observations from imaging and thermocouples into faster-than-real-time thermomechanical simulations. We achieve this via an ensemble Kalman filter, an approach widely used in the meteorological community. Recently, Wood et al. [2] demonstrated the use of an ensemble Kalman filter for additive manufacturing, albeit with synthetic “experimental” data from a simulation. In this presentation we show the application of an ensemble Kalman filter using real experimental data from IR cameras and thermocouples from a directed energy deposition (DED) experiment. Our contributions are four-fold: 1) a flexible pipeline to collect, analyze, and transport in-situ characterization data, 2) raytracing capabilities to map image pixels to locations on a finite element mesh, 3) a performant finite element code that permits faster-than-real-time component-scale calculations, 4) a ensemble Kalman filter implementation that is tightly integrated into the finite element simulation software.

COMPUTATIONAL MODELING OF MEMBRANE TENSEGRITY STRUCTURES

Sanjay Dharmavaram[*1], Ranajay Ghosh[2] and Muhammad Shahjahan Hossain[2]*

[1]Bucknell University
[2]University of Central Florida

ABSTRACT

Traditional tensegrity structures are spatial structures with strings in tension isolating struts in compression, together providing the necessary structural resistance to loads. These structures have found diverse applications in aerospace, structural, programmable matter, and soft robotics. Recently, there has been a growing interest in membrane-tensegrity structures, which are two-dimensional analogs with compressible elements (rods) embedded in a thin membrane. Here, the rods are in compression, isolated from each other, and are held in equilibrium by the tension in the membrane. These structures combine the advantages of lightweight and tailorability of traditional tensegrity with advantages of enclosed volume. Hence, such structures have found application in lightweight architectural domes [1,2]. Beyond civilian applications, these structures can potentially transform the frontiers of programmable material by integrating phase-transforming materials, sensors, and actuators. However, such expansion is not possible without computational tools for architecture-property prediction tools, which are currently absent.

This presentation presents a thin-shell computational model to study such systems. The membrane is modeled as a two-dimensional surface and links as elastic rods embedded in the membrane. We use a thin-shell finite element framework to compute the equilibrium configurations. Through a combination of computations and experiments, we will explore the subtle equilibrium landscape of this system, including the possibility of multi-stability.

FAILURE UNDER IMPACT LOADING OF FOAM CORE IN SANDWICH STRUCTURES WITH FIBER-REINFORCED COMPOSITE FACE SHEETS

Monica Dhinde[*1] and Romesh Batra*[1]

[1]*Virginia Tech*

ABSTRACT

We analyze transient deformations of a sandwich plate with glass fiber-reinforced vinyl ester composite face sheets and three layers of equal thickness of CorecellTM foam cores to delineate its deformations. The face sheet material is modeled as linearly elastic and transversely isotropic with the axis of transverse isotropy along the fiber. The damage is assumed to initiate at a point in a face sheet according to Hashin's failure criteria. The Matzenmiller et al.'s [1] approach is used for damage evolution and degrading the material elasticities. Bazant and Oh's [2] crack-band model that incorporates a material characteristic length into the analysis is adopted for deleting an element. The foam is modeled as an elastic-plastic material obeying the Johnson-Cook (JC) effective stress-effective plastic strain relation that accounts for strain-hardening, strain-rate hardening, damage induced softening, and assumes the material to be isotropic and plastic deformations to be isochoric. The failure is assumed to initiate at a critical value of the damage computed using the JC damage criterion. The material elasticities and the flow stress are then degraded to zero by specifying an effective plastic displacement. Elements with essentially negligible values of the elastic moduli and the flow stress are deleted from the analysis. The plastic strain component with the maximum magnitude is associated with the failure mode.
Values of foam parameters in the JC relation are identified by using the experimental axial stress–axial strain curves included in Wang et al. [3]. The numerical solution of the problem by the finite element method based software, Abaqus, is found to qualitatively compare well with test findings [3]. However, the two quantitatively differ somewhat that can partially be attributed to neglecting in the analysis the anisotropy of the foam, uncertainties in values of its parameters found by using the axial stress – the axial strain data, assuming plastic deformations of the foam to be isochoric, and discrepancies in the experimental and simulated boundary conditions and the loads applied.

COMPOSABLE DESIGN OF MULTIPHASE FLUID DYNAMICS SOLVERS IN FLASH-X

Akash Dhruv[*1] and Anshu Dubey*[1]

[1]*Argonne National Laboratory*

ABSTRACT

Multiphysics fluid dynamics simulations play a crucial role in understanding and predicting the intricate behaviors of complex engineering systems. Numerical modeling of interactions among solids, fluids, and multiple phases, such as liquid and gas, has generated significant research interest in recent decades. This has led to the development of open-source simulation tools and commercial software products targeting specific applications or general problem classes in computational fluid dynamics. As the demand increases for these simulations to adapt to platform heterogeneity, ensure composability between different physics models, and effectively utilize inheritance within partial differentiation systems, a fundamental reconsideration of numerical solver design becomes imperative. To address these challenges, we will present our work on Flash-X (https://flash-x.org), as a potential solution. The software design strategies that we employ can serve as a guide, offering insights into navigating the intricate terrain of performance portability, composability, and sustainable development. We will demonstrate how generative AI can be leveraged to improve design of both new and existing simulation tools grappling with these challenges. By incorporating the principles outlined in the Flash-X approach, engineers and researchers can enhance the adaptability, efficiency, and overall effectiveness of their numerical solvers in the ever-evolving field of multiphysics simulations.

THE BREAKING OF THREE-DIMENSIONAL WAVES

Frederic Dias[*1] and Ayoub Mansar*[2]

[1]*University College Dublin, ENS Paris-Saclay*
[2]*ENS Paris-Saclay*

ABSTRACT

The breaking of ocean waves contributes significantly to wave energy dissipation and marks the transition from laminar flow to turbulent mixing at smaller scales on the ocean surface. The implications of wave breaking extend to particle transport, influencing the fate of oil spills and plastic pollutants.

Numerical codes for the computation of water waves must include breaking criteria and models for energy dissipation in order to accurately predict water surface changes, energy loss, and turbulence. Numerous onset criteria have been proposed over the past seven decades, through theoretical studies, numerical simulations, laboratory experiments, and field observations.

Measuring the properties of 3D waves, especially breaking and near-breaking waves, presents challenges due to their steepness, rapid spatial variations, and the technical difficulties in accessing turbulent flow fields and size distributions of drops and bubbles during active breaking times.
Recent advancements in computational capacity and numerical methods have made three-dimensional Direct Numerical Simulations (DNS) of breaking waves feasible, providing an appealing tool without the need for parameterizations. These simulations allow for the investigation of the three-dimensional two-phase flow dynamics from initiation to post-breaking, and have shown reasonable agreement with available laboratory data.

We perform direct numerical simulations for the breaking of the simplest non-trivial three-dimensional waves: The short-crested wave system, defined as doubly periodic waves in the plane. This wave system, more prevalent in nature than its two-dimensional counterparts on complex oceanic surfaces, is generated within a wind fetch, from intersecting swell waves, or leeward of offshore islands or structures due to diffracted wave interactions.

In addition to the controlling parameters of the breaking waves of two-dimensional waves which exhibit regularity in terms of their crests, we investigate the effect of the wave obliquity on the breaking onset dynamics through some of the commonly used geometrical and kinematic criteria. We also analyze its impact on energy dissipation and post-breaking processes.

DAMAGE PROPAGATION IN ARCHITECTED MATERIALS

Marcelo Dias[*1] and Leo de Waal*[1]

[1]*University of Edinburgh*

ABSTRACT

In this study, we explore fracture propagation within a two-dimensional Maxwell lattice. Traditionally, elastic brittle materials undergo catastrophic failure due to stress concentrations at crack tips. Maxwell lattices, operating at the brink of mechanical stability, offer an avenue to manipulate damage propagation and mitigate defects. We elucidate the underlying principles governing fracture control in a kagome lattice and demonstrate their application in engineering fracture paths within the lattice. Lattices are modelled as networks of sites interconnected by harmonic springs exhibiting elastic brittle behaviour. Our findings demonstrate the efficacy of these principles in governing crack behaviour and consequently enhancing the fracture toughness of the lattice.

TOPOLOGICAL METHODS FOR MODEL ORDER REDUCTION FOR SCALAR TRANSPORT EQUATIONS

Pavel Bochev[1], *Candace Diaz**[1] *and Denis Ridzal*[1]

[1]*Sandia National Laboratories*

ABSTRACT

It is well-known [1] that proper orthogonal decomposition is not the most appropriate model order reduction (MOR) approach for hyperbolic problems. An alternative approach was proposed in [1] which uses L1 residual minimization over a solution dictionary to advance a solution forward in time from an initial condition. Success of this approach depends on the ability to find a small enough dictionary of solutions that captures the underlying dynamics.

Our previous work [2] demonstrated that the methods of computational topology [3], can be applied to reduce the dictionary size offline before solving the L1 minimization problem. In so doing we were able to reduce the computational cost of the L1 optimization problem, which was key to being able to obtain an effective reduced order model (ROM) for a model scalar transport equation.

We extend this work by demonstrating that in certain cases, one can estimate proto-basis functions, that can be refined into feasible basis functions for reduced order models, in 1 and 2 dimensional problems. Our approach is to use generators from persistent homology computed on spatial modes of an initial set of solutions to the model transport equation, which are optimal in terms of having a minimum size or measure. We then reconstruct the original dictionary elements as linear combinations of the topological basis functions and seek the solution of our model problem by interpolation between these sets of coefficients, followed by L1 minimization. We also will describe some recent enhancements to the L1 optimization procedure in terms of speed and stability.

This work will showcase the nascent fruits of an innovative and ambitious new effort for approaching reduced order models for hyperbolic systems which involves a largely unexplored application of algebraic topology to this problem domain.

PHYSICS-INFORMED NEURAL NETWORKS FOR MATERIAL PARAMETER IDENTIFICATION IN QUASI-REAL PROBLEMS

Christian Diaz-Cuadro[*1] and Mauricio C. Vanzulli Pena*[1]

[1]*UDELAR*

ABSTRACT

Physics-Informed Neural Networks (PINNs) have emerged as a promising approach for solving scientific and engineering problems that involve partial differential equations or physical constraints. PINNs are a type of Neural Network (NN) that incorporates physical laws or governing equations into its learning process. By combining the strengths of deep learning and physics-based modeling, PINNs can learn complex patterns and relationships from data while simultaneously satisfying the physics of the problem.

In this work, we explore the capabilities of PINNs to solve physical problems while identify material properties simultaneously. The validation example is a three-dimensional rectangular prism with a Neo-Hookean material, submitted to a compressive load. In this example, the estimated parameters were the first and second Lame's parameters. The reliability of the results was assessed by comparing them against the ground truth displacement data, which were obtained from the analytical solution. These values were used as input to evaluate the loss data function, while the remaining loss functions were derived from the physics of the problem.

With this validated PINN, two more realistic cases were studied. The first case attempts to simulate a simplified femoral cartilage, which is loaded with a known force, resulting in the deformation of the cartilage. The second case aims to simulate a breast undergoing compression in a mammography study, where the compression force is also known. Both cases were simulated using FEBio software to obtain displacements data.

The PINN, as implemented in the validation example, failed to accurately identify the material parameters for realistic cases. Consequently, the incorporation of new strategies into the PINN are studied. A loss function was implemented to balance the forces on the loaded faces based on the integral of the stress tensor. Additionally, independent networks were used for displacements and the parameters to be identified. Alongside this, a regularization loss function was implemented to incorporate prior knowledge about the material parameter constraints.

The results of this study suggest that PINNs have the potential to be an effective tool for both material identification problems and real-time prediction of the physical solution. However, it is important to note that further research and dedicated efforts are required to fully explore and harness the capabilities of PINNs in these domains.

CONTINUOUS DATA ASSIMILATION AND LONG-TIME ACCURACY IN A FEM FOR THE CAHN-HILLIARD EQUATION

Amanda Diegel[*1] and Leo Rebholz*[2]

PATIENT-SPECIFIC ATHEROSCLEROTIC ANALYSIS SUPPORTING MEDICAL DECISION MAKING

Pedro Diez[*1], Stephan Gahima[12], Marco Stefanati[3], Jose Felix Rodriguez-Matas[3] and Alberto Garcia-Gonzalez[12]*

[1]*Universitat Politecnica de Catalunya*
[2]*Centre Internacional de Mètodes Numèrics en Enginyeria*
[3]*Politecnico di Milano*

ABSTRACT

Geometries of arterial cross-sections are extremely diverse from patient to patient, as well as the distribution of their atherosclerotic plaque intrusions. Medical decision on whether a patient has low or high risk of rupture is made on the basis of this information, mostly of geometrical nature. Mechanical models analyzing stress distribution under internal pressure and the corresponding stress concentrations are of great help to support decision making. This is far of being integrated in clinical practice because the conversion of medical images into mechanical outputs of interest is a laborious process. The standard approach to tackle this problem consists in 1) processing the medical image into a segmented geometry, 2) to generate a compliant finite element mesh for the analysis, and 3) to solve the mechanical problem and compute the outputs of interest. Each of three steps is time demanding and jeopardizes the practical and translational use of these tools.

The aim of this research is to provide further tools allowing a seamless integration of the full process, minimizing the human intervention and providing robust and reliable computational outputs to support clinical decision making. First, an unfitted approach is devised for this specific case, allowing to encapsulate all the geometrical information in form of level sets supported in a background mesh to be used also in the computation of the mechanical problem. This presents the advantage of precluding the need of a constructing computational mesh, conformal with all the geometrical features of the section and its inclusions.

Moreover, this approach paves the way for a using Reduced Order Models (ROM) and therefore to drastically accelerate the computation. Nevertheless, the variability of the arterial cross-sections is a serious drawback for using ROM. The elements of the training set (snapshots) are too diverse to extract common features, and the new elements to be analyzed have little in common with the database from which the ROM has learned.

The work contributes to shape the mechanical problem statement with new boundary conditions, to provide insightful analysis of the dispersion of the observed different geometries, to devise a specific unfitted approach, and to test the ROM strategy in this scenario.

A MESH MORPHING APPROACH TO ADDRESS THE EFFECT OF DEFORMABLE BOUNDARIES IN CFD SIMULATION OF AORTIC FLOW

Elena Di Martino[*1], Amir Hassaniazardary[1], Arianna Forneris[2], Alice Guest[1] and Randy D Moore[1]*

[1]University of Calgary
[2]ViTAA Medical Solutions

ABSTRACT

Altered local hemodynamics are recognized as a key contributor to aortic weakening leading to expansion and adverse outcome in aortic aneurysms. [1]. Computational fluid dynamic (CFD) simulations have been proposed as a clinical tool to stratify patients with respect to disease progression. However, as with most numerical simulations, these approaches require several assumptions including the velocity at inlet and outlet, the effect of external tissues, and the mechanical properties of the aorta and intraluminal thrombus [2]. To overcome these limitations, this study combines CFD on the fluid domain and structural analysis on the solid domain using a mesh morphing method [3] to prescribe displacement of the wall-blood interface directly to the numerical solver.
Four patients diagnosed with abdominal aortic aneurysm were included in the study. For each patient, strain on the aortic wall and on the lumen surface were obtained from pre-operative multi-phase CT scan. The changes in thickness of the thrombus were also computed to identify compression patterns within the thrombus. Nodes of the lumen surface mesh were defined as control points to use a radial basis function approach to morph the initial lumen geometry into each configuration throughout the cardiac cycle. The CFD simulation starts with a reference volumetric mesh that is replaced with isomorphic meshes at pre-defined time steps during the cardiac cycle. Two additional simulations were performed on the volumetric mesh at the diastolic and systolic configurations with rigid boundary conditions. Results from the simulations are compared in terms of time-averaged wall shear stress (TAWSS) and velocity streamlines at peak systole and diastole time points. Results show varying degree of difference between the rigid body and deformable wall simulations. Higher wall strain was associated with higher lumen displacements and resulted in greater difference between the moving wall and rigid simulations, suggesting that more accurate simulations can be obtained using this technique for patients with more deformable walls.
The dynamic mesh morphing technique to incorporate wall movement in CFD simulations enables more realistic and patient-specific simulation of aortic flow without introducing the uncertainty and computational cost that affect FSI simulations. The proposed technique could significantly improve CFD simulations, particularly for aortas with localized abnormal wall movement indicative of local weakening.

TURBULENT PIPE FLOW MANIPULATION USING TARGETED WALL SHAPES: A NEW TECHNOLOGY FOR ENERGY EXTRACTION

Yaren Dincoglu[*1], Suyash Verma[1] and Arman Hemmati[1]*

[1]*University of Alberta*

ABSTRACT

Geothermal energy has become a leading alternative for energy supply to achieve near zero-emissions due to its high capacity factor. Wide-spread commercialization of geothermal energy harvesting technologies require advancements in efficient extraction of high-to-moderate temperature geothermal resources. To this end, we explored the development of a novel pipe-flow manipulation concept to lower frictional drag, increase extraction flow rate, and reduce heat losses to the ground formation. The flow manipulation is achieved through induced non-equilibrium wall-bounded turbulence using targeted wall shapes, as pre-placed inserts in fixed increments inside the geothermal pipe casing. The inserts adopt a shape of three-dimensional distinct azimuthal Fourier modes: m=3, 15, 3+15. In previous studies, a second-order pattern of recovery in turbulent flow was observed, which suggested long-lasting changes in flow properties. The studies further revealed the inserts achieve a maximum drag reduction of ~25% with the manipulated flow recovering to a regular state within 19D – 45D, depending on the wall-shape, at a range of Reynolds numbers, Re = 5×10^3 - 1.58 ×10^5. The behavior of axial gradient of peak mean velocity and turbulent kinetic energy downstream of the insert revealed that m=15 and 3+15 cases experienced a second-order response, while m=3 depicted a non-oscillatory trend. Using this information, the geometry was further modified by varying perturbation amplitudes and lengths to optimize the proven concept for commercial design. The oscillatory behavior of a perturbed flow is likely to cause vibrations and structural fatigue, making it important to investigate the fluid-structure interaction between the turbulent flow and pipe walls. We numerically modeled the altered geometries as incompressible pipe flows using an FSI-based solver in OpenFOAM. The FSI solver was implemented to investigate the turbulent flow-induced stress on the pipe, and to gain insight into the coupled fluid-structure effects of manipulated turbulent flow. The unsteady results will also provide us with critical design information regarding fatigue and structural vibrations induced by the flow manipulation. The performance of numerical models, along with the fluid and structural behavior, were assessed for design optimization. With its direct application to industry, this work holds importance in the field of renewable energy systems. Furthermore, this work expands our understanding of wall-bounded turbulent flow manipulation and FSI.

MODELING ON THE MULTI-FIELD COUPLING DELAYED HYDRIDE CRACKING BEHAVIOR OF IRRADIATED ZIRCONIUM ALLOYS

Guochen Ding[*1], Zhongjia Xia[1], Jing Zhang[1] and Shurong Ding[1]*

[1]*Fudan University*

ABSTRACT

Zirconium alloys are widely used as the materials of nuclear cladding tubes or some other structural components due to their high strength, high corrosion resistance and low neutron absorption cross section. The chemical reaction between zirconium and coolant water in-reactor results in the absorption of hydrogen. Furthermore, the appearance of stress concentration facilitates the migration of hydrogen atoms towards the crack tip, which may induce delayed hydride cracking (DHC) and pose a potential threat to nuclear safety. In this study, an innovative multi-field coupling theoretical framework is formulated, integrating variables such as temperature, stress, damage factor, hydrogen concentration, hydride volume fraction, and hydride average orientation. To replicate the cracking process, a three-dimensional damage mechanical constitutive model, damage revolution model and the critical value of damage for damaged zirconium alloys are developed. The comprehensive model involves the effects of hydride-induced hardening and embrittlement, hydride orientation contributions and irradiation effect. In addition, a model for the irradiation-enhanced hydrogen diffusion coefficient is introduced to elucidate the influence of irradiation on hydrogen diffusion in zirconium alloys. Based on the differential governing equations for the concerned multi-field, the equivalent integral weak forms are derived for numerical implementation. The consistence between the predicted DHC velocities and experimental data, along with the representation of subcritical cracking traits, validates the effectiveness of the newly developed models. The irradiation-induced influence mechanisms for the delayed hydride cracking are analyzed and elucidated by the spatial distribution and evolution of multi-field results. This structured approach aims to provide a foundation for understanding the delayed hydride cracking behavior.

TOPOLOGY OPTIMIZATION METHOD OF LIGHTWEIGHT DAMPING COMPOSITE STRUCTURE

Xiaohong Ding[*1], Qian Wang[1] and Heng Zhang[1]*

[1]*University of Shanghai for Science and Technology*

ABSTRACT

Sandwich structures have the characteristics of high stiffness and light weight, and are widely used in aerospace, automotive, bridge, ship and other fields. Powder particle damper is a new type of damping structure based on additive manufacturing, which achieves damping by the collision energy loss between powders and between powder and the wall of damper. A concurrent topology optimization method for sandwich damping composite structure is proposed to improve the lightweight, load-bearing and damping performance, which includes stiffener layout, variable thickness skin and powder particle damper layout optimization. First, the damping characteristics and equivalent mechanical model of the powder particle damper are studied by experimental design and homogenization method; Secondly, the adaptive growth method based on the mechanism of biological branching system is adopted to optimize the layout of the stiffener rib. For structures with mass center position requirements, a mass center coordinate constraint technology is introduced. In order to further improve the damping performance and achieve lightweight of the structure, the concurrent topology optimization design of sandwich damping composite structure is carried out with the stiffener layout, variable thickness skin and powder particle damper position as design factors. Taking the rudder structure of high-speed aircraft as an example, the optimal design results shows that the vibration resistance performance of the structure is significantly improved while further reducing the structural weight. The proposed design method innovatively adopts the built-in powder particle damper as the damping means, combining the concurrent topology optimization of the stiffener layout and variable thickness skin, which provides a new approach for the design of sandwich damping composite structures.

A UNIFIED SAMPLING AND LEARNING FRAMEWORK FOR TEXTILE-BASED METAMATERIALS

Xiaoxiao (Catherine) Ding[*12] and Chris Rycroft*[2]

[1]*Harvard University*
[2]*University of Wisconsin-Madison*

ABSTRACT

Textile-based metamaterials have become widely used in engineering applications ranging from wearable sensors, health monitoring devices to soft robotics. The richness exhibited in their energy landscapes, which can be manipulated for desirable functionality, calls for a systematic sampling and learning framework. We propose a generalized parameterization to reconstruct 3D fibrous networks from 2D representative structures, assembled with varying local curvature and topology based on a yarn representation. This is a first step to enhance the data availability of textile-based metamaterials beyond conventional design. Using a first-principles computational model based on Lagrangian mechanics, we characterize their constitutive behavior through efficient sampling. We first show that a wide range of energy states can be explored from the process-structure-property mapping. Then, we facilitate the design of textile-based metamaterials to achieve tailored mechanical responses through machine learning techniques.

EFFECTS OF SURFACE ENERGY AND SUBSTRATE ON MODULUS DETERMINATION OF BIOLOGICAL FILMS BY SPHERICAL AND CONICAL INDENTATIONS

Yue Ding[*1] and Gangfeng Wang*[1]

[1]*Xi'an Jiaotong University*

ABSTRACT

Micro-/nano-indentation has become prevalent in evaluating the mechanical characteristics of biological samples, such as cells and tissues. However, the existing contact models describing conical indentation ignore the joint effects of surface energy and substrate, and consequently cannot accurately extract the Young's modulus of biological samples deposited on substrate. Through finite element methods, we examine the spherical and conical indentations of biological films on substrates while taking surface energy into account. Based on the dimensional analysis, the explicit relationship between load and indentation depth is achieved for films with their moduli varying from 0.001 to 100 times that of the substrate. If the classical contact models were employed to analyze the load-depth data, the modulus mismatch between film and underlying substrate would lead to an overestimation of modulus for the film on a stiffer substrate, but an underestimated modulus for that on a softer substrate. Meanwhile, in micro-/nano-indentations, neglecting the contribution of surface energy would result in an overestimation of the Young's modulus of films depending on the contact size. The analytical expressions provided here can be utilized to precisely deduce the mechanical characteristics of biological films deposited on substrate from the load and indentation depth data of indentations.

ABSTRACT

Parametric partial differential equations arise in many computationally intensive applications like real-time computational design and optimisation. While model order reduction techniques provide an established methodology to effectively handle such problems, their computational cost still constitutes a bottleneck for problems involving many parameters and, possibly, multi-physics processes.
In this talk, we present a recent approach [1] that combines overlapping domain decomposition (DD) methods and proper generalized decomposition (PGD) to reduce the computational cost of constructing surrogate models for boundary value problems governed by linear parametric partial differential equations. The proposed methodology involves an offline phase where local surrogate models are computed by PGD, and an online phase where overlapping Schwarz DD methods are used to couple the local models, without the need to introduce Lagrange multipliers nor to solve any additional problems.
The application of the DD-PGD framework to the Stokes-Darcy problem to model the filtration of an incompressible fluid through a porous medium at low Reynolds number will be outlined. In this context, the suitability of adopting overlapping DD methods will be discussed both from a physical and a computational point of view [2,3].
Numerical results showing the effectiveness, accuracy and robustness of the proposed DD-PGD framework will be presented.

A MULTI-FIDELITY STRATEGY FOR OPTIMIZATION UNDER UNCERTAINTY WITH ROBUST CONSTRAINTS

Thomas Dixon[*1] and Alex Gorodetsky*[1]

[1]*University of Michigan*

ABSTRACT

Effective solutions for optimizing systems under uncertainty are crucial for ensuring the success of missions, enhancing the reliability of robotics, and preventing system failures. However, the conventional optimization under uncertainty approach often comes with substantial computational costs, making real-time implementation or thorough uncertainty propagation challenging using a costly simulation model alone. In this context, we propose an innovative multi-fidelity optimization under uncertainty algorithm with robust constraints that leverages inexpensive, low-fidelity simulations to alleviate computational burdens.

We employ a sample average approximation technique to transform the traditionally stochastic optimization problem into a deterministic framework. Our strategy involves integrating high-fidelity samples with a more extensive set of cost-effective low-fidelity samples for precise estimation of both the objective function and constraints. Specifically focusing on general convex optimization problems, we study the impact of multi-fidelity constraints on the robust optimization results. The incorporation of low-fidelity models may introduce bias into the constraint estimate, impacting optimization results while concurrently aiming to diminish the variance of the robust constraint estimate. This study conducts a comprehensive analysis of the trade-offs associated with multi-fidelity optimization, providing insights into how errors in low-fidelity sampling propagate through the optimization problem.

Additionally, we present preliminary results on a trajectory optimization under uncertainty problem, demonstrating safe and robust trajectory generation. We test a simple bi-fidelity strategy for accelerating trajectory optimization under uncertainty in the presence of robust constraints. Specifically, we accelerate the optimization using additional samples of low-fidelity models for assessing whether or not a risk constraint is violated. The low-fidelity model's purpose is thus to reduce the uncertainty in the estimate of constraint violation, at the expense of introduction of bias. Our empirical test on a simulation of glider dynamics tasked with avoiding a region indicates an order-of-magnitude less failures using the bi-fidelity strategy.

MULTIRATE TIME-INTEGRATION BASED ON DYNAMIC ODE PARTITIONING THROUGH ADAPTIVELY REFINED MESHES FOR CONVECTION-DOMINATED FLOWS

Daniel Doehring[*1], Michael Schlottke-Lakemper[1], Gregor Gassner[2] and Manuel Torrilhon[1]*

[1]*RWTH Aachen University*
[2]*University of Cologne*

ABSTRACT

A classic problem in the simulation of instationary convection-dominated flows is the restriction of the maximum stable timestep due to the presence of locally refined grid cells in the computational domain. When integrated in time with explicit methods the maximum stable timestep is restricted to some form of CFL condition which causes unnecessary effort in the non-refined parts of the domain, thereby impairing the computational efficiency. This is a problem that has been addressed by many authors in the past by means of various approaches going under names such as local time-stepping, multirate, and multiscale time integration.

Recently, a new approach to this problem has been proposed by Vermiere et. al. [1, 2] which is based on the idea of employing different stabilized Runge-Kutta schemes for differently sized cells in the domain. In particular, the approach developed in [1, 2] requires no changes in the spatial discretization which makes them easily implemented in codes which employ a method of lines (MoL) approach. In the original works [1, 2] the authors applied the so-called Paired-Explicit Runge-Kutta (P-ERK) schemes successfully to static, non-uniform meshes for the simulation of the compressible Navier-Stokes equations.

In [3] we explored the possibility to apply the P-ERK schemes to dynamically partitioned systems arising from adaptive mesh refinement (AMR). We show that despite the additional overhead due to the dynamic re-assignment of flagging variables speedup for a set of hyperoblic and hyperbolic-parabolic testcases can be realized compared to a range of state of the art Runge-Kutta methods. In particular, we consider hydrodynamic instabilities such as Kelvin-Helmholtz and Rayleigh-Taylor besides the ideal magnetohydrodynamics (MHD) rotor and the Orszag-Tang vortex for the visco-resistive MHD equations. We implemented the P-ERK schemes with dynamic partitioning in the open-source, high-order discontinuous Galerkin code Trixi.jl written in Julia.

V - TANGENT KERNELS

Akshunna S. Dogra[1] and Martin Peev*[1]*

[1]*Imperial College London*

ABSTRACT

Machine learning (ML) has been profitably leveraged across a wide variety of problems in recent years. Empirical observations across many disciplines show that ML models from suitable functional spaces are capable of adequately efficient learning across a wide variety of disciplines. In this work (first in a planned sequence of three), we build the foundations for a generic perspective on ML model optimization and generalization dynamics. Specifically, we prove that under variants of gradient descent, “well-initialized” models solve sufficiently well-posed problems at "a priori" or "in situ" determinable rates. Notably, these results are obtained for a wider class of problems, loss functions, and models than the standard mean squared error and large width regime that is the focus of conventional Neural Tangent Kernel (NTK) analysis. The v - Tangent Kernel (vTK), a functional analytic object reminiscent of the NTK, emerges naturally as a key object in our analysis and its properties function as the control for learning.

We exemplify the power of our proposed perspective by showing that it applies to diverse practical problems solved using real ML models, such as classification tasks, data/regression fitting, differential equations, shape observable analysis, etc. We end with a discussion of the numerical evidence, and the role νTKs may play in characterizing the search phase (focus of the planned future work) of ML optimization which leads to the “well-initialized” models that are the crux of this work.

LEVERAGING UNCERTAINTY QUANTIFICATION IN DEEP GENERATIVE MODELS FOR MANUFACTURING PROCESS DISCOVERY

Tuba Dolar[1], Daniel Quispe[1], Jian Cao[1] and Wei Chen[1]*

[1]*Northwestern University*

ABSTRACT

Deep generative models (DGMs) are commonly employed for capturing complex, high-dimensional probability distributions, and subsequently generate realistic synthetic samples. One prominent use of DGMs is manufacturing process discovery where novel processes are inversely designed to satisfy desired process characteristics. Variational autoencoders (VAEs) are among DGMs and their architecture contains an encoder for compressing the input into a low-dimensional latent space and a decoder for reconstructing the dataset. A drawback of VAEs is the information loss caused by the encoding and decoding process which can produce unrealistic samples that lack the consistency of the input dataset. Additionally, a VAE model is valuable for exploring areas of the latent space for which data was unavailable initially. However, unrealistic processes would be discovered unless reliability of the generated samples are quantified. Quantifying uncertainties of the generated processes is critical for assessing these problems as high uncertainties would signal such issues. We propose leveraging epistemic uncertainty of the VAE decoder while designing a myriad of new manufacturing processes with varying energy inputs, workpiece materials, processing times, surface qualities, and tolerances. We start by introducing a manufacturing process language that allows the interpretation of a multitude of processes by defining process characteristics shared across diverse processes. This language is used for the analysis of 55 processes; including welding, machining, sintering, additive manufacturing, etc.; then a VAE model is used for extracting the complex relationships between these processes. In the VAE architecture, we implement Monte Carlo dropout in the decoder while generating new processes by sampling from the latent space. The adaptation of uncertainty quantification allows obtaining probability distributions for the process characteristics of the generated process instead of point predictions. These probability distributions are valuable for evaluating how certain the model is in terms of satisfying the desired process characteristics. Contributions of our work include 1) identifying probability distributions for the desired process characteristics instead of point predictions in manufacturing process discovery, 2) allowing the user to validate the designed manufacturing process by assessing whether the process characteristic variations are within acceptable limits, and 3) driving further data collection efforts for enhancing the input database. Using the inverse design of a process that uses mechanical and thermal energy, we demonstrate the benefits of our approach in three process discovery cases. Firstly, we search for processes that achieve high removal speeds, then tight tolerances in forming processes, and finally large volume prints in additive manufacturing.

FORMULATIONS OF GRIFFITH PHASE-FIELD FRACTURE WITH STRENGTH: ON MODEL VALIDATION AND VARIATIONAL THEORIES

John Dolbow[*1]*

[1]*Duke University*

ABSTRACT

We discuss several recent advances in phase-field models of fracture that illustrate the importance of accurately representing material strength. Our motivation stems from a recent study on model validation, consisting of simulations of crack nucleation from V-notches in quasi-brittle metallic alloys. The study illustrates how model validation based on an energetic threshold for nucleation simply fails to reproduce the results across the full spectrum of V-notches. Instead, our analysis indicates that a stress envelope is capable of adequately explaining nucleation, and that any complete theory of phase-field fracture must account for arbitrary material strength. We will discuss the merits of such a complete theory, as demonstrated by its ability to resolve long-standing misconceptions behind the Brazilian test. Additional results from problems in dynamic, brittle fracture will also be presented to support the necessity of such a complete theory. Finally, I will share a recent result that illustrates how an existing phase-field model of fracture with arbitrary material strength can in fact be recast as a variational theory.

ABSTRACT

Extreme weather events can potentially pose threats to human lives and cause significant economic losses. Predicting such events and implementing appropriate responses can mitigate their harmful impacts. In this work, we propose a new explainable AI framework to predict and better understand extreme events, based on [1]. By pinpointing the relevant information used by neural networks, we can bridge AI knowledge to existing physical knowledge. As part of this work, we also provide a benchmark dataset of extreme events that researchers can use to test their AI solutions within this context.

A DAMAGE PHYSICS-GUIDED APPROACH TO ACOUSTIC EMISSION SIGNALS IDENTIFICATION IN COMPOSITE MATERIALS

Fan Dong[*1], Yazhi Li[1], Biao Li[1] and Xiaopeng Li[1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

Cluster techniques have proven to be highly effective in identifying acoustic emission (AE) signals of composite damages. Nevertheless, traditional clustering models usually ignore the underlying physical mechanisms of the complex failure process of composites, limiting the comprehensive understanding and analysis of damage mechanisms. Notably, throughout all stages of damage evolution in the composite laminates under load, except for the initial stage that is dominated by matrix cracking, all the subsequent stages are characterized by the combination and interaction of multiple damage modes. Therefore, this study proposes an AE signal identification method guided by the physical mechanisms of damages in composite materials. Firstly, a sliding window is utilized to capture short-term variations of the AE energy within the window over a time series. Aligning with the initiation and accumulation process of micro-damages observed during penetrant detecting, the AE data are segmented to distinguish the time periods in which damage modes such as matrix cracking, crack coupling-interfacial debonding, delamination, and fiber breakage occur and develop. Secondly, given that the AE data in the first stage is related solely to matrix damage, a classification model of the semi-supervision guided deep neural network is established to predict matrix damage in the second stage. A confidence threshold is then set and a clustering algorithm is applied to the second stage data that was not explicitly labelled by the proposed classification model. The classification model is used to identify known damage mode, while clustering algorithm is used to explore and define new damage modes. The results of the classification and clustering are then combined for labelling, and the classification model is further optimized and updated by the alternative use of classification and clustering. The results of the classification and clustering will then be used as the input of the next stage. The above process is repeated, during which the cross-stage learning capability of the classification model is enhanced iteratively, as such to finalize a deep neural network classification model. Finally, the full AE data labels are updated to provide comprehensive damage identification. Our approach incorporates domain knowledge and provide new perspectives and more explanatory solutions for damage identification in composites.

DESIGN OF IN-MOLD DECORATION MOLD FOR COMPLEX THIN-WALLED PARTS

Jilong Dong[1], Dongyan Shi[1] and Jiuqiang Wang[1]*

[1]*Harbin Engineering University*

ABSTRACT

In order to address the issues of warping deformation and long-term production of complex thin-walled parts during In-Mold Decoration (IMD) production, the structure design of the IMD mold was carried out with the upper cover of the refrigerator humidifier as the production object. To ensure the flow characteristics of molten plastic in the mold during the injection molding process, the hot-runner mold is improved to mix cold-and-hot-runner, that is, the main-runner is set as a hot-runner, the sub-runner is set as a cold-runner, and use a multi-point injection cold gate solution. And construct a complex structure numbering method to arrange and design various complex core pulling and parting mechanisms, design a special structure with a slanted top to simultaneously pull cores from two inverted buckles in the same direction. Simultaneously complete the molding, parting, and demolding and ejection of plastic parts using a tilting mechanism. Finally, design the cooling system and demolding mechanism separately. To optimize product quality and improve production efficiency, providing theoretical and empirical support for the production of complex thin-walled parts with in mold injection molds. Based on Moldflow software, the final flow of plastic part warping deformation is analyzed. The maximum warping deformation of the designed product is 0.7055mm, while the maximum warping deformation of the traditional cold runner mold is 0.8519mm, reducing the warping deformation of the product.

RANDOMIZED NEURAL NETWORKS FOR COMPUTING INVERSE PARAMETRIC PDE PROBLEMS

Suchuan Dong[*1]*

[1]*Purdue University*

ABSTRACT

We present a method for computing the inverse parameters and the solution field to inverse parametric partial differential equations (PDE) based on randomized neural networks. This extends the local extreme learning machine technique originally developed for forward PDEs to inverse problems. We develop three algorithms for training the neural network to solve the inverse PDE problem. The first algorithm (termed NLLSQ) determines the inverse parameters and the trainable network parameters all together by the nonlinear least squares method with perturbations (NLLSQ-perturb). The second algorithm (termed VarPro-F1) eliminates the inverse parameters from the overall problem by variable projection to attain a reduced problem about the trainable network parameters only. It solves the reduced problem first by the NLLSQ-perturb algorithm for the trainable network parameters, and then computes the inverse parameters by the linear least squares method. The third algorithm (termed VarPro-F2) eliminates the trainable network parameters from the overall problem by variable projection to attain a reduced problem about the inverse parameters only. It solves the reduced problem for the inverse parameters first, and then computes the trainable network parameters afterwards. VarPro-F1 and VarPro-F2 are reciprocal to each other in some sense. The presented method produces accurate results for inverse PDE problems. For noise-free data, the errors of the inverse parameters and the solution field decrease exponentially as the number of collocation points or the number of trainable network parameters increases, and can reach a level close to the machine accuracy. For noisy data, the accuracy degrades compared with the case of noise-free data, but the method remains quite accurate. Several numerical examples will be presented to demonstrate the characteristics and accuracy of the current method. It will be compared with the state-of-the-art neural network-based method for inverse PDEs.

MODELLING THE MECHANICAL BEHAVIOUR OF SANDWICH PANELS MADE OF ARUNDO DONAX CORE AND FLAX FIBRE REINFORCED EPOXY COMPOSITE SKINS

Giovanni Donini[*1], Letizia Crociati[1], Luisa Molari[1] and Vincent Placet[2]*

[1]*University of Bologna*
[2]*FEMTO-ST, Universitè del Besancon*

ABSTRACT

In recent years, the use and interest in eco-friendly solutions in the field of civil engineering and construction have significantly increased. Specifically, building panels represent a key area where the use of bio-based materials offers significant opportunities to improve the sustainability of the life cycle of constructions [1].
This study aims to model the behavior of a sandwich panel with a core made of Arundo Donax rings and skins made of flax fiber-reinforced epoxy composites. The rings and skins are connected using an epoxy resin, which, during the curing phase, fills the voids inside the core, ensuring a connection between the rings constituting the core itself. A finite element model has been developed to simulate the nonlinear behavior of the panel subjected to bending tests, using Abaqus software.
It is assumed that the non-linearity of the panel is due to the bonding area between the skins and Arundo rings. Arundo rings and the skin have been modeled as orthotropic materials. The model includes cohesive surface contacts between the skins and bamboo rings, for which a damage initiation stress value was imposed, derived from pull-off experimental tests. The contact between elements of the Arundo core is modeled using hard contact in the normal direction and a penalty to consider friction in the tangential direction.
The model has been validated with the experimental campaign described in [2]. Subsequently, the model was used to conduct a parametric analysis to understand how the performance is influenced by geometric parameters such as ring diameters. During the parametric study, it was observed that with an increase in the diameter of Arundo rings in the core, there was an increase in the maximum load and the maximum failure stress of the panel, panel bending stifness, while the contact area between the rings in the core and the skins remained constant.

RAY TRACING FOR INVERSE DESIGN OF GRADED METAMATERIAL WAVEGUIDES

Charles Dorn[1] and Dennis Kochmann*[1]

[1]*ETH Zurich*

ABSTRACT

While periodic metamaterials have been well studied for guiding elastic waves, spatially graded metamaterials offer a much larger but comparatively unexplored design space. Due to the bottleneck of modeling efficiency, the use of spatial grading for wave control has been limited to simple gradings or long wavelengths. In this work, we present an inverse design methodology that leverages ray tracing as an efficient forward modeling tool. An optimization framework is developed to minimize cost functions based on ray trajectories [1]. In this framework, efficient forward modeling is provided by ray tracing, while the adjoint state method is used to obtain cost function gradients for gradient-based optimization. This provides a flexible and efficient methodology for designing arbitrary spatial gradings to control dispersive high-frequency wave propagation. We demonstrate the design of graded mass-spring networks as well as graded truss metamaterials modeled with beam finite elements. Example design objectives include elastic wave focusing, broadband wave steering, and frequency sorting. These objectives are out of reach of periodic architectures, demonstrating the potential of spatially graded metamaterials for wave guidance applications.

EXTENDED B-SPLINE MATERIAL POINT METHOD FOR STRONGLY COUPLED DIFFUSION IN HYDROGELS

Berkin Dortdivanlioglu[*1] and Ashkan Ali Madadi*[1]

[1]*The University of Texas at Austin*

ABSTRACT

The Material Point Method (MPM), a hybrid Eulerian-Lagrangian particle-based continuum approach, emerges as a robust alternative to conventional mesh-based finite element methods. Its effectiveness in handling extreme deformations and no-slip contact conditions without requiring additional algorithmic treatments makes it particularly promising. When modeling highly deformable materials like elastomers, hydrogels, and biological tissues, an implicit time integration is preferred due to its computational robustness for modeling and testing materials under quasi-static conditions. However, challenges arise, particularly within implicit solvers, including the ill-conditioning of the stiffness matrix due to fewer material points near the boundaries and the complexities involved in imposing boundary conditions. Furthermore, modeling at the quasi-compressible limit of soft polymeric materials requires multi-field discretizations, such as the displacement-chemical potential, to capture strongly coupled diffusion in hydrogels. Mixed discretizations, if not handled correctly, may lead to numerical instabilities related to the so-called inf-sup condition. In this presentation, we will address these challenges using a subdivision-stabilized mixed formulation and further extend the subdivision-stabilization to the extended B-spline technique. Additionally, we will exploit the Nitsche method for imposing boundary conditions. Through the use of the Nitsche method, essential boundary conditions are weakly imposed directly on the Lagrangian particles instead of the Eulerian background grid where the solution is obtained. The extended B-spline shape functions address the ill-conditioning by interpolating the displacement and chemical potential fields near the detected physical boundaries to the interior ones using polynomials. The developed subdivision-based extended B-spline method achieves an oscillation-free, inf-sup stable mixed discretization when modeling hydrogels under instantaneous loading. We will test the stability and accuracy of our mixed B-spline MPM at extreme deformations and verify it by comparing our results with benchmark problems, including the buckling of cylindrical hydrogels, confined-compression of hydrogel beads, and swelling deformations under constraints. These examples showcase the effectiveness of the developed particle-based method in modeling practical soft material applications without encountering any numerical instabilities.

ABSTRACT

The finite element method (FEM) is a well-known approach to solve partial differential equations. It has important applications in structural engineering. A notable example is topology optimization (TO), in which the distribution of material in a structure is altered to optimize a goal, such as weight minimization and structural natural frequency maximization. TO involves, at each iteration, the solution of a structural problem via FEM, which could lead to high computational costs. Therefore, a line of research developed over the years focusing on using machine learning (ML) to accelerate TO. Particularly, researchers proposed Artificial Neural Networks (ANNs) to significantly speed-up the process by eliminating the iterative algorithm which is intrinsic to TO. Since ANN is a supervised ML method, in the present work, first a dataset of 138,600 2D finite element analysis (FEA) cases is generated, containing FEA inputs (boundary conditions), volume fraction, strain energy density and von Mises fields, and final topologies. Afterwards, following the standard pipeline for ML projects, the dataset is filtered. Many samples, with diverse types of problems, are removed from the dataset. This increases the quality of the data, avoiding samples which could mislead or slow down model training. The issues considered are: plasticity, intermediary densities, geometrical nonlinearities, disconnections, and isolated features. In total, 12% of the initially generated samples were filtered out. With the data filtered, the model is trained to map fields of physical quantities, such as the von Mises stress, to the final optimized structure. Over the years, distinct types of generative deep learning approaches were applied to TO, such as variational autoencoder and generative adversarial networks (GANs), which is composed of two ANNs, the generator and the discriminator. The present work uses a specific development of this framework, Wasserstein GANs (WGANs). Additionally, the generator is inspired by a recently proposed architecture (“ConvNeXt”); and the loss function used to train this network was also influenced by the “pix2pix” approach. The designs obtained by the approach developed adhere better to TO solutions, when compared to recent results in the field. Furthermore, these improvements are achieved with much less computational cost than both the standard TO method and an alternative GANs model. Finally, interpretability (XAI) techniques were also applied to the trained networks, to better understand what information in the input is more relevant, and how the output was determined.

ABSTRACT

We present a numerical scheme, applicable on generic polytopal meshes, for a model of flows in porous medium with fractures. The model is mixed-dimensional, that is the rock matrix is represented as a 3D model in which fractures are 2D hypersurfaces, that takes into account poro-mechanical effects. We consider frictional contact, taking into account the Coulomb law via Lagrange multipliers. We use a hybrid finite volume scheme for the flow, a piecewise constant space for Lagrange multipliers, and a low-order fully discrete scheme for the matrix displacement; this scheme uses vertex unknowns complemented by "bubble"-like degree of freedom, designed to ensure the inf-sup condition of the displacement jumps with the space of Lagrange multipliers. This fully discrete scheme is equivalent to a Virtual Element scheme. We prove the inf-sup condition, as well as the convergence of the scheme in the case of pure contact mechanics. Numerical tests for the complete coupled problem will also be presented.

ADVANCING UNDERSTANDING OF HIGH-DIMENSIONAL QUASI GEOSTROPHIC SYSTEMS.

Ahmad Droobi[*1] and Mustafa Mohamad*[1]

[1]*University of Calgary*

ABSTRACT

The goal of this work is to advance our understanding of high-dimensional Quasi Geostrophic (QG) systems through partial measurements in the context of time-sequential state estimation. Our focus lies in the accurate reconstruction of the turbulent QG flow field's Eulerian energy spectra, from a stream of noisy measurements derived from Lagrangian tracers or drifters. These tracers, instrumental in atmospheric and oceanic measurements, serve as dynamic data collectors, offering real-time insights as they traverse the velocity field.

Employing numerical simulations, we solve the QG equation to obtain the true values of the high-dimensional QG system. Subsequently, we seek to design an innovative hybrid filter, incorporating ensemble Kalman filter and particle filter methodologies. This filter aims to predict the recovery and behavior of the QG system, matching predictions as closely as possible with the ground truth derived from numerical simulations.

This work extends conditionally Gaussian nonlinear filters that are tailored for Lagrangian data assimilation. We address questions concerning the extent to which turbulent Eulerian energy spectra can be recovered through assimilation of Lagrangian trajectory data. We quantify the recovery of various energetic scales relative to the ground truth and assess the impact of model error through reduced order models.

Demonstrating the efficacy of our hybrid filter, we showcase high recovery skill in reconstructing the two-dimensional turbulent energy spectra. The proficiency is shown across diverse scenarios, including an inverse cascade spectrum with a slope of \begin{math}k^{-5/3}\end{math} and a direct cascade spectrum with a slope of k^{-3}. Our approach involves localization of the covariance matrix, rendering it more computationally efficient compared to exact filters. We assess spectral energy recovery skill on the number of tracers and the spectral truncation grid size. The overall goal is to contribute to the development of a filter that can recover the behavior of the QG system from partial Lagrangian measurements.

ABSTRACT

Smart structures exploit the synergy between several coupled physical phenomena to produce materials and structures with enhanced properties. Such structures incorporate integrated sensors and actuators, mechanical and electronic components and control. The design of smart structures is a multidisciplinary challenge, which is of high importance for viability and resilience of industry. Usage of piezocomposites with integrated nonlinear shunted circuits for vibration suppression improves effectiveness and accuracy of many high-value products. The finite element method is widely used to simulate the mechanical response of composite materials and multi-physics problems [1], [2]. In this work a numerical investigation is conducted on small scale beams aiming to improve their vibration response by applying piezoelectric shunted circuits. Finite element models are developed in MATLAB, simulating graphene-reinforced nanocomposite piezoelectric beams with shunted circuits under vibration excitations. Piezoelectric materials are applied to the beams to allow for the interaction between electric charge and mechanical deformation. In addition, shunted circuits, which are paired with piezoelectric elements, are used to provide damping (vibration suppression) of one or more critical eigenfrequencies [3].
To derive the optimal vibration response, a particle swarm optimization (PSO) algorithm is adopted. Optimization is then aimed to minimize the vibration amplitude as well as optimize the mechanical and electrical parameters of the investigated system. Results illustrate the accuracy and reliability of the present finite element formulation for the considered frequency response analysis of the piezoelectric composite beams.

NUMERICAL INVESTIGATION OF NON-NEWTONIAN FLUIDS IN SINGLE SCREW EXTRUDERS: HEAT TRANSFER AND CFD MULTIPHYSICS STUDIES

Pablo Druetta[*1], Tim Kousemaker[1] and Francesco Picchioni[1]*

[1]*University of Groningen*

ABSTRACT

Plastic extrusion is one of the cornerstones of the polymer processing industry and it plays a pivotal role in manufacturing a vast myriad of products, for instance pipes, films and profiles, and it is also used in the automotive industry and consumer goods. Since its first application, it has completely change the way we create plastic components, becoming in an essential tool in many industry sectors. Therefore, in order to achieve an efficient, cost-effective, and sustainable production, the completely understanding of the process is considered vital to minimize its environmental impact. Moreover, in recent years, Computational Fluid Dynamics (CFD) has revolutionized our ability to analyze and optimize, among others, plastic extrusion processes. CFD offers a powerful tool to simulate, design, optimize and predict the behavior of the intricate fluid dynamics and thermal phenomena that govern plastic material behavior within the barrel. This allows gaining insight into the complex interplay of factors that impact extrusion performance, such as temperature distribution, pressure gradients, melt flow behavior, screw geometry, and material properties. We present the study of a 3D single screw extruder model. The definition of the physical and mathematical model is introduced in detail and a series of steady-state studies analyzing the behavior of the system are discussed. In order to develop a suitable model, mass, momentum and heat conservation equations are modelled, coupled with non-Newtonian fluid models in a novel approach, where a shear-thinning/-thickening, temperature-depending rheology correlation is modelled in COMSOL, in order to reproduce the processing of polymer solutions. Steady-state studies show that considering only shear-thinning behavior underestimates crucial parameters such as pressure, viscosity and thermal profile due to differences in the velocity field and viscous stress tensor. Moreover, the influence of the screw in the heat transfer process cannot be considered negligible, since the metal creates a recirculation circuit, which influences the polymer entering into the barrel. These studies provide the first step in a series of further advances in 3D modelling of extrusion processes, by considering the multiphysics behavior in a dynamic, rotating, polymer processing machinery.

FAILURE SIMULATION OF BRITTLE MATERIALS UNDER DYNAMIC LOADS BASED ON SCALED BOUNDARY FINITE ELEMENT METHOD

Chengbin Du[*1] and Zhiwei Zhao*[1]

[1]*Hohai University*

ABSTRACT

In this study, a nonlocal multiscale damage model [1] that considers the effect of a strain rate for quasi-brittle materials is presented. The scaling centre of each scaled boundary finite element method (SBFEM) subdomain was selected as the material point, and the bond connecting two material points was referred to as the material bond. Microscopic damage was quantified based on the stretch rate of the material bond, and macroscale topological damage was calculated by taking the weighted average of the microscopic damage over the bonds within the influence domain. The bell distribution function is chosen as the weight function in the calculation of the nonlocal weight function. To account for the impact of the strain rate during dynamic loading, an effective rate R [2] is introduced to enhance multiscale damage by modifying the damage threshold and bond softening coefficient throughout the analysis process. By analysing the energetic degradation function of the phase field, which establishes a connection between the macroscale topological damage and energy-based damage, a nonlocal multiscale damage model was incorporated into the framework of the SBFEM. Four typical dynamic cracking examples were simulated using the proposed model, and the results were compared with the relevant experimental results and references. The results show that the method is suitable for accurate dynamic failure simulation in quasi-brittle materials. Moreover, the results indicate that the proposed method can spontaneously simulate dynamic crack bifurcation without introducing additional crack bifurcation criteria. For a compact tensile test of concrete under different loading rates, the method proposed in this study can accurately simulate the corresponding failure modes. The results also show that without considering the effect of the strain rate, the damage develops rapidly in an unconstrained state, which is inconsistent with the actual case.

ABSTRACT

Soft Materials are ubiquitous in everyday life and are crucial in many different forms of revolutionary technologies. One property of Soft Materials is their ability to self-assemble into intricate structures from a finite set of building blocks with continuously tunable parameters. This giant design space of building blocks is a double-edged sword: on one side it provides researchers infinite possibilities to design building blocks for targeted functions, while on the other side it might take forever to search the design space. Here, we propose a new inverse design method that captures both interaction and geometry of building blocks. By enabling rigid body functionalities in JAX-MD, an end-to-end differentiable molecular dynamics engine, we can create soft materials model with components that are simple enough to design yet powerful enough to capture complex materials properties. In this talk, I will discuss the implementation of the methods alongside examples to showcase its potential applications.

AUTOMATED MULTILEVEL SUBSTRUCTURING BASED ON LDLT FACTORIZATION

Hui Du[1], Pu Chen[1] and Shuli Sun[1]*

[1]*Peking University*

ABSTRACT

Generalized eigenvalue problems are crucial in finite element modal analysis, yet traditional methods typically struggle with efficient resolution of a large number of vibration modes. Kaplan's classic implementation of automated multilevel substructuring (AMLS)[1] significantly advanced the efficiency of solving numerous modes in FEA. This paper presents new and improved AMLS implementations designed for large scale eigenvalue problems, such as those involving 30 million DOFs.

In our research, it was found that the block Gaussian elimination of stiffness matrices in the classic AMLS can effectively be replaced by widely-adopted LDLT factorizations in FEA. The key to our implementations, explicit automated multilevel substructuring based on LDLT factorization (LDLT-EAMLS) and implicit automated multilevel substructuring based on LDLT factorization (LDLT-IAMLS), is built upon the existing and highly-optimized LDLT factorization used in applications and enables the bypassing of the LDLT process. The computational cost of LDLT-EAMLS including factorization is equivalent to that of the classic AMLS. As the size of the problem increases, the cost of LDLT factorization may escalate, making the advantages of LDLT-EAMLS even more pronounced. In addition, LDLT-EAMLS significantly reduces the storage requirements in comparison with the classic AMLS.

For problems involving more than ten million DOFs, both the classic AMLS and LDLT-EAMLS approach impracticality. This is primarily due to the exorbitant cost associated with the explicit computation of diagonal blocks in the condensed mass matrix, as size of the substructures, particularly the interface substructures, expands. These methods become increasingly challenging with the escalation in the size of the substructures. To address this challenge, LDLT-IAMLS was developed. The algorithm solely performs the operations of mass matrix-vector multiplication without explicitly forming the block mass matrix. Compared to explicit methods, LDLT-IAMLS noticeably reduces the need for solving linear equations, offering substantial benefits for large-scale problems.

Numerical tests with 1 million DOFs demonstrate that LDLT-EAMLS reduces solution time by approximately 30% to 50% compared to the classic AMLS. Furthermore, in larger-scale problems, such as those involving 7 million DOFs, LDLT-IAMLS exhibits an acceleration of over 3 times compared to LDLT-EAMLS. Additionally, it has been successfully demonstrated that LDLT-IAMLS can efficiently solve problems with up to 32 million DOFs.

FREE VIBRATION ANALYSIS OF AXIAL-LOADED BEAMS WITH VARIABLE CROSS SECTIONS AND MULTIPLE CONCENTRATED ELEMENTS

Yunxing Du[*1]*

[1]*Hunan University*

ABSTRACT

A transfer matrix method is used to study free vibration characteristics of an axial-loaded Euler–Bernoulli beam with variable cross sections and multiple concentrated elements in the article. The differential equation for bending vibrations of the beam element is solved by the Frobenius method, and the solution is in power series form. Then, the transfer matrix method is applied to establish the state vector equation for both ends of the beam. Combined with boundary conditions, the frequency equation is obtained and expressed in a two-order determinant. The numerical results in this article are compared with those of the finite element method, which illustrates the accuracy of the method we proposed. The influence of the size of each concentrated elements and axial force on the natural frequency coefficients and the influence of the concentrated elements on the first critical buckling load are discussed.

MECHANICS MODEL AND INJURY MECHANISM OF BLAST-INDUCED TRAUMATIC BRAIN INJURY

Zhibo Du[*1], Zhanli Liu[1] and Zhuo Zhuang[1]*

[1]*Tsinghua University*

ABSTRACT

In the context of modern warfare, Traumatic Brain Injury (TBI), particularly blast-induced Traumatic Brain Injury (bTBI), has seen a marked increase, becoming a hallmark injury. This research domain is inherently interdisciplinary, encompassing mechanics, medicine, and biology, and is challenged by unclear injury mechanisms and a lack of evaluative indicators and methods. This paper establishes a mechanics model to elucidate the mechanical injury mechanism of bTBI, with significant findings including:

Development of a micromechanical constitutive model of brain tissue, integrating diffusion tensor imaging data. This model considers the deformation and damage of anisotropic axons and isotropic matrix, alongside an axonal equivalent strain-based damage initiation criterion. This enhances understanding of brain tissue's nonlinear behavior, anisotropic response, strain rate dependency, and specific damage behavior under complex stress states.

Creation of a high-precision fluid-structure coupling numerical model elucidating the mechanical mechanisms of bTBI from blast overpressure transmission and skull deformation. We determined that the direct transmission of the blast wave forms the positive peak of Intracranial Pressure (ICP), while skull deformation leads to the negative peak and oscillatory ICP pattern. The skull-brain tissue interface emerges as a critical vulnerability zone in blast wave propagation.

Construction of a multi-layer head structure model reflecting angular acceleration response characteristics, and proposing a bTBI indicator based on axonal strain rate. Under acceleration loading, the corpus callosum and upper brainstem exhibit high-speed axonal deformation responses, correlating with medically identified injury areas. This suggests that excessive axonal strain rate is a primary cause of diffuse axonal injury under acceleration overload.

Development of a dynamic test system using a high-fidelity surrogate head and neck model. We established an evaluation method for bTBI based on a shock tube experimental platform, proposing a comprehensive standard incorporating ICP and acceleration indicators. The fluid-structure coupling simulation under shock tube conditions confirms the platform's accuracy in measuring physical responses during blast overpressure propagation.

These results offer a theoretical foundation for medical diagnosis and protection strategies in bTBI, presenting substantial scientific significance and engineering application value.

LAGRANGIAN PARTICLE METHOD FOR MULTI-PHASE AND MULTI-PHYSICS PROBLEMS: A HIGH-PRECISION AND VERSATILE APPROACH

Guangtao Duan[*1] and Mikio Sakai*[1]

[1]*University of Tokyo*

ABSTRACT

With the recent breakthrough advancements, the high-precision particle method has gradually become a reliable and mature method, overcoming the fundamental limitations in accuracy, stability, and boundary condition within traditional particle methods. This presentation provides an overview of its latest advancements and applications in multi-phase and multi-physics problems.

First, high-precision schemes are typically derived from the least squares method and Taylor series expansion. In this process, various boundary conditions have been newly considered as additional constraints for straightforward and precise imposition. Second, the biased neighbor support is found to be the main reason for error accumulation and numerical instability [1]. Two strategies have been combined to avoid biased neighbor support and instability: particle shifting techniques and accurate free-surface detection. Various particle shifting techniques were proposed for internal and boundary-vicinity particles to regulate particle distributions. Novel free-surface-detection conditions based on the employed high-precision schemes have been developed to effectively maintain the stability near free surfaces [1]. Third, the high-precision particle method provides new promise for multiphase flows with high-density ratio by separately calculating the gas and liquid phases. In this approach, the free-surface-tension model was a key bottleneck. Fortunately, high-precision particle method can straightforwardly realize an accurate and versatile model for the free surface tension [2]. An exact sharp-interface model can then be proposed for bubble flows, even surpassing conventional mesh methods in capturing interface coalescence and breakup. Finally, the conventional phase-change models and fluid-solid interaction models can be easily integrated into the high-precision particle method, enabling the reliable simulations of multi-physics problems.

Before multi-physics applications, the developed high-precision particle method has been verified and validated through various theoretical and experimental benchmark cases without tuning parameters. Meanwhile, the developed particle method can consistently produce reliable smooth velocity and pressure distributions. Lastly, various applications in nuclear severe accidents and metal additive manufacturing demonstrated promising capabilities of the developed method.

MULTI-SCALE VARIABLE STIFFNESS DESIGN OPTIMIZATION OF COMPOSITE LAMINATES FOR MINIMUM STRUCTURAL COMPLIANCE WITH CONSIDER ADDITIVE MANUFACTURING FIBER CONTINUITY

Zunyi Duan[*1], Yi Liu[1], Bin Xu[1], Jun Yan[2] and Jihong Zhu[1]*

[1]*Northwestern Polytechnical University*
[2]*Dalian University of Technology*

ABSTRACT

Structural lightweight design is the eternal theme of aerospace equipment structure. Fiber-reinforced composite laminates have become the ideal material and structural form for lightweight and functionalization aerospace structures due to their excellent material properties and the designability of their material microstructures. Especially in recent years, with the rapid development of continuous fiber additive manufacturing technology, which provides the possibility to manufacture optimized multi-scale fiber-reinforced composites. One of the challenges in the variable stiffness design optimization of discrete fiber composite laminates is how to avoid the explosion of design variable combinations caused by the increase in the number of alternative discrete fiber laying angles. The Normal Distribution Fiber Optimization (NDFO) interpolation scheme has the numerical advantage that the design variables do not increase with the increase in the number of alternative discrete fiber laying angles. However, the traditional NDFO interpolation scheme uses the normalization penalty parameters, which leads to the discrete fiber laying angle selection falling into the local optimal prematurely. At the same time, the normalization of penalty parameters ignores the convergence differences of discrete fiber laying angles at different element in the macro-scale structure topology, leading to time-consuming and unstable optimization iteration. Therefore, considering the difficulties and challenges in the multi-scale variable stiffness design optimization of fiber-reinforced composites, an improved Adaptive Normal Distribution Fiber Optimization (ANDFO) interpolation scheme is proposed, and the feedback mechanism of the convergence rate of the element design variable and the objective function is introduced to realize the adaptive reduction of the penalty parameters. Based on the modified ANDFO interpolation scheme, a multi-scale optimization model of fiber-reinforced composite laminates is established considering the macro-scale structure topology and micro-scale discrete fiber laying angel selection. The explicit sensitivity of the objective function of minimizing structural compliance to the macro-scale topological design variables and the micro-scale fiber laying angle design variables is derived. Considering the manufacturability of additive manufacturing based on the optimized design results, a multi-scale nonlinear continuous filtration strategy for discrete fiber laying angle is adopted to improve the continuity of local fiber laying path. Numerical examples systematically compare the differences between the proposed ANDFO and the traditional NDFO model in fiber laying path and objective function, verifying the effectiveness of the proposed interpolation scheme.

NON-INTRUSIVE MULTISCALE STRUCTURAL MODELING WITH STANDARD AND GENERALIZED FINITE ELEMENT METHODS

Haoyang Li[1], Javier Avecillas-Leon[1], Nathan Shauer[2] and Armando Duarte[1]*

[1]University of Illinois Urbana-Champaign
[2]Campinas State University

ABSTRACT

High-fidelity resolution of fine-scale defects, such as cracks and localized material damage, and structural features, such as welds and bolted connections, is critical for the accurate prediction of service life or failure of structures. Three-dimensional models with detailed meshes and advanced modeling techniques are usually required to capture accurate fine-scale responses. However, adopting such models on the structural/global scale is computationally inefficient and sometimes impractical for problems involving a large number of local features. A coarse mesh is often sufficient for predicting the global behavior of a structure.

In this talk, we present a multiscale computational framework that couples Abaqus models and 3D Generalized FEM discretizations based on numerically-defined enrichment functions – the so-called GFEMgl. The structural-scale problem is modeled in Abaqus using a coarse mesh of 3D or shell elements suitable for capturing the macro-scale response of the structure. Fine-scale problems solved in parallel provide enrichment functions for the GFEMgl. These functions enable the GFEMgl to accurately approximate localized phenomena such as crack propagation and material damage using coarse meshes. The interactions between structural (Abaqus) and GFEMgl models are captured using the Iterative Global-Local (IGL) method. Numerical examples show that this methodology provides accurate solutions even when a classical global-local/sub-modeling analysis fails.

ENERGY PRESERVATION OF HIGH-ORDER MIMETIC DIFFERENCES FOR SYSTEMS OF CONSERVATION LAWS

Miguel Dumett[*1], Johnny Corbino[1] and Jose Castillo[1]*

[1]*San Diego State University*

ABSTRACT

We prove energy conservation of high-order mimetic difference schemes for linear and nonlinear systems of conservation laws. Furthermore, we numerically validate the theoretical foundation of our approach by showing that high-order mimetic schemes converge to the exact solution of general nonlinear systems of conservation laws preserving all quantities of interest.

AN INVERSE-FREE KRYLOV ALGORITHM FOR COMPUTING THE FIRST EIGENPAIRS OF NONLINEAR SYMMETRIC EIGENVALUE PROBLEMS

Ney Dumont[*1], Renan Sales[1] and Wellington Carvalho[2]*

[1]Pontifical Catholic University of Rio de Janeiro
[2]Cefet/RJ

ABSTRACT

We propose an algorithm to compute the set of eigenpairs corresponding to a given number of smallest eigenvalues of a nonlinear, positive definite eigenvalue problem. This has application not only to assess the vibration response of a structure but also to model its general dynamic behavior in terms of an advanced modal analysis, which has been previously developed. The method generalizes an inverse-free Krylov subspace algorithm, which now can solve nonlinear eigenvalue problems expressed either exactly, in terms of closed-form functions, or as a matrix power series. Once an eigenpair is obtained, we resort to a general deflation scheme that may be considered a penalty function accrued to the original problem to prevent already obtained results from being re-evaluated. The proposed algorithm works even when the introduced penalty function does not reflect the problem's symmetry, which is also assessed numerically. When the combined subspace iteration and the deflation schemes are applied to an eigenvalue problem in terms of closed-form, exact analytical matrix functions, we may also consider viscous damping, which is associated with a complex symmetric problem. Convergence is assessed for a few numerical examples. We show that classical preconditioners may be applied to save computational time when dealing with large linear algebra problems, as also illustrated.

TOPOLOGY OPTIMIZATION METHOD APPLIED TO FLUID FLOW CONSIDERING RESONANCE FREQUENCY CONSTRAINT

Alberto Duran[*1], Luis Fernando Nogueira de Sá[1] and Emilio Carlos Nelli Silva[1]*

[1]*University of Sao Paulo*

ABSTRACT

Greenhouse gases (GHG), such as carbon dioxide (CO2), have detrimental effects on the environment. Consequently, nations worldwide are developing projects to mitigate these effects, such as carbon capture and storage (CCS). These projects typically involve three stages: separation of CO2 from other gases, compression and transportation, and injection. The compression stage involves increasing pressure and temperature beyond the critical point. Due to these conditions and the high rotation velocities, in the compressor impeller's design, it is necessary to consider compressible flow and take care of resonance frequency. This work approaches some of these considerations: compressibility and maximization of resonance frequency. The Topology Optimization Method (TOM) is used due to its capability to achieve non-intuitive topologies and initiate the optimization process from an arbitrary initial guess. A weighted multi-objective function is defined considering the minimization of flows viscous dissipation and maximization of the solid material resonance frequency. A volume constraint is also considered. The FEniCS finite element software is used to solve the state equations, considering the perfect gas model, and the pyadjoint library is used to compute the fluid flow sensitivities by automatic differentiation in conjunction with a matlab routine to calculate the resonance frequency sensitivity. The SciPy optimization library is used to update the design variables. The results show channel designs with optimized energy dissipation and improved resonance frequency.

A MIXED FINITE ELEMENT APPROACH TO SOLVING LINEAR COSSERAT EQUATIONS

Wietse Marijn Boon[1], Omar Duran[2] and Jan Martin Nordbotten[2]*

[1]Politecnico di Milano
[2]University of Bergen

ABSTRACT

The objective of this study is to explore the equations that govern Cosserat materials in three spatial dimensions [1, 2], also known in the engineering community as (micro-)polar materials [3]. A Cosserat material extends linearized elasticity equations by adding local rotations as independent variables as well as displacements, providing greater generality for modeling complex materials, such as granular media, cell-like and crystallized solids, and composite porous media [4]. Previous studies have focused on finite element methods for the second-order formulation, particularly in terms of displacement and rotation [5,6], but our interest lies in presenting it as a first-order formulation. The approach explicitly incorporates mechanical stress and coupled stress, with the former associated with spatial variations of rotation field.

Our contributions include identifying the operators in the Cosserat equations as a differential complex, termed the Cosserat complex. This complex is isomorphic to six copies of the de Rham complex, inherits its properties and establishes the L^2 version as the suitable framework for proving well-posedness. Additionally, we demonstrate the well-posedness of the first-order formulation through standard Ladyzhenskaya–Babuška–Brezzi (LBB) theory, revealing a connection to the Hellinger-Riessner formulation of elasticity with weak symmetry. This connection positions the Cosserat equations as a continuous extension of the elasticity equations.

Furthermore, we show that the two perspectives on well-posedness lead to distinct families of stable and convergent mixed-finite element discretizations, labeled as strongly coupled and weakly coupled, respectively. Notably, the non-conforming discretization remains stable in the continuous transition between Cosserat and elastic materials.

COMPUTATIONAL MECHANICS OF GRANULAR MATERIALS WITH A LEVEL SET SHAPE DESCRIPTION

Jérôme Duriez[*1] and Cédric Galusinski*[2]

[1]*INRAE, Aix-Marseille University, RECOVER*
[2]*IMATH, Université de Toulon*

ABSTRACT

In order to be quantitatively relevant, computational modeling of granular materials as per a Discrete Element Method (DEM) requires to either adopt an enriched contact model between spherical particles in the numerical world or a more faithful shape description of soil grains [1]. Among the various DEM implementations enabling the latter, a Level Set (LS)-based approach may implicitly describe grains shape through the zero-level set of the distance function to a grain surface [2,3]. Doing so, shape description starts by defining on a particle-centered grid appropriate values for the shortest distance to the grain, which is by convention taken to be positive outside of the particle and negative inside, while being naturally zero over its surface. Ensuring the versatility of the method, such a discrete distance field can be obtained for any surface through, e.g., a Fast Marching Method algorithm. For the purpose of contact detection, surface nodes furthermore discretize the particle boundary and can be obtained at will from the distance field. The method logically induces significant computational costs, be it either in terms of memory for the distance grid, or in terms of simulation time for looping over surface nodes when searching for an intersection with another particle (showing negative distance values in its inner region). The latter costs are carefully measured in the case of an implementation into the YADE code and discussed with respect to the obtained precision of the method. It is also shown how parallel, OpenMP, computing together with algorithmic improvements may help alleviating these costs, with a special focus on an optimized definition and manipulation of the surface nodes. This eventually enables the method to be conveniently applied to various cases stemming from convex superquadrics to non-convex rock aggregates.

DISCRETE ELEMENT SIMULATIONS OF SEA ICE IN TRIAXIAL TESTS UNDER DIFFERENT CONFINEMENTS AND BOUNDARY CONDITIONS

Scott Durski[*1], Ali Khosravi[2] and Jennifer Hutchings[1]*

[1]*Oregon State University*
[2]*Auburn University*

ABSTRACT

ABSTRACT. The design of engineered structures in offshore areas in Arctic waters requires an estimation of the forces that can be produced by sea ice interacting with these structures. During an ice impact event, the load acting on the structure is transmitted through localized short-lived zones of intense high pressure along the contact surface, called high-pressure zones (HPZ). The sea ice experiences a complicated and random failure process over the HPZ. At the edge of the layer with relatively low pressures, microcracking and recrystallization are the primary failure mechanisms. In the central zone, with relatively high pressures, recrystallization and possible pressure melting influence the material properties of the ice materials. Due to the complexity and random nature of the ice failure over the HPZ, predicting the maximum ice pressure over time and its spatial distribution across the loaded area has been a challenge for researchers and practitioners. This paper presents a numerical model to quantify maximum sea ice pressure and to understand the effect of the ice state and characteristics. In particular, triaxial tests will be numerically simulated with spherical, bonded particles in a three-dimensional discrete element method-based PFC3D. Numerical simulation was performed for ice specimens subjected to vertical and radial stresses before shearing. After reaching an equilibrium state, shearing was simulated by applying incremental vertical displacements to the top wall. The flat-joint contact model was used for bonds between particles and the linear contact model was used for those between particles and the boundary walls. The model properly simulated the pre-failure behavior of sea ice. We characterized how boundary conditions (shape, stress, flexibility) and specimen packing (porosity and particle packing) affect macro- (strength or stiffness values and the post-peak behavior) and micro- (particle displacement and cracking) behavior of the sea ice. The model failed to capture the post-failure softening behavior of the sea ice. While sea ice under confinement is expected to exhibit strain-softening behavior in the post-failure range, the strength behavior of the sea ice in the numerical model changes abruptly to residual conditions more akin to brittle material behavior. We conclude that accurate prediction of sea ice’s post-failure behavior requires proper consideration of elastoplastic coupling for the degradation of elastic modulus with increasing plastic deformation.

Theory and application of provably-robust and efficient high-order methods for high-fidelity computational fluid dynamics

VORTICITY, ENERGY, AND ENTROPY CONSERVATION IN DG METHODS FOR THE SHALLOW WATER AND THERMAL SHALLOW WATER EQUATIONS

Kieran Ricardo[1], Kenneth Duru[1] and David Lee[2]*

[1]The Australian National University
[2]The Bureau of Meteorology

ABSTRACT

We develop a novel structure preserving discontinuous Galerkin method for the shallow water and thermal shallow water equations in vector invariant form. The numerical method is nonlinearly stable and preserves important invariants in the system, including energy, vorticity, linear geostrophic balance, and buoyancy variance. These conservation properties are achieved by the discrete approximations on arbitrary curvilinear meshes through novel numerical fluxes and a skew symmetric formulation of the equations. Numerical experiments are presented to demonstrate the robustness of the method and verify the theoretical results on a cubed sphere mesh.

RECENT DEVELOPMENTS IN FINITE CELL ANALYSIS OF MICROSTRUCTURED MATERIALS

Alexander Düster[*1], Mahan Gorji[1], Seyed Farhad Hosseini[1], Lars Radtke[1] and Roman Sartorti[1]*

[1]*Hamburg University of Technology*

ABSTRACT

Immersed-boundary methods and fictitious domain approaches are gaining popularity due to their ability to handle complex geometries without the need for body-conforming meshes. The finite cell method (FCM) is a combination of the fictitious domain approach with high-order finite elements. It offers the advantage of simplified pre-processing due to the use of Cartesian meshes. However, special attention must be paid to numerical integration, local refinement of the approximation, and the treatment of boundary conditions due to the non-conformity of the meshes to the problem's geometry.

This presentation will provide a brief overview of the finite cell method and showcase its applications in the structural analysis of microstructured, heterogeneous materials. These applications include the numerical treatment of material interfaces, fracture modeled by phase-fields, and simulation of acoustic properties of foamed material. The presentation will highlight the capabilities and challenges of the finite cell method in these contexts.

INFLUENCE OF PLASTICITY ON INERTIALESS VISCOELASTIC INSTABILITIES

Vedad Dzanic[*1], Christopher S. From[2] and Emilie Sauret[1]*

[1]*Queensland University of Technology*
[2]*The University of Manchester*

ABSTRACT

Many important practical applications involving porous media, cosmetics, biological systems, and food processing involve the transport of non-Newtonian fluids, which possess non-linear material properties. Elastoviscoplastic fluids are indeed a complex example, simultaneously involving viscous, elastic, and plastic properties. Purely elastic effects have previously been shown in viscoelastic fluids (i.e., solvent mixed with polymer additives) to transition the flow into a chaotic turbulent-like state, characterized by enhanced mixing, increased flow resistance, as well as strong flow fluctuations, even in the absence of inertia. In this study, we conduct numerical simulations of elastoviscoplastic fluids using a hybrid lattice Boltzmann solver in order to investigate the impact of plasticity, characterized by the Bingham number, on inertialess viscoelastic instabilities at high elastic effects. Notably, we investigate these effects across a range of different flow regimes. Results obtained using the four-roll mill and cellular-forcing scheme benchmark cases, which produce a strong elongational flow regime, reveal the emergence of three distinct flow states over time. The transition and behavior between the different flow states are found to strongly depend on the interplay between elasticity and plasticity. Moreover, we demonstrate that the general effect of the Bingham number in elongational flows is to increase the unyielded regions in the flow, which ultimately laminarize and suppress the flow fluctuations in the late stages. On the other hand, the unyielded regions in shear-dominated problems, such as the Kolmogorov flow, appear to enhance the turbulent characteristic of inertialess viscoelastic instabilities with increasing plasticity. Overall, the work presents preliminary results that demonstrate the contrasting effects of plasticity on inertialess viscoelastic instabilities depending on the flow type.

STABILIZED VIRTUAL ELEMENT METHOD FOR THE NONLINEAR CONVECTION-DIFFUSION-REACTION PROBLEM

Natarajan E[1]

[1]*Indian Institute of Space Science and Technology*

ABSTRACT

Convection-diffusion problems are of significant interest to both engineers as well as mathematicians. The Galerkin finite element approximation to this problem produces large non-physical oscillations and hence is unsuitable for this problem. This happens when the problem is either convection dominated and/or reaction-dominated. This drawback is addressed with the help of residual-based stabilization techniques such as streamline-upwind/Petrov-Galerkin (SUPG) and edge stabilization. In practical applications, the SUPG method produces inaccurate numerical solutions near the layers, and one needs to evaluate the second derivative when using high-order elements. To overcome this unwanted feature of SUPG methods, alternative methods are proposed and discussed in the literature, such as variational multiscale method, CIP method, orthogonal subscales method.

In this work, we have proposed and analyzed local projection stabilization for the virtual element discretization of the nonlinear convection-diffusion-reaction equation. A streamline-derivative-based stabilization is considered in the discretization of the model problem. This stabilization term is more general and preserves the stability property. We provide the existence of the discrete solution and then prove the optimal convergence rate in H^1 and L^2 norms, respectively. Numerical experiments show the better performance of the proposed VEM-LPS scheme compared with the gradient-based local projection stabilization method. The proposed method is more compact and offers the computational advantage that one need not compute the second-order derivative terms in the VEM-SUPG method.

A PORT-REDUCED HYPERREDUCED REDUCED BASIS ELEMENT METHOD FOR MODEL REDUCTION OF COMPONENT-BASED NONLINEAR SYSTEMS

Mehran Ebrahimi[1] and Masayuki Yano*[2]

[1]*Autodesk*
[2]*University of Toronto*

ABSTRACT

This work introduces a reduced basis element (RBE) method for model reduction of parametrized, component-based systems in continuum mechanics governed by nonlinear partial differential equations (PDEs). The present work extends upon previous works on RBE methods for linear PDEs (e.g., [1]), which leverage the fact that many engineering structures consist of identical or similar components. In these approaches, a library of archetype components is created in the offline phase and is subsequently used in the online phase to build a reduced model for the systems instantiated from these pretrained components. While some extensions of the concept to nonlinear PDEs have been explored (e.g., [2]), they have been limited to systems with localizable nonlinearities or have not accommodated online interchangeable components.

To overcome these limitations, we present a port-reduced hyperreduced RBE (HRBE) method, which can handle global, nonlocalized nonlinearities and enables model reduction of large-scale problems with numerous continuous and topology-varying parameters. The primary ingredients of the method are as follows: an extension of the empirical quadrature procedure [3] to the component-wise reduced-basis construction and, in particular, hyperreduction of components; a library of archetype components comprising HRBEs of varying RB and hyperreduction fidelities; port-reduction, which provides a rapidly converging modal representation of solutions at component interfaces [1]; and an online adaptive scheme that is informed by the Brezzi-Rappaz-Raviart theorem and selects the appropriate HRBE fidelity for each component to meet the user-prescribe error tolerance at the system level in the online phase. We assess the formulation using large nonlinear hyperelasticity systems.

A VERY HIGH-ORDER FRAMEWORK FOR FLUID STRUCTURE INTERACTION SIMULATIONS

Laura Edreira Marzoa[*1], Luis Ramírez[1], Xesús Antón Nogueira Garea[1] and Ignasi Colominas[1]*

[1]*Universidade of A Coruña*

ABSTRACT

To accurately understand the complex flow phenomena surrounding machinery and structures, where fluid forces exert significant influence on the structures, fluid-structure interaction (FSI) simulations are crucial. These simulations consider the interaction between the fluid and structure, which is vital for analyzing the aerodynamic loads and the aeroelastic behaviour of the system. High-order, accurate, and cost-effective FSI methods are fundamental for improving the efficiency of existing structures or proposing new typologies and configurations. However, simulating body movements or relative motion of different parts while keeping computational costs low can be challenging.

The methodology proposed in this study combines the very high-order accuracy of the Finite Volume method based on Mean Preserving Moving Least Squares (FV-MP-MLS) [1] with the efficiency of the Chimera/overset grid framework [2, 3] to solve the Euler and Navier-Stokes equations. This approach offers a cost-effective solution for accurately analyzing and simulating fluid-structure interaction problems. The proposed method has been tested by solving a diverse set of benchmark problems, where the accuracy and performance of the method have been thoroughly evaluated and demonstrated.

DEEP LEARNING FOR SURROGATE MATERIAL MODELING: CLASSICAL ELASTOPLASTICITY

Mahdad Eghbalian[*1]*

[1]*University of Calgary*

ABSTRACT

In this work, we present a deep neural network architecture specifically tailored for efficiently serving as a surrogate model for classical elastoplastic constitutive relations. The network is intricately enriched with essential physics principles inherent to classical elastoplasticity, encompassing the additive decomposition of strains into elastic and plastic components, alongside nonlinear incremental elasticity. This leads to a Physics-Informed Neural Network (PINN) model named here as Elasto-Plastic Neural Network (EPNN). Detailed analyses elucidate that incorporating these fundamental physics elements into the neural network architecture not only facilitates a more efficient training of the network with less training data, but also enhances the network's extrapolation capability to loading scenarios beyond the training dataset. The architecture of EPNN is model and material-independent, rendering it adaptable to a diverse array of elastoplastic material types, encompassing geomaterials. Moreover, the potential integration of experimental data directly into the network training process further extends its versatility. To showcase the robustness of our proposed architecture, we tailor its general framework to encapsulate the elastoplastic behavior of sands. Utilizing synthetic data derived from material point simulations based on an advanced dilatancy-based constitutive model for granular materials, we undertake the training of the neural network. The efficacy of EPNN is unequivocally demonstrated by its outperformance of conventional neural network architectures, particularly evident in its accurate prediction of unseen strain-controlled loading paths for sands exhibiting distinct initial densities. In essence, our work presents EPNN as a cutting-edge neural network architecture capable of efficiently emulating classical elastoplastic constitutive relations. The integration of crucial physics principles not only makes the network training more efficient, but also broadens the applicability of the model across diverse material types. The adaptability of EPNN to geomaterials, coupled with its potential utilization of experimental data, positions it as a powerful tool with far-reaching implications in the realm of computational material modeling.

ELASTOPLASTICITY OF PAPER SHEETS: A CONTINUUM MICROMECHANICS APPROACH

Pedro Miguel Jesus de Sousa Godinho[1] *and Mahdad Eghbalian**[2]

[1]*Vienna University of Technology*
[2]*University of Calgary*

ABSTRACT

It is a well-known fact that paper materials exhibit elastoplastic behaviour. However, virtually all theoretical models that have been proposed to date are of the macromechanics (or “continuum”) type. Hence, the microstructural determinants of elastoplasticity in paper sheets remain elusive. Recently, some progress has been made in this regard, with a proposition based on continuum micromechanics and on extrapolation from elastic concentration relations and from a single fibre parameter covering complex elastoplastic events taking place at the microscopic scale at which fibres appear, being employed to theoretically predict the in-plane, ultimate strength of paper sheets [1]. However, the abovementioned single fibre parameter is a “black box”, so to say, having no direct relation with any experimental determinations related to the actual elastoplastic events. Accordingly, we herein go a step further in the process of fully connecting our theoretical model for the in-plane, ultimate strength of paper sheets with physically meaningful experimental determinations, and propose a much more sophisticated theoretical model relying on extensions to Dvorak’s classical transformation field analysis that make explicit consideration of plastic strains (in the form of eigenstresses), and which have recently been successfully used to address the elastoplastic behaviour of materials such as bones or rocks. Thereby, we reemploy large collections of experimental determinations that had been used to estimate volume fractions as well as other relevant quantities related to various, multiscale constituents of paper sheets made of softwood-based, unbeaten, chemical pulp fibres; and make use of several parameters related to a non-associated plasticity, to theoretically predict the complete stress-strain curve of the abovementioned variety of paper sheets [2]. Theoretically predicted relations between strain and stress up to ultimate strength agree outstandingly well with respective, experimentally determined curves [2]. These groundbreaking results open the way to more efficient and reliable, sustainable, theory-assisted, production, research and development, as well as use, of such materials.

MACHINE LEARNING PREDICTION OF THE IMPACT OF H2O, NO2, SO2, AND H2S IMPURITIES ON THE CORROSION RATE OF CO2 TRANSPORT PIPELINES

Joan Ejeta[1], Tolu Emiola-Sadiq[2] and Kristen Rhinehardt[1]*

[1]*North Carolina Agricultural and Technical State University*
[2]*University of Saskatchewan*

ABSTRACT

Despite significant efforts and investments in the renewable energy sector, fossil fuels continue to provide most of the world's energy supply. Transmission pipelines, extensively used in the oil and gas industry, are vulnerable to various failure mechanisms, such as corrosion. Corrosion control of gaseous CO2 transportation pipelines containing impurities such as water, H2S, NO2, and SO2 is important to the safe operation of pipelines. Correctly estimating the corrosion rate of CO2 transport pipelines helps to determine the allowable concentration of various impurities to estimate their integrity. This research provides a practical implementation of six machine-learning models for accurate internal corrosion rate prediction in oil and gas pipelines. Bagging Regression (BR), Ridge Regression (RR), Support Vector Regression (SVR), Random Forest (RF), Gradient Boosting Decision Tree (GBDT), and eXtreme Gradient Boosting (XGBoost) were among the predictive data models developed. These prediction models' implementation approach incorporates a comprehensive library of six system attributes from the literature. The significance of the input variables is determined through extra tree regressor feature importance selection criteria and statistical methods of feature selection using p-values with variance importance factor (VIF). Furthermore, k-fold cross-validation ensures good performance and generalization. The extreme gradient boosting model indicates the highest performance in predicting the internal corrosion rate of CO2 pipelines based on a mathematical RMSE score value of an internal corrosion rate of 0.031 mm/y. The results obtained were compared with experimental results from the literature and indicated the eXtreme Gradient Boosting model had the best performance with an R score of 0.885

MULTISCALE MODELING OF FRACTURE NUCLEATION AND PROPAGATION IN RATE-DEPENDENT POLYMER NETWORKS

Ahmed Elbanna[*1], Ahmed Ghareeb[1] and Chunhui Zhao[1]*

[1]*University of Illinois Urbana Champaign*

ABSTRACT

Materials with network-like microstructures, such as polymers, gels, and rubbers, are foundational in both natural and synthetic systems, including biological tissues, metamaterials, and soft robotics. Fracture processes in these materials are inherently multiscale and complex, necessitating advanced modeling techniques due to the computational challenges of fully discrete approaches in large-scale systems. We introduce an adaptive numerical algorithm, extending the Quasi-continuum (QC) method, to model fracture in networked materials with a focus on polymer networks. This method incorporates both material and geometric nonlinearities and employs a micro-macro energy consistency condition to achieve an anisotropic material tensor consistent with the network's underlying structure.

In areas of critical interest, such as near crack tips, we maintain an explicit representation of the local topology and represent each polymer chain as a nonlinear element governed by the worm-like chain model. Away from these imperfections, we limit the degrees of freedom and computationally homogenize the network structure. Our nonlinear finite element framework dynamically transitions between continuum and discrete scales, allowing for accurate modeling of crack propagation without a priori constraint on the fracture energy while maintaining the influence of large-scale elastic loading in the bulk

Expanding upon this methodology, we incorporate rate-dependent behavior into the QC approach to account for the viscoelastic behavior of polymer chains and dynamic bond breakage and formation. This includes a homogenization rule for the viscous forces and an updated adaptive mesh refinement algorithm. The framework's predictor-corrector scheme accurately resolves nodal displacements and velocities under varying loading conditions.

Our method demonstrates high accuracy and efficiency in modeling fracture in networked materials, as verified against fully discrete simulations. We explore the effects of network topology, disorder, and loading rates on fracture characteristics, highlighting the method's implications for multiscale analysis and discovery of new phase diagrams for crack patterns in viscoelastic systems. This extended approach offers a comprehensive tool for understanding and predicting fracture behavior in rate-dependent polymer networks.

TOPOLOGY OPTIMIZATION WITH STOCHASTIC GEOMETRIC PERTURBATIONS FOR WAVEGUIDE DESIGN

Philip Elbek[1], Niels Aage[1], Rasmus E. Christiansen[1] and Ole Sigmund[1]*

[1]*Technical University of Denmark*

ABSTRACT

Uncertainties in manufacturing processes are found everywhere in industry and for this reason devices usually operate with tolerances. But some products are so sensitive that even small perturbation alters their performance dramatically. Such devices are often found in compliant mechanisms or wave propagation problems, e.g. propagation of elastic-, acoustic- or electromagnetic waves, where a small perturbation of the device geometry can easily degrade performance significantly.

Standard topology optimization approaches including geometric uncertainties through robust formulation exist, e.g. in [1] for acoustic waves and [2] for mechanics, using an over- / under etching technique. The standard approach is computationally heavy and perturbation methods have been tried [3] but encountered challenges for large material contrasts as found in e.g. structural problems.

This study build on the knowledge in [3] but for an optical problem, which has a high chance of showing good results due to smaller material contrasts. The method emulates perturbations of the design caused by fabrication, such as electron beam lithography, using stochastic fields. A design robust to the specified variation results directly from the optimization with performance assigned a mean and standard deviation. The method only requires a single factorization of the system matrix per iteration, whereas standard robust topology optimization techniques [1, 2] requires multiple.
This study optimizes optical waveguides, which are used as components in larger circuits. Within the variations assumed for the manufacturing process, a robust optical waveguide is demonstrated to appear from the optimization. Having knowledge of the natural variation in performance helps us assess the performance of other components in the circuit, or the entire circuit itself. Other applications will include slow-light and extreme dielectric confinement waveguides.

STRUCTURE-PRESERVING, HIGH-ORDER, OSCILLATION-LIMITING, BOUNDS-PRESERVING (SPHOOL-BP) TRANSPORT OPERATORS FOR ARBITRARY K-FORMS USING DISCRETE EXTERIOR CALCULUS

Christopher Eldred[*1]*

[1]*Sandia National Laboratories*

ABSTRACT

Many fluid dynamical systems can be described by a (convective) velocity and a set of state quantities such as mass density, specific entropy and electromagnetic fields, etc. When the dynamics are reversible and the state quantities are advected (their behavior is governed entirely by a Lie derivative), then the resulting set of equations have a special semi-direct product structure that leads to a Lie-Poisson Hamiltonian formulation (or equivalent forms obtained through a change of variables such as Curl-Form). In these formulations, each advected quantity induces a corresponding term in the momentum equation, governed by a diamond operator.

In this talk we will discuss the development of structure-preserving, high-order, oscillation-limiting, bounds-preserving (SPHOOL-BP) transport operators using discrete exterior calculus (DEC) for state quantities that are scalar-valued differential k-forms (SVDFs), including discrete versions of both Lie derivatives and diamond operators. This builds on previous work for \scalar-valued volume forms such as mass density or entropy density, extending it to arbitrary scalar-valued k-forms such as electromagnetic fields or specific entropy.

SPHOOL-BP transport operators offer: (1) preservation of geometric mechanics structure, in particular anti-symmetry of the Poisson bracket needed for energy conservation; (2) high-order accuracy in smooth regions and high-resolution in regions of sharp gradients or discontinuities; (3) oscillation-limiting through WENO or related reconstructions; and (4) (local) bounds-preservation through flux corrected transport.

If time permits, there will be discussion of preliminary work on how to extend these ideas to arbitrary (vector) bundle-valued differential forms (BVDFs), which would be required to treat quantities such as fluid momentum or tensor order parameters in models with fluid microstructure.

GROUP ESTIMATORS FOR MULTIFIDELITY SAMPLING

Michael Eldred[*1], Alex Gorodetsky[2], John Jakeman[1] and Gianluca Geraci[1]*

[1]Sandia National Laboratories
[2]University of Michigan

ABSTRACT

Multifidelity uncertainty quantification can be an effective tool for quantifying the effects of statistical variability for physics simulations that require expensive high-fidelity computational models. By optimizing the allocation of computational resources among multiple models of varying accuracy and cost, accurate estimates of statistical quantities of interest can be obtained at significantly lower cost than for single-fidelity approaches. Recent work has explored refinements that aid in the practical deployments of multifidelity sampling methods, including iterated pilot management, selection of the most performant approximation memberships and relationships (ensemble and DAG selection), and hyper-parameter model tuning. These refinements target the full set of available sampling estimators, but have been observed to be most effective given the addition configuration freedom in non-hierarchical cases, i.e. in approximate control variate (ACV), generalized ACV, and multilevel best linear unbiased estimator (ML BLUE) contexts.

In this work, we dive deeper into group estimators, including ML BLUE and recent extensions which seek to relax certain constraints enforced in the ML BLUE formulation. Group formulations can directly facilitate ensemble selection using semi-definite approaches to resource allocation, and we seek to augment this capability with effective approaches for online/offline pilot management and hyper-parameter model tuning.

ABSTRACT

IsoGeometric Analysis was introduced as an “extension” of Finite Element Methods which obtains better results by increasing the polynomial degree p and refining the mesh size h. However, its application implies great computational challenges since the cost increases rapidly with the degree p. This communication focuses on novel techniques like Matrix-Free and Fast Diagonalizationmethods which, coupled with IGA, enable to:
• reduce storage memory and computation time by not constructing/storing the matrices but instead using an iterative solver with efficient matrix-vector products;
• enhance the convergence rate of the Krylov solver by introducing an inexpensive, easy to code and effective preconditioner.
The objective of this communication is to illustrate the synergy between these approaches applied to space and space-time problems considering heat transfer and elasto-plasticity. We will show that the proposed method will illustrate significant cost reductions.

Novel mathematical and numerical models for multiphysics and multiscale systems
July 21-26, 2024, Vancouver Convention Centre, Vancouver, British Columbia, Canada

HIGH-ORDER DG METHODS FOR THE CELL-BY-CELL ELECTRONEUTRAL NERNST-PLANCK FRAMEWORK

Ada Johanne Ellingsrud[*1] and Miroslav Kuchta*[1]

[1]*Simula Research Laboratory*

ABSTRACT

Despite the fundamental role of movements of molecules and ions in and between cellular compartments for brain function [1], most computational models for excitable tissue assume constant ion concentrations. Although these models have provided valuable insight into how neurons function and communicate, they fail to describe vital processes related to signalling and brain homeostasis, and pathologies involving substantial changes in the extracellular ion composition such as epilepsy and spreading depression.

Here, we discuss the emerging KNP–EMI framework [2], describing the coupling of ion concentration dynamics and electrical properties in excitable tissue with explicit representation of the cells, allowing for morphologically detailed descriptions of the neuropil. In contrast to classical homogenized models, the highly detailed KNP-EMI framework enables modelling of single cells and small collections of cells, uneven distributions of membrane mechanisms, and how the cellular morphology affects tissue dynamics.

The system consists of non-linear, highly coupled, and mixed-dimensional partial differential equations. Numerical strategies for approximating the system must as such be chosen with care. We present a novel numerical strategy with three key components: (i) a splitting scheme to decouple the PN equations governing ionic transport and the equation arising from the electro-neutrality assumption, (ii) a high-order Discontinuous Galerkin (DG) discretization of the decoupled system, and (iii) a robust and scalable solver. We further analyse and discuss stability and convergence properties of the proposed scheme, and show that our solution approach is robust and scalable allowing for large-scale, high-realism in-silico studies of electrodiffusive processes in excitable tissues.

MESHFREE FRAGMENTATION AND ANALYSIS OF MASS DISTRIBUTIONS FROM EXPLOSIVE EVENTS

William Elmer[1] and Colton Ross*[1]

[1]*Lawrence Livermore National Laboratory*

ABSTRACT

Meshfree Fragmentation and Analysis of Mass Distribution from Explosive Events.
Aug. July 21-26, Advances and applications in meshfree, particle, and peridynamic methods, in Conference: WCCM 2024/PANACM 2024, Vancouver, Canada.

Meshfree methods appear to be well suited for problems involving fragmentation because no mass is lost in the service of preserving numerical stability under extreme deformation, i.e. meshfree methods do not require element deletion. Natural fragmentation is the process by which solid bodies, subject to extreme events like hypervelocity impact or explosive loading, fracture into small pieces of material. Robust treatment of fracture is necessary for capturing the resulting mass distribution of fragments because fragmentation is a race between the ongoing loading of the structure and unloading caused by fracture (1).

However, despite the apparent benefits of Meshfree methods, computational methods used to generate fragments are limited not only by the mesh resolution, but also inaccuracies as fragments approach this size. Numerical techniques that accommodate failure and fragmentation typically maintain conservation of mass and momentum by forming particles or “fragments” on the order of the mesh discretization. “Fragments” that are generated below a certain size cease to encode relevant information about the physics of the explosive event, and instead represent a-priori construction of the mesh. We will study the role of statistical damage seeding, relation to static failure tests, and mesh resolution.

Using a previously developed technique (2) for the quantitative comparison between explosive events that generate fragments, comparisons will be shown between empirical pipe-bomb events numerical simulations from ALE3D utilizing the meshfree SPH formulation Spheral (3). We use the method (2) to assess the suitability of different numerical methods to calculate observed fragment sizes within the bounds established by experiment. The empirical dataset contains a test matrix of two different high explosives with high and low brisance, and three heat-treatments of 4340 steel: displaying a 50% variation in elastic modulus and a 57% variation in ultimate tensile strength.

DISCOVERY OF COMPOSITE MATERIAL ARCHITECTURES USING PERPETUAL MACHINE LEARNING

Bassam El Said[*1]

[1]*University of Bristol*

ABSTRACT

Architectured materials, such as composites, gives the designer the ability to tailor a material's performance to each specific structural application. These materials often exhibit strong heterogeneity manifesting as coupling between the material internal architectures and the structural geometry. Examples of this behaviour can be seen in 3D woven composites and tow steered composites, where the fibre paths are dependent on the structural geometric features, but also the manufacturing methods used. As a result, complex and computationally expensive multi-scale and multi-physics simulations are often needed to predict the mechanical performance on the structural scale, as well as the impact of manufacturing methods on the material architecture. While these models are very effective as analysis tools, their prohibitive computational cost make them unsuitable for design and optimisation tasks. Multi-scale data-driven approaches has seen wide use in optimisation and design of such structures. This is often achieved by sampling the material design space in advance and building a surrogate model to represent the materials' response as a function of their architecture, which is later used in design/ optimisation. However, with large scale structure and complex material architectures, this sampling process is often very expensive and time consuming.

In this work, a novel approach based on perpetual machine learning is introduced. This approach enables the simultaneous discovery and optimisation of material architectures, structural geometries, and accurate multiscale representations of both. The perpetual learning framework continuously trains two machine learning models, a classifier representing a given problem constraints such as the occurrence of failure or structural buckling, and a surrogate model representing the structural behaviour inside the design space. The discovery process is carried out in an iterative manner, where in each iteration an optimiser finds an interim optimal point based on information from the surrogate model and the classifier. Following, the training database is enriched using multi-scale simulations at key test points, chosen based on the confidence margins of the classifier and surrogate model, as well as the interim optimal solution. Using this iterative process, the framework continually samples the material and structure design space to develop a better description of the structural response and the conditions at which failure might occur. The proposed approach has demonstrated the ability to discover machine learning models for a variety of analytical problems and realistic composite material and structures.

ACTIVE CONTROL OF FLUID-STRUCTURE INTERACTION SYSTEMS USING DEEP REINFORCEMENT LEARNING

Mosayeb Shams[1] *and Ahmed H. Elsheikh**[1]

[1]*Heriot-Watt University*

ABSTRACT

This study introduces an innovative deep reinforcement learning (DRL) approach for the active control of fluid-structure interaction (FSI) in a laminar flow environment. Focusing on active flow manipulations using actuators within FSI systems, we develop effective control policies for the displacement control of the simulated structures. For the simulations, we rely on an open-source coupling library for partitioned multi-physics simulations (preCICE), integrated within the reinforcement learning Gym-preCICE framework. The uniqueness of this research lies in using the Proximal Policy Optimization (PPO) algorithm, a state-of-the-art on-policy DRL method, to actively control the system using a predefined reward function.

To the best of authors' knowledge, this research represents the first attempt to use DRL for active control of complex FSI scenarios involving 2D dynamics of rigid (Vortex-Induced-Vibration, VIV) and flexible (Fluid-Induced-Deformation, FID) bodies. Our results show that the DRL-controlled system, employing the PPO algorithm, can adaptively and efficiently control FSI systems, offering a superior alternative to traditional control methods. This approach holds significant potential for applications in engineering structures where FSI is a primary concern, such as in bridge aerodynamics, marine structures, and wind turbines. Future work will aim to expand the scope of this method to include more dynamic and realistic FSI scenarios, potentially revolutionizing how FSI phenomena are addressed in various engineering applications.

COMPUTATIONAL MODEL FOR LOCAL BUCKLING OF COMPRESSIVELY LOADED OMEGA-STRINGER-STIFFENED PANELS

Cherine El Yaakoubi-Mesbah[*1] and Christian Mittelstedt*[2]

[1]*TU Darmstadt*
[2]*Technische Universität Darmstadt*

ABSTRACT

Thin-walled composite structures are used in applications such as aircraft and spacecraft due to their low weight and corresponding high stiffness properties. To optimize the potential of these structures to the fullest extent, a complete understanding of their stability behavior is required. Thereby, uniaxial compression describes an important load case that is investigated. A closed-form analytical method based on the energy method for determining the local buckling load of omega-stringer-stiffened panels is presented. The stiffened panel under consideration consists of the skin plate with eccentrically attached stringer feet along the longitudinal sides of the panel, while the remaining part of the omega-stringer is modeled by corresponding elastically restrained edges. Due to the applied stringer feet, stiffness discontinuities occur in the stiffened panel. This is covered by the presented method, whereas in comparable studies in the literature, a homogeneous stiffness is often assumed across the entire panel. To evaluate the new analysis method, a comparison with the numerical solution of the corresponding Lévy-type solution and the finite element analysis is being drawn.

[2]*University of Missouri*
[3]*Zagazig University*

ABSTRACT

Superstructures of bridges are susceptible to fatigue loading when subjected to service loads, potentially leading to premature structural failure. This study presents experimental findings obtained from fatigue loading tests conducted on composite beams with various configurations. These fatigue tests involved subjecting the beams to one million cycles of four-point loading with varying shear stress ranges at a consistent amplitude. Additionally, the research investigated the influence of external post-tensioning and the strength of the shear connection. In order to evaluate the residual strength of the fatigued specimens, static tests were performed until failure. Throughout the testing process, we monitored mid-span deflections, slippages between concrete slabs and steel beams, strains in the shear connectors, and strains in the concrete slabs and steel beams. The experimental results revealed that as the number of cycles increased, the shear studs caused damage to the concrete slab, resulting in a loss of stiffness in the shear connection. This led to increased residual deflections and plastic slippages. The control of longitudinal fatigue cracks in the concrete slab was largely dependent on the strength of the shear connection between the steel beams and concrete slabs. Additionally, the shear stress range in the shear connectors influenced the formation and distribution of fatigue cracks in the concrete slab. Furthermore, the application of external post-tensioning significantly reduced the strains in the steel beam, concrete slab, and shear connectors. Remarkably, the tendons displayed excellent fatigue performance with no signs of distress at the anchors.

DESIGN OF ACOUSTIC METASURFACES FOR LOUVERS OF ENGINE ROOM USING TOPOLOGY OPTIMIZATION CONSIDERING VISCOSITY AND TEMPERATURE BOUNDARY LAYERS

Hiromitsu Emoto[*12] and Takayuki Yamada*[1]

[1]*The University of Tokyo*
[2]*Advanced and Core Technology Center, Komatsu Ltd*

ABSTRACT

Sound radiation from the engine compartment louvers of construction machinery and automobiles poses a significant noise pollution challenge to urban residents and others. To address this problem, we used topology optimization to design an acoustic metasurface specifically tailored as a louver structure. This design strategically directs sound from its source in selected directions, regardless of the direction of the incident sound. The optimization process employed the Sequential Linearized Navier-Stokes model, which meticulously accounts for the effects of viscous and thermal boundary layers using the level set method. A comparative analysis was performed to evaluate the impact of these boundary layer effects on the optimization results. The mechanism of the optimized structure was rigorously modeled, and its frequency response was numerically analyzed. This analysis revealed that the response depends on the specific dimensions of the structure. Based on these findings, we proposed a simplified version of the louver structure designed for ease of fabrication. The performance of this streamlined structure was then numerically validated, demonstrating its potential effectiveness in mitigating urban noise pollution.

ABSTRACT

Quantum annealing machines are attracting attention as next-generation solvers to solve combinatorial optimization problems. Physics simulation can be one of the useful areas where quantum annealing machines can be applied. It is because some physical phenomena are simulated to find minimum energy states, and quantum annealing machines accelerates to find them as combinatorial optimization problems. It could also be used to optimize the initial conditions for better results.

In this study, we focus on a method of representing real numbers using binary variables, or quantum bits. To use a quantum annealing machine, all problems must be converted to combinatorial optimization problems of binary variables. On the other hand, since general physics simulation problems involve real numbers in the decision variables, real numbers must be expressed as a combination of binary variables. We have found that the method of representation of real numbers causes a significant change in the quality of the results obtained by the quantum annealing machine. We also find that the most appropriate representation method depends on the size and difficulty of the problem to be solved, and that these differences show consistent trends across the two annealing solvers. Finally, we explain the reasons for these differences using a simple model, the minimum number of simultaneous bitflips required, and one-way stochastic bitflip energy minimization.

BOUNDS FOR GOAL ORIENTED ERROR ESTIMATION

Bernhard Endtmayer[*1], Ulrich Langer[2] and Thomas Wick[1]*

[1]Leibniz University Hannover
[2]Johannes Kepler University Linz

ABSTRACT

In many applications, the primary focus is not on solving the partial differential equation but rather on a quantity of interest that depends on the solution. In this talk, we will derive goal-oriented error estimation and mesh adaptivity for this quantity of interest. This process requires either a hierarchical approach or interpolation. We will provide efficiency and reliability results for both, assuming that a saturation assumption for the quantity of interest is met. Here, both the partial differential equation and the quantity of interest may be nonlinear. In conclusion, the numerical findings will be supported by numerical examples.

ABSTRACT

Structures with Triply Periodic Minimal Surfaces (TPMS) have gained significance for various applications in biomedical engineering, including tissue scaffolds. TPMS bone tissue scaffolds possess interconnected pores and a large surface area, which can facilitate cell adhesion and nutrient diffusion. To enhance the biomimetic nature of these TPMS scaffolds, functional gradients such as pore size and porosity variations are often incorporated into these scaffolds. While functionally gradient scaffolds have been shown to achieve better bone regeneration outcomes, variations in their pore size and porosity distributions can significantly influence their mechanical behaviour, which needs to be carefully considered when designing these structures. Recent studies have investigated the mechanical characteristics of functionally gradient scaffolds under axial loading. However, bone scaffolds usually undergo far more complex loading conditions, including compression, shear, and torsion. Hence, the mechanical behaviour of these scaffolds must be investigated in various loading scenarios to ensure their efficacy in real-world applications.

This study systematically investigates the mechanical properties of functionally gradient TPMS structures in various loading conditions. Two different TPMS scaffolds, including gyroid and primitive, are designed with various porosity distributions while the overall porosity is kept constant between all groups. Finite element analysis (FEA) is conducted on each scaffold with a cylindrical shape to evaluate their stress distribution, stiffness, and strength under three different loading scenarios, including compression, shear, and torsion. To validate the FEA results, the scaffolds are fabricated from Acrylonitrile butadiene styrene (ABS) using PolyJet™ 3D printing technique. Then, in-house experimental mechanical tests are conducted on the scaffolds using customized jigs to replicate the loading conditions used in the FEA simulations. The computational results indicate that a decrease in the porosity of the scaffolds toward their centre can significantly enhance their stiffness and strength. Moreover, it is demonstrated that a sharper decrease in porosity can further increase the stiffness and strength of the scaffolds. Furthermore, the FEA results are validated by our in-house experimental data obtained from the compression, shear, and torsion testing on the scaffolds.

This study concluded that TPMS structures with functionally gradient pore size and porosity could significantly improve the mechanical properties of bone scaffolds in complex loading conditions. Moreover, the rate of variation in the pore size and porosity distribution could further control the mechanical behaviour of these porous structures. This study is expected to provide significant insight into the design of functionally gradient structures for applications in tissue engineering and bone implants.

ATOMISTIC SIMULATIONS OF DIFFUSION PROCESS IN MATERIALS SUBJECT TO EXTREME CONDITIONS

Aylin Ahadi[1] and Namsson Eom[*1]*

[1]Lund University

ABSTRACT

To explore various physical and chemical phenomena at the nanoscale, in which materials often exhibit properties divergent from their bulk counterparts, atomistic modelling tools prove more advantageous than the traditional thermodynamic approach. Among them, Molecular Dynamics (MD) simulations stand out as a pivotal and influential tool, offering an in-depth exploration of physical phenomena within nanostructures at the molecular level. MD simulations enable the precise prediction of atom trajectories within molecular systems, guided by interatomic potentials, thereby facilitating a profound understanding of nanostructure evolution. This includes elucidating the elusive atomistic intricacies of diffusion phenomena, which are often challenging to observe both experimentally and through a thermodynamic approach.

In this study we aim to explore physical and chemical phenomena at the nanoscale, in which materials often exhibit properties divergent from their bulk counterparts. We will employ MD simulations to characterize mutual diffusion behavior, as well as the intricate structure and evolution processes of bimetal systems at their interfaces and our overarching goal is to undertake a comprehensive exploration of diffusion phenomena at bimetallic interfaces, spanning diverse film-substrate systems. Employing advanced machine learning methods, including data dimension reduction techniques and neural network, our aim is to identify the optimal multimetal film compositions with the best diffusion properties and to enhance our understanding of the fundamental principles governing the phenomena.

We will consider factors such as cohesive energy, surface energy, atomic size, and electronegativity, as the features (descriptors) in the machine learning. We will also investigate chemical reactions occurring within the film-substrate systems, facilitated by, for example, carbon and oxygen, and how the newly formed species act as diffusion barriers. This exploration will entail the use of reactive molecular dynamics using ReaxFF potential.

Furthermore, we will investigate the chemical reactions occurring within thin films, particularly in conjunction with carbon and oxygen, and how the newly formed species act as diffusion barriers. We present simulation of diffusion behavior for various multimetallic film-substrate combinations using MD approach and predict the optimal metallic combinations for the film using neural network. In addition our simulation will add the effect of chemical reactions on the diffusion process and we will develop a methodology for a holistic understanding of interdiffusion mechanisms in multimetallic structures at the atomic level.

[3]*Korea Institute of Machinery & Materials*

ABSTRACT

Vibration measurement during ship trials is crucial for safety and the lifespan of structures. However, field engineers often face challenges in accurately measuring vibrations due to various difficult environments. In response, the industry has increasingly demanded a flexible, accurate, and stable vibration measurement tool. Our research has developed a mobile-based vibration processing system using image processing techniques. A key method employed is the phase correlation-based template matching, known for its effectiveness in vibration measurement. This approach involves extracting the Region of Interest (ROI) and comparing phases to determine changes in vibration. A major focus of this study has been on mitigating the variability in measurement accuracy due to the way the ROI is established. As a result, we have conducted research and development focused on optimizing the placement of ROI for improved accuracy in vibration measurement. Additionally, this study has analyzed the challenges encountered during sea trials on real ships, focusing on deriving results from actual vibration measurements. These analyses included identifying environmental factors that negatively impact the accuracy and reliability of these measurements. We identified and categorized various factors that could potentially impact the results and identified those with the most significant influence. This process helped us determine which aspects to focus on for in-depth analysis before proposing solutions.

ACOUSTIC SHAPE OPTIMIZATION USING ENERGY STABLE CURVILINEAR FINITE DIFFERENCES

Gustav Eriksson[*1] and Vidar Stiernström*[1]

[1]*Uppsala University*

ABSTRACT

It is well known that high-order finite difference methods (HOFDM) are well suited for long-time simulations of wave propagation problems. An established approach for obtaining efficient and robust HOFDM is to discretize in space using schemes satisfying a summation-by-parts property [1]. Summation-by-parts finite difference operators are designed to satisfy a discrete version of integration-by-parts, allowing for semi-discrete energy estimates that mimic the equations in the continuous setting. This leads to provably stable high-order schemes that can be implemented with the computational efficiency typical of finite difference methods.

Historically, summation-by-parts finite differences have mostly been used to obtain approximate solutions to partial differential equations (the forward problem). In this work (see preprint in [2]), we apply the summation-by-parts finite difference method to shape optimization problems constrained by the acoustic wave equation. The new approach makes use of state-of-the-art summation-by-parts finite difference techniques together with a gradient-based method to obtain an efficient solver for the shape optimization problem. Representing the design domain through a coordinate mapping from a reference domain, the design shape is obtained by inversion of the discretized coordinate map. The adjoint state framework is employed to efficiently compute the gradient of the loss functional.

Using the summation-by-parts properties of the finite difference discretization, we prove stability and dual consistency of the semi-discrete forward and adjoint problems. This means that the "discretize-then-optimize" and "optimize-then-discretize" approaches are equivalent for this problem. We also verify the accuracy of the finite difference scheme numerically and demonstrate the capabilities of the shape optimization method by solving two two-dimensional model problems with real-world relevance. First a bathymetry problem (determining the shape of ocean floors) and then the problem of optimizing the shape of an acoustic horn to minimize the reflected sound.

In my talk I will present the basic ideas behind summation-by-parts finite differences, our approach to the shape optimization problems, and numerical experiments demonstrating the capabilities of the method.

[4]*Université de Sherbrooke*

ABSTRACT

Packed beds find various industrial applications such as catalytic reactors, filtration and separation, food processing as well some niche applications in mining like heap leaching and underground thermal energy storage. One of the most critical design parameters in packed beds is the pressure drop along the bed, often characterized by the friction factor coefficient. Although many correlations are readily available relating the friction factor to the flow Reynolds number (Rem), the impact of critical factors such as particle shape, size distribution, and tube-to-particle diameter ratio (N) on the friction factor remains less explored. Some authors have proposed correlations including sphericity for particle shape and an equivalent diameter for size distribution, yet there is no clear consensus on how tube-to-particle diameter ratio can be taken into account in friction factor correlation. This study investigates the effect of tube-to-particle diameter ratio and assess the validity of available correlations on finite beds with low N values. Pore-scale modeling based on particle-resolved Computational Fluid Dynamics (CFD) is performed to study the airflow dynamics within the packed bed of rocks, offering a detailed examination of the fluid dynamics at microscopic level. These findings underscore the necessity to revisit existing correlations in friction factor assessments, bringing attention to the nuanced role of N in the determination of pressure drop in packed bed of particles.

A DATA-DRIVEN REDUCED ORDER MODEL OF FLUID FLOW WITHIN A FEMORAL VEIN

Fateme Esmailie[*1], Mason Forshage[1] and Ricardo Rodriguez[1]*

[1]*University of North Texas*

ABSTRACT

Venous thromboembolism (VTE), including Deep Vein Thrombosis (DVT) and Pulmonary Embolism (PE), are two major cardiovascular diseases worldwide [1]. Deep vein thrombosis and pulmonary embolism impose more than $10 billion/year economic burden on the USA's health system [1]. Therapeutic methods that are commonly used to treat DVT include anticoagulant medication, catheter-directed intra-thrombus thrombolysis (CDIT), Inferior Vena Cava (IVC) filter, pharmacomechanical catheter-directed thrombolysis (PCDT), percutaneous mechanical thrombectomy (PMT), and ultrasound catheter-based thrombolysis [2,3]. Anticoagulants such as heparin, warfarin, and blood thinners are prescribed to prevent or resolve venous thrombi by interrupting the clotting cascade. Anticoagulant therapy increases the risk of bleeding, impacts the coagulation cascade in the whole body, and is less effective due to the longer time of clot dissolution. IVC filters, CDIT, PMT, PCDT, and ultrasound are localized methods to dissolve or physically remove the clot, offering potentially higher efficiency compared to anticoagulants. However, these methods are invasive and may lead to an increased risk of stroke, embolization, perforation, and thrombosis. To address the limitations of current thrombus management techniques, it is crucial to predict the risk of DVT and develop non-invasive thrombolysis methods. A fluid dynamic model integrated with a coagulation cascade model is required to predict the risk of DVT. The time required to solve full-order FSI and CFD models is much higher than the actual time taken for thrombus formation. Therefore, it is challenging to apply full-order CFD and FSI models to predict the DVT before it occurs. We developed a reduced order model (ROM) of flow within deep vein valves to reduce the computational time related to solving Navier-Stokes and structural mechanics equations. We fabricated five femoral vein silicone phantoms and placed them in a flow loop to record the leaflet displacement, wall shear stress, velocity vectors, and pressure data using a particle image velocimetry system (PIV). We tested the flow under various heart rates. These data were stored as a snapshot library to develop a ROM FSI. Using proper Orthogonal Decompositions (POD)-Galerkin, the FSI governing equations were projected into the ROM basis and then were solved. The ROM model developed in this work is five times faster than using a full-order FSI simulation to model blood flow within a femoral vein.

HYBRID STRUCTURE HEALTH MONITORING TECHNIQUE FOR ENHANCING MODAL PARAMETER IDENTIFICATION ACCURACY

Mudahemuka Eugene[1] and Kyosuke Yamamoto*[1]

[1]*University of Tsukuba*

ABSTRACT

SHM relies on the possibility of estimating structural modal parameters, such as mode shapes, natural frequencies, and damping, from the structure's measured data. Nevertheless, modal parameter estimation still faces accuracy problems. Traditionally, measured data were obtained by instrumenting bridge structures with connected sensor systems which faced many technical problems such as high cost, maintenance issues, safety, and traffic disruption among others. Later, a practice shift favored indirect SHM (iSHM) methods among which drive-by using passing instrumented vehicle is well researched [1,2]. These methods still don't solve the problem with modal parameters identification accuracy especially higher mode of vibration believed to be sensitive to localized bridge damage which limits the widespread adoption of iSHM methodologies [1,3]. A combination of the two prominent methodologies is proposed to address the limitations of existing methods by combining the advantages of indirect monitoring and direct monitoring. This is thought to improve the modal parameters identification including the higher modes of vibration for localized damage detection and structural assessment.
The proposed approach uses GPS-time synchronized sensors to ease the simultaneous measurement of vehicle and bridge vibration data. Furthermore, the proposed method is verified by numerical simulation assuming a multi-run scenario over the same bridge. The key findings of this study highlight the potential of the hybrid SHM technique in significantly improving the accuracy of indirect structural health monitoring. The results demonstrate that the integrated approach outperforms the existing methods by providing more reliable and precise modal parameter estimates, especially higher modes of vibration, allowing the identification of the bridge's localized damage.
Keywords: Hybrid structure health monitoring, GPS clock synchronization, modal parameters identification.

NONLINEAR CONJUGATE GRADIENT SOLVERS FOR LARGE DEFORMATION NONLINEAR FINITE ELEMENT MODELS

Sam Evans[1]*

[1]*Cardiff University*

ABSTRACT

Although finite elements are widely used for large deformation, nonlinear problems, conventional solvers using BFGS quasi-Newton or similar methods are often slow and frustratingly unreliable, especially where severe nonlinearities such as buckling are present. The size of models that can be solved is limited by the memory required for the tangent stiffness matrix. Explicit solvers are increasingly widely used to try to avoid these problems, but can also be frustratingly slow, especially for quasistatic problems. Direct solution using nonlinear conjugate gradient methods is an interesting alternative that could perform much better for large, highly nonlinear problems.

A nonlinear conjugate gradient solver using the Hager-Zhang CG-DESCENT algorithm with a modified linesearch was implemented in the FEBio software package. Various test models were used to benchmark the algorithm against the standard BFGS solver.

For small models the conjugate gradient algorithm was significantly slower, but for large models it was up to two orders of magnitude faster for moderately nonlinear models. It was also able to solve models an order of magnitude larger. For highly nonlinear models that were difficult or impossible to solve using the BFGS solver, the conjugate gradient algorithm converged reliably, often in a single timestep, although this often required a long solution time.

Because displacements propagate slowly across the mesh over many iterations, prescribed displacement boundary conditions can cause excessive mesh distortion and must be applied with care. However, inadequate constraints do not cause large and uncontrolled displacements as they do with Newton-Raphson solvers, which is very helpful for multibody contacts and similar problems.

Where different nodes have significantly different stiffnesses, for example for different materials or midside nodes in quadratic elements, some nodes can move faster than others during the solution causing mesh distortion. This can be alleviated by using a preconditioner, for example the main diagonal of the tangent stiffness matrix, although in general this did not consistently improve the performance of the algorithm. No doubt better preconditioners could give significant performance improvements.

In summary, nonlinear conjugate gradient algorithms have considerable potential for large, highly nonlinear problems and there is great potential to develop them further.

PROBABILISTIC LEARNING IN NONLINEAR COMPUTATIONAL STOCHASTIC DYNAMICS: INVESTIGATING A PARTIALLY OBSERVED UNCERTAIN NOZZLE MODEL

Olivier Ezvan[*1], Evangéline Capiez-Lernout[1] and Christian Soize[1]*

[1]*Université Gustave Eiffel*

ABSTRACT

This papers deals with the numerical application of the Probabilistic Learning on Manifold (PLoM) method to construct a statistical surrogate model consistent with a small and incomplete target dataset. The structure under consideration is a three-dimensional engine nozzle, made up of an homogenized elastic material and subjected to random internal pressure excitation. The dynamical model assumes large displacements. A target dataset is assumed to be given, which is constituted of a subset of the normal displacements located in the nozzle exit, and expressed in the frequency domain. These random frequency response functions form a subset of the Quantities of Interest (QoI) that will be considered as the model outputs. A parameterized Stochastic NonLinear Computational Model (SNLCM) representing the nozzle dynamics is constructed. Its control parameters describe the power spectral density of the stochastic excitation force. Furthermore, the elasticity matrix is homogeneous, anisotropic and random, whose mean value corresponds to an isotropic elasticity matrix. Due to the complexities of such a nonlinear computational model, the calculation of the dynamical response for a given set of parameters induces a high computational cost. First, the SNLCM is used as a prior model to generate a so-called training set, that is constituted of the QoI and associated control parameters. These control parameters belong to an admissible set, and are randomly drawn following a uniform distribution. Second, the target dataset is obtained through numerical simulations, using the SNLCM, where the elasticity matrix is taken as deterministic, as slightly stiffened with respect to the mean elasticity matrix. Also, the control parameters used for generating the target dataset belong to the same admissible set as for the training set, randomly drawn following a uniform distribution within cells of a regular grid. Once both the target dataset and the training dataset are obtained, the PLoM algorithm with constraint is used for obtaining a statistical surrogate model that is devoted to updating the statistical prediction of the QoI with respect to the control parameters. The PLoM algorithm generates a so-called learned dataset with same format as the training dataset, that takes into account the target subset of QoI. The learned dataset yields updated QoI as model outputs, which are updated with respect to the training dataset, so as to better match the target.

MULTISCALE SIMULATION OF SLOT DIE COATING USING DARCY-BRINKMAN-BIOT APPROACH

Samuel Fagbemi[*1] and Tequila Harris*[1]

[1]*Georgia Institute of Technology*

ABSTRACT

The penetration of coating fluids in porous systems during single-layer slot die coating processes has been studied in various fields of manufacturing including fuel cells, photovoltaics and paper manufacturing. An adequate level of penetration is usually required during such a process to ensure proper adhesion of the coating fluid to the substrate. Insufficient or excessive penetration is undesirable because it can reduce the overall quality of the finish. Most computational studies carried out to study this phenomenon during the coating process generally adopt a decoupled approach due to the difficulty in coupling the pressure in the coating bead to the porous material. Attempts that have been made to study this concept within a fully coupled system, typically implement a visco-capillary model for the coating bead region and employ a 1D or 2D Darcy model for predicting the fluid penetration within the porous region. However, to fully understand the dynamics within the fluid domain, a 3D model fully coupled model is required. In this work, we employ the Darcy-Brinkman method to carry out the multiscale simulation of single-layer slot-die coating by introducing an extra drag term in the momentum equation that enables the direct coupling of flow in the coating bead to the flow in the porous material. This gives rise to a micro-continuum framework that solves for flow in the coating bead using the Navier-Stokes equation, while the flow in the porous medium is captured using the Darcy equation, thus creating a fully coupled system. This approach satisfies pressure and velocity continuity across the boundaries of both domains while still having distinct domains. Due to the porovisco-plastic nature of the coated substrate, our model also captures flow-induced material deformation such as wrinkling which can during this coating process. Such deformation is described by directly coupling the Darcy-Brinkman equation with the Biot equation for the deformed solid matrix. The model is then validated against single-layer slot die experiment with Carbon paper Toray 090 paper as the substrate, coated with a Newtonian bio-polymer fluid to accurately capture the depth of penetration in the deformable medium.

ADAPTIVE STRATEGIES FOR VALIDATING AND SELECTING PREDICTIVE PHYSICS-BASED AND MACHINE LEARNING SURROGATE MODELS

Danial Faghihi[*1], Pratyush Kumar Singh[1] and Kathryn Maupin[2]*

[1]University at Buffalo
[2]Sandia National Laboratories

ABSTRACT

This work presents two computational frameworks derived from the Occam-Plausibility ALgorithm (OPAL) for selecting an "optimal" predictive model from a multitude of potential physics-based and neural network surrogate models, each differing in fidelity and complexity. OPAL relies on the notation of prediction pyramid signifying the hierarchy of scenarios to systematically inform the model and leverages Bayesian inference for model calibration and validation and the notion of model plausibility to systematically select the simplest valid model that delivers sufficiently accurate computational prediction. The critical feature to ensure the model's predictive ability is the design of model-specific validation experiments to provide observational data reflecting, to some extent, the structure of the target prediction. The applications of these frameworks in multiscale modeling of microscale materials and neural network surrogate models of mesoporous building insulation components will be discussed.

ABSTRACT

This work introduces a novel framework, built on the Occam-Plausibility Algorithm (OPAL), for strategically discovering of "optimal" predictive neural network surrogate models for high-fidelity physical simulations. Leveraging hierarchical Bayesian inference to determine neural network parameters and hyper-parameters, along with Bayesian model validation principles for credibility assessment, the proposed OPAL-Surrogate systematically identifies the simplest credible (“optimal”) surrogate model capable of delivering accurate and reliable predictions. The proposed strategy embraces the concept of a prediction pyramid, representing a hierarchy of scenarios to inform the model systematically. A key aspect ensuring the model's predictive ability is the design of model-specific high-fidelity scenarios to provide training data reflecting the structure of the target prediction. The application of this framework in surrogate modeling includes multiscale simulations of mesoporous building insulation materials and turbulence combustion simulations, which will be discussed.

CHARACTERIZATION AND MODELLING OF THE EFFECTS OF WEAVING DEFECTS ON THE MECHANICAL BEHAVIOUR OF L-ANGLE THERMOSET COMPOSITE SPECIMENS.

Christian Fagiano[1], Anton Koenig[1], Claire Fougerouse[1], Florence Saffar[1] and Frédéric Laurin[1]*

[1]*ONERA - Université Paris-Saclay*

ABSTRACT

Structural parts made of laminated composite materials with long carbon fibers are used today in a growing number of high-performance industrial applications. However, due to their manufacturing process, composite structures have different types of initial defects which can lead to a significant reduction in their mechanical properties. Regarding the scientific literature, the analysis of out-of-plane waviness effects within L-angle thermoset composite specimens has been approached both experimentally [1] and with numerical simulations [1,2]. These defects can induce significant reductions in their mechanical strength due to premature failure by delamination. These reductions depend on the characteristics of the waviness defects, i.e. their geometry (length, amplitude, etc.) and their position in the part. Predicting the reduction in mechanical properties is essential for defining acceptance and certification criteria for structural parts in presence of initial defects representative of those observed at industrial production sites.

The purpose of this work is to better understand the damage and failure scenarios of L-angle thermoset composite specimens subjected to four-point bending tests in presence of out-of-plane waviness defects. To do this, a numerical strategy for predicting these reductions, based on finite element simulations, has been implemented at ONERA. The geometry of the defect is explicitly considered in the mesh from microscopic or tomographic observations of the specimens tested. In order to validate the proposed numerical approach, an experimental campaign of multi-instrumented tests is carried out.

First, L-angles specimens with initial defects of industrial interest are manufactured. Then, mechanical characterization through heavily instrumented mechanical tests is performed. The experimental setup definition is assessed by preliminary simulations and 3D virtual modelling techniques. Finally, finite element simulations of the experimental tests are simulated using Zébulon (finite element solver of the Z-set suite) by means of parametrical models available at ONERA. The comparison between numerical simulations and experimental observations show a good agreement and allows a better understanding of the characteristic damage mechanisms.

ABSTRACT

Numerous scientific and engineering systems are inherently high-dimensional and multi-modal. We present GM-VAE, an unsupervised generative learning method that provides dimension reduction and clustering of complex, high-dimensional scientific data. The GM-VAE model comprises a variational autoencoder with a Gaussian mixture model in the latent space. During training, the model learns an evolving low-dimensional latent manifold of the data, facilitating disentanglement into clusters and yielding optimal dimension reduction and clustering. We propose a training strategy that combines the expectation maximization (EM) algorithm and gradient descent for improved accuracy. Through experiments with large-scale datasets from turbulent combustion systems, representations learned by the GM-VAE model provide a physically interpretable dimension reduction, enabling a better understanding of the high-volume, high-dimensional data from various sources. In addition, the GM-VAE framework facilitates comparisons between different physical mechanisms, modeling fidelities, and experiments against simulations.

CONSTITUTIVE MODELING AND NUMERICAL SIMULATION OF BIGHORN SHEEP HORN UNDER IMPACT LOADING

Howie Fang[*1] and Qian Wang*[2]

[1]*Liberty University*
[2]*Manhattan College*

ABSTRACT

Bighorn sheep (Ovis canadensis) is known for its giant spiral horns that can sustain impact loading at a speed up to 5.5 m/s during ramming without causing severe damage or head concussion. The horn of the bighorn sheep is composed of a keratin-based biological material with a tubule-lamella structure. This special structure gives the horn material anisotropic hardening characteristics under impact loading. Investigating the mechanisms of energy dissipation of bighorn sheep horn can inspire the design and development of new materials with high capacity of energy dissipation and/or impact mitigation.

In this study, a transversely isotropic constitutive model with anisotropic hardening and strain-rate effects was developed for predicting the mechanical responses of the horn under impact loading. The characterization of material properties was conducted using test data from uniaxial compression tests of the horns under both quasi-static and dynamic loading. The constitutive model was later implemented into the commercial finite element code, LS-Dyna, as a user-defined material subroutine and was validated against test data. The user-defined constitutive model was subsequently used in finite element simulations of dynamic impacts on the bighorn sheep horn to study the mechanical responses of the horn material subjected to large impact loads without causing severe damage. The mechanism of energy absorption and dissipation, stress distributions, and propagation of displacement waves was also investigated.

ABSTRACT

A long-standing problem in the modeling of non-Newtonian hydrodynamics of polymeric flows is the availability of reliable and interpretable hydrodynamic models that faithfully encode the underlying micro-scale polymer dynamics. The main complication arises from the long polymer relaxation time, the complex molecular structure, and the heterogeneous interaction. We developed a deep learning-based non-Newtonian hydrodynamic model, DeePN^2, that enables us to systemically pass the micro-scale structural mechanics information to the macro-scale hydrodynamics for polymer suspensions. The model retains a multi-scaled nature with clear physical interpretation and strictly preserves the frame-indifference constraints. We show that DeePN^2 can faithfully capture the broadly overlooked viscoelastic differences arising from the specific molecular structural mechanics without human intervention.

ABSTRACT

Damage tracking and monitoring from digital twins and in situ measurements, through the DDDAS framework, has been one of the numerous research topics addressed by J.T. Oden. In his memory, the talk will present some recent developments on this critical issue, which aim to design smart and autonomous mechanical structures able to perform online control of their health and take anticipated actions during service. An innovative cross-disciplinary approach will thus be presented, which performs fast sequential data assimilation from hybrid twins. This approach couples several advanced numerical methods such as model reduction, adaptive modeling, or Kalman filtering, together with a specific cost function which brings robustness faced to highly nonlinear models, various uncertainty sources, and real-time computation constraints. Its capabilities will be shown on several practical engineering applications when inferring real data on-the-fly and performing online health monitoring on large scale structures.

HYDROMECHANICAL CONSTITUTIVE TENSOR AND INSTABILITY ANALYSIS OF PARTIALLY SATURATED GEOMATERIALS VIA A DISCRETE ELEMENT APPROACH

Mojtaba Farahnak[*1], Richard Wan[1], François Nicot[21] and Mehdi Pouragha[3]*

[1]*University of Calgary*
[2]*Université Savoie Mont-Blanc*
[3]*Carleton University*

ABSTRACT

The current research employs a micromechanical approach to characterize the hydromechanical behavior of partially saturated geomaterials within the pendular saturation regime. Using Discrete Element Method (DEM) modeling, this study focuses on elucidating the hydromechanical constitutive relationship and instability of densely packed granular materials under triphasic (solid, water, and air) conditions involving isolated liquid bridges.

Within the elastoplasticity framework, a new numerical scheme is proposed to derive a general hydromechanical constitutive tensor (tangent operator) considering the appropriate stress and strain conjugates. The incremental tangent operator is numerically reconstructed through a complete multi-directional DEM probing at various reference material states. The computed constitutive tensor can be integrated into a bifurcation analysis by evaluating its spectral characteristics.

The second-order work instability criterion is evaluated through DEM simulations by applying perturbations near the stress limit state of a deviatoric loading path. In a partially saturated state, defining the second-order work instability criterion is involved due to the interplay between stress and strain variables, influenced by coupled hydromechanical effects [1]. The multiphysics and multiphasic interactions arising from the capillary effect at the microscale result in intricate macroscale behaviors under triphasic conditions. In this regard, the external and internal second-order works are evaluated using DEM to capture the instability with respect to stress-strain variables in wet conditions. Consistent with the spectral analysis of the computed constitutive tensor, and the vanishing of its mechanical part, the second-order work results support the ‘effective’ role of contact stress in describing failure in wet granular materials.

Finally, a mesoscale analysis is presented to detect shear band localization and validate the well-known Rice criterion [2] within a micromechanical framework. The DEM sample is divided into mesoscale cells, each regarded as a representative elementary volume, allowing the correlation of mesoscale stress and strain through a constitutive law. The presented methodology, which incorporates the use of the tangent operator in the acoustic tensor, interestingly reveals that Rice’s localization criterion reasonably detects the orientation of shear bands when applied to the mechanical part of the hydromechanical tangent operator.

ABSTRACT

This presentation focuses on the construction of accurate and scalable data-driven reduced models of large-scale simulations with complex dynamics and sparse training data sets. In these settings, standard, single-domain approaches may be too inaccurate or may overfit and hence generalize poorly. Moreover, the memory and computing resources to train such models can be prohibitive in practice. To address these challenges, we introduce a domain decomposition formulation into the construction of a data-driven reduced model. In doing so, the basis used in the reduced model approximation become localized in space, which can increase the accuracy of the domain-decomposed approximation of the complex dynamics. The decomposition furthermore reduces the memory and computing requirements to process the large-scale training data set. We demonstrate the effectiveness and scalability of our approach in a large-scale three-dimensional unsteady rotating detonation rocket engine simulation scenario with over 75 million degrees of freedom and a sparse training data set. Our results show that compared to the single-domain approach, the domain-decomposed version reduces both the training and prediction errors for pressure by up to 13% and up to 5% for other key quantities, such as temperature and fuel and oxidizer mass fractions. Lastly, our approach decreases the memory requirements for processing by almost a factor of four, which in turn reduces the computing requirements as well.

A NONPARAMETRIC PROBABILISTIC FRAMEWORK FOR DIGITAL TWINNING

Charbel Farhat[*1] and Marie-Jo Azzi*[1]

[1]*Stanford University*

ABSTRACT

A digital twin (DT) usually refers to a digital replica of an asset that can be used, for example, to optimize in near real-time the operation and/or life cycle management of the asset; or more generally, to drive the Intelligent Enterprise by linking engineering and operations such as maintenance. The enabler often advocated for such a technology is the integration of artificial intelligence, machine learning, and software analytics with data, to create living digital simulation models capable of updating themselves as their physical counterparts evolve. Preliminary forms of such DTs are often presented as the result of a synergy between data analytics and the model-based prediction of a few, scalar, quantities of interest (QoIs). This lecture however will question whether a few QoIs can always be identified to represent the critical state of a newly designed then deployed physical platform. It will argue that whereas Digital is the relatively easy part of a DT that everyone talks about, Twin is the more difficult part that few are working on. Yet, the biggest concern that most stakeholders have is the risk of misrepresenting the physical asset they want to replicate using a DT. To this end, the lecture will present a more robust approach for realizing DTs based on adaptable, stochastic, low-order but high-fidelity computational models grounded in physics. The proposed approach features novel mathematical ideas for integrating the modeling and quantification of model-form uncertainty with probabilistic reasoning, projection-based model order reduction, and machine learning. It constructs stochastic, physics-based computational models that self-adapt using information extracted from sensor data; and operate in real time or near-real-time. Finally, the lecture will demonstrate the potential of the proposed approach for digital twinning using several realizations, including: a DT of a small-scale replica of an X-56 type aircraft for ground vibrations assessment; a DT of the front bumper of a 2013 Honda Accord EX-L for crash prediction and analysis; and a DT for the structural health monitoring of an aircraft wing.

HYPERELASTICS.JL: THE LARGEST COLLECTION OF HYPERELASTIC MODELS FOR SOFT MATERIAL MODELING AND SIMULATION

Carson Farmer[*1] and Hector Medina*[1]

[1]*Liberty University*

ABSTRACT

For soft matter simulations in various applications, an appropriate selection of the hyperelastic material model is necessary for accurate prediction and calibration. In most commercial codes, a limited number of hyperelastic models have been implemented, which limits applications in various fields such as biomimicry, medical, etc. We have developed and deployed Hyperelastics.jl, a Julia language-based library that contains the largest set of implemented hyperelastic models to date. Within Hyperelastics.jl, over 70 compressible and incompressible models have been implemented for automatic differentiation. The use of automatic differentiation within the package limits the barrier to entry for developing new material models by requiring only a form for the strain energy density function. The package provides the most common analytical methods and extensions of models for compressible materials. Further, the package provides some data-driven methods for prediction. By using the Julia language, the models are readily compatible with FEA methods from Gridap.jl and Ferrite.jl. Further, the package includes extensions for material model calibration from multiple uniaxial and biaxial tests with customizable loss functions. The simplicity of the package aims to decrease the barrier for implementing and testing less common hyperelastic models for soft matter simulations. Future works will aim at expanding to the modeling of other non-linear—such as viscoelastic, other mechanical, electro-mechanical, and opto-mechanical—mechanisms with the goal of developing a more complete soft material modeling suite.

ABSTRACT

Extraordinary points (EPs) are required to represent manifold surfaces with arbitrary topological genus. G-splines are a generalization of B-splines that deal with extraordinary points by imposing G1 constraints across their spoke edges. As explained in [1], G-splines combine the following distinctive characteristics: (1) Only vertex-based control points are used and they behave as geometric shape handles, (2) any control point of the control net can potentially be an EP, (3) global C1 continuity in physical space is obtained without introducing singularities, (4) faces around EPs are not split into multiple elements, i.e., meshes with uniform element sizes are obtained, and (5) good surface quality is attained. After comparing the spectral accuracy when solving eigenvalue problems, the accuracy in L2 and H1 norms when solving linear elliptic problems, and the surface quality, we conclude that G-splines are more suitable for IGA than EP constructions based on the D-patch framework [2, 3].

INTEGRATING PHYSICS-INFORMED NEURAL NETWORKS AND COMPUTATIONAL FLUID DYNAMICS TO OPTIMIZE BAKING OVEN PERFORMANCE

Ehsan Fattahi[1] and Thomas Becker*[1]

[1]*Technical University of Munich*

ABSTRACT

This study introduces an innovative method to enhance the precision of simulations for baking ovens by merging traditional Computational Fluid Dynamics (CFD) techniques with Physics-Informed Neural Networks (PINNs). Our effort is concentrated on creating a detailed representation of airflow and heat distribution within a commercial baking oven by integrating fan modeling techniques into the turbulent, unsteady simulation of the baking chamber. This integration effectively captures the fan's influence on the oven's airflow patterns and temperature distribution.

Utilizing Moving Reference Frame (MRF) data provides a deeper insight into the fan's effect on the oven's internal environment, leading to enhanced simulation outcomes. However, this method in unsteady simulation introduces a limitation due to the fan geometry being fixed in the global reference frame, resulting in non-physical low-velocity regions in the wake of the blades. Although the Sliding Mesh (SM) approach offers greater accuracy by utilizing an unsteady solver, it demands higher computational resources. By training the PINNs with fan data through MRF and SM, we simulate the fan with its actual geometry at different rotation speeds quickly and accurately. We achieved airflow and temperature profile with accuracy comparable to conventional CFD methods but with reduced computational costs across various operating conditions. Incorporating PINNs into CFD simulations that are used for the whole oven simulation not only boosts efficiency and accuracy but also addresses the limitations of traditional CFD models, particularly in the high computational cost of capturing transient behaviors and complex flow phenomena. This signifies that our PINN-CFD methodology holds significant promise for designing and optimizing ovens, potentially elevating their functionality. Furthermore, it paves the way for employing machine learning techniques in thermal and fluid flow engineering, an invaluable asset in situations where computational resources are scarce or swift simulations are essential without sacrificing precision.

TIME-STEPPING STRATEGIES FOR NON-LINEAR MULTI-SCALE FLUID-STRUCTURE DYNAMICS WITH PARTITIONED COUPLING

Vincent Faucher[*1] and Maria Adela Puscas*[1]

[1]*CEA*

ABSTRACT

The present contribution is dedicated to providing some review, insights and recent advances in the field of time algorithms for fluid-structure dynamics with non-linear structural behaviour solved within a partitioned coupling between specific software. The structural non-linearities can be related to internal behavior, contact/impact and/or rupture and fragmentation, implying the resort to explicit time integration for the sake of robustness of the structure solver. Such a choice naturally introduces time-multiscale problematics in the coupled problem, since fast waves setting the critical time step in the structure are likely to generate a significantly more restrictive stability constraint than for the fluid, which on the other hand is likely to concentrate most of the computational effort.

Several configurations shall be considered to provide significant results for the community. First, the most classical situation of compressible transients with explicit time integration for both fluid and structure will set the bases of the multi-scale time stepping with various sound velocity for fluid and structure. Second, the compressible fluid solver will be replaced by an incompressible CFD solver, for a different range of transients in the vibratory dynamics and flow induced vibrations regime. Here, the question of Arbitrary Lagrangian Eulerian approaches for the fluid shall be particularly considered, with specific time scale possibly introduced by the management of the arbitrary fluid grid motion itself. Finally, the last configuration will add contact and impacts to the fluid-structure problem, introducing the complementary need for adaptive subcycling strategies following the thorough monitoring of impact history, to provide both computational efficiency and accuracy in terms of fluid response to severe discontinuities in the structural forces.

Examples will be provided in the field of safety and performance for nuclear pressurized water reactors. Some past references are provided for illustrative purposes.

CRITICAL PLANES ANALYSIS OF THE IMPACT OF POROSITIES ON THE FATIGUE OF METAL SOLIDS

Françoise Fauvin[*1], Eric Feulvarch[1] and Gregory Debono[1]*

[1]*Université de Lyon, Ecole Centrale de Lyon, Tribology and System Dynamics Laboratory*

ABSTRACT

In this work, we take interest to the impact of defects present in metal solids manufactured by material fusion or by additive manufacturing on their fatigue life during cycling loading. Indeed, we observe a more or less strong local plasticity around the defects even if the stresses remain below the elastic limit, which can strongly impact the fatigue life of such solids. In the case of a part obtained by steel casting, it is the retassures that make the part most vulnerable. In the case of solids obtained by additive manufacturing, the most damaging defects are surface roughness and porosities linked to a lack of fusion. In order to estimate the fatigue life of such solids, it is necessary to observe the states of stress and deformation around the defects during a cycle. As stress levels can be relatively high locally, critical plane type criteria are relevant for estimating the fatigue life of such solids. In order to carry out a fatigue analysis of a part obtained by steel casting or by additive manufacturing, we propose to model it by finite elements, with a refinement of the elements around the porosities, then to calculate the local stress and deformation states, and finally to implement a critical plan type criterion, like the Fatemi-Socie criterion. The critical planes are the planes on which the maximal shear deformation amplitudes occur. The local stress and strain states can be highly multi-axial. So the determination of the critical planes can be very computationally and storage consuming. In the present work, an analysis in the space of deviators of the deformation tensor makes possible determination of such planes in each of the numerous nodes of the mesh[1]. These three steps of calculation, correlated with experimental tests, makes it possible to envisage obtaining fatigue life laws for numerous metallic materials presenting defects.

EMERGING ANISOTROPY AND TETHERING WITH MEMORY EFFECTS IN FIBROUS MATERIALS

Antonino Favata[*1], Andrea Rodella[1] and Stefano Vidoli[1]*

[1]Sapienza University of Rome

ABSTRACT

Fibrous materials may undergo an internal reorganization, which turns out in the emergence of preferential directions. This is a peculiar behavior of many biological tissues, which drive reorientation by external stimuli at chemo-mechanical levels. In particular, it is detected that contractile cells can reorganize fibrous extracellular matrices and form dense tracts of aligned fibers (tethers), that guide the development of tubular tissue structures and may provide paths for the invasion of cancer cells. Tether formation is caused by buckling instability of network fibres under cell-induced compression. We present a simple phase-fiel model that captures the essential aspects of these phenomena. The model qualitatively describes: (i) the emergence, induced by local compressive strain, of anisotropy, where fibrous materials exhibit directional preferences; (ii) the occurrence of micro-buckling, which leaves a lasting plastic deformation in the material; and (iii) the formation of localized field patterns, which contribute to the overall behavior of the material.

HYPERBOLIC MODELING OF GRADIENT DAMAGE AND ONE-DIMENSIONAL FINITE VOLUME SIMULATIONS

Nicolas Favrie[*1], Adrien Renaud[1] and Djimedo Kondo[2]*

[1]*Aix Marseille Université*
[2]*Sorbone Université*

ABSTRACT

This study [1] provides a new formulation of gradient damage model which allows an efficient explicit numerical solution of dynamics problems. The proposed methodology is based on an "extended Lagrangian approach" developed in [2] for the nondissipative and dispersive shallow water equation. By using this strategy, the global minimization problem commonly derived for gradient damage models is recast as a purely local hyperbolic one with source terms that can be easily solved using finite volumes. The numerical solution of the governing system is then based on a fractional-step method consisting of a classical Godunov-type scheme and an implicit Ordinary Differential Equation solver for the local source terms. Numerical results are presented on the one-dimensional multi-fragmentation and spalling tests for illustration purpose.

ABSTRACT

Turbidity currents are major agents of sediment transport in land and aquatic environments. They are important for their potential environmental hazards and volume share on the deep sea's clastic accumulations [1]. Turbidity flows are formed when the density difference between sediments and fluids generates a driving force that induces fluid motion. Numerical simulations considering the discretization of the governing Partial Differential Equations (PDEs) usually offer detailed insights with the cost of being computationally expensive, given the complex nature of the physics of the problem. This study focuses on developing a modular workflow that creates surrogate models for turbidity currents to replace costly simulations with more efficient data-driven alternatives. The workflow orchestrates steps such as data ingestion, data normalization, linear and nonlinear dimensionality reduction, data splitting, and the Scientific Machine Learning (SciML) model for training and inference and data post-processing. Having a computational workflow that is able to generate multiple surrogate model configurations allows faster experimentation and model selection for better predictions. Here, we employ stabilized finite elements to generate the training data for surrogate modeling. Two distinct applications for surrogate models are explored: temporal predictions for estimating future flow and extrapolation of simulated parameters for further exploration. We test the behavior of different SciML techniques to address the two aspects of surrogate modeling mentioned above. The list includes Dynamic Mode Decomposition [2], Gaussian Processes, and Neural Networks [3]. The study's applications are tested using the lock-exchange configurations, incorporating various physical aspects such as deposition and erosion, allowing a more comprehensive evaluation of the surrogate models' performance under diverse conditions. Preliminary results showcase the effectiveness of the surrogate models in accurately predicting turbidity currents. The temporal prediction approach demonstrates its potential for forecasting future flow conditions, while the parameter extrapolation approach extends the applicability of the models beyond the simulated scenarios.

QUASI-DYNAMIC PHASE-FIELD MODELING OF IN-PLANE DEFORMATION AND GROWTH OF GEOLOGIC FAULTS

Fan Fei[*1], Md Shumon Mia[2], Ahmed E. Elbanna[2] and Jinhyun Choo[3]*

[1]Lawrence Livermore National Laboratory
[2]University of Illinois Urbana-Champaign
[3]Korea Advanced Institute of Science & Technology

ABSTRACT

Earthquakes are typically triggered by the dynamic deformation and growth of geologic faults which are discontinuities or narrow zones within the Earth's crust. During and after the earthquake process, a fault system commonly exhibits a variety of geometric features (e.g., fault kinking and branching) due to structural and material complexities. These intricate geometric features, however, pose a substantial challenge to existing fault rupture models that treat the fault as a lower-dimensional manifold in a continuous domain. To overcome this challenge, a phase-field model has recently been developed to simulate quasi-dynamic sliding and growth of rate- and state-dependent frictional faults [1]. Nevertheless, this preliminary work restricted its focus to a 2D anti-plane condition, while the fault system under an in-plane or more general 3D condition manifests more realistic and complex structural properties (e.g. en enchelon faults). In this work, we extend the previous anti-plane model to an in-plane version by incorporating additional kinematics and pressure-dependent shear strength. Numerical simulation of a benchmark example verifies that the extended phase-field model can accurately capture the quasi-dynamic, rate- and state-dependent frictional behavior in an in-plane setting. Additional simulations involving fault nucleation and propagation under in-plane boundary conditions further demonstrate the capability of the phase-field model to handle arbitrary geometric features emanating from structural complexities and material heterogeneities. This phase-field model enables more efficient and realistic modeling of fault systems, with potential to improve the understanding of seismic source mechanics and consequently advance the next-generation seismic hazard models.

LARGE SCALE DIRECT NUMERICAL SIMULATIONS OF FORCED CONVECTIVE BOILING

Linlin Fei[1], Alessandro Gabbana*[2], Federico Toschi[2] and Jan Carmeliet[1]*

[1]*ETH Zurich*
[2]*Eindhoven University of Technology*

ABSTRACT

Advancing our understanding of forced boiling convection is essential for optimizing heat transfer and energy efficiency in various industrial processes. While general insights into boiling phenomena exist for pool boiling systems, where the vapor bubbles and heated liquid are influenced solely by gravity, forced boiling has received much less attention, with few recent preliminary works reporting results from 2D simulations [1,2].

In this work, we present results of fully 3D numerical simulations of forced boiling convection. We leverage on a highly optimized cascaded lattice Boltzmann method (LBM) code [3] based on the Multi-GPU accelerated computations by the hybrid OpenACC and MPI approach, allowing for an extensive parameter scan to analyse the impact of external forcing on the boiling curve, depicting the relationship between heat flux and wall superheat. We show that within an optimized parameter range, the window of nucleate boiling for highly efficient heat transfer is extended while mitigating the risk of transition to film boiling.

ADAPTIVE APPROXIMATION OF STOCHASTIC PROCESSES

Michael Feischl[*1]

[1]*TU Wien*

ABSTRACT

There are many stochastic processes which are known to be arbitrarily hard to approximate when using uniform timesteps.
This can even happen if the coefficients (drift and diffusion) of the governing stochastic differential equation are smooth. Practically more relevant is for
example the Cox-Ingersoll-Ross process, which has a square root singularity in the diffusion term. It is known that uniform approximations of the process converge
with arbitrarily small algebraic rate. We demonstrate numerically, that adaptive mesh refinement in time can overcome this barrier and deliver the expected convergence rates
of 1/2. This is particularily interesting since multi-level approximations require exactly this rate to offer a significant performance gain.

ERROR ESTIMATION FOR REDUCED-ORDER MODELING OF PARAMETRIC NONLINEAR DYNAMICAL SYSTEMS

Lihong Feng[*1], Sridhar Chellappa[1] and Peter Benner[12]*

[1]*Max Planck Institute for Dynamics of Complex Technical Systems*
[2]*Otto-von-Guericke-Universität Magdeburg*

ABSTRACT

Model order reduction (MOR) for parametric dynamical systems has been an active research topic for many years. We present two new contributions to this topic: 1) accurate error estimation for reduced-order models (ROMs) solved with any black-box time-integration solver. 2) Inf-sup-constant-free output error estimation for ROMs of parametric dynamical systems. Accurate error estimation plays an essential role in constructing ROMs with reliable accuracy. For most of the existing a posteriori error estimation approaches, e.g., the residual-based error estimators proposed for the reduced basis method, details of the time integration scheme must be accessible. This poses a challenge when libraries with automatic ordinary differential equation integrators are used to solve the original dynamical systems and/or the corresponding ROMs. To address this issue, we present a data-enhanced approach [1] for a posteriori error estimation. This new approach enables residual-based error estimators to be independent of any time integration method. To this end, we introduce a data-driven closure term to a user-defined time-integration scheme. The closure-term aided error estimator can accurately estimate the error of the target ROM that can then be solved by any time integration solver. We use radial-basis function interpolation to accurately learn the closure term, using only a modest amount of training data. The new error estimator is incorporated within a greedy process to obtain parametric reduced-order models. Existing techniques of error estimation for time-evolution systems entail computing the parameter-dependent smallest singular values of a large matrix with the original system dimension. This is not only time-consuming for large-scale systems, but also makes the error estimation rough for problems with smallest singular values being close to zero. The smallest singular values are the so-called inf-sup constants. We propose an inf-sup-constant-free output error estimation [2] for time-evolution systems. Numerical tests on several engineering problems justify our theoretical analysis, showing that the proposed error estimation techniques outperform other existing error estimators.

A ROBUST TOPOLOGY OPTIMIZATION FRAMEWORK UNDER MULTIPLE UNCERTAINTIES AND LARGE DEFORMATIONS

Nan Feng[*1] and Kapil Khandelwal*[2]

[1]*University of Michigan - Ann Arbor*
[2]*University of Notre Dame*

ABSTRACT

In real-world applications, uncertainties in load, material, and geometric properties are present that should be addressed in a design process. To this end, a computational topology optimization framework is proposed for designing robust structures that are insensitive to the target stochastic variations in load, material, and geometric properties. In the proposed framework, various uncertain sources are modeled by random vectors or random fields. With good computational efficiency and accuracy, a stochastic perturbation approach is adopted within a stochastic finite-element-based method to compute statistical moments of structural end compliance under large deformations. The excessive mesh distortion issue under large deformations is addressed by leveraging an adaptive linear energy interpolation scheme based on modifications in free energy. In addition, the design sensitivities are computed by utilizing a consistent analytical adjoint analysis approach that is used in a gradient-based optimization formulation. Verification is performed both for the implementation of the uncertainty quantification and sensitivity analysis methods. Numerical results show that the response of robust designs is less sensitive to the variations of target uncertainties compared to their deterministic counterparts. Moreover, even without enforcing stability constraints, the robust optimization formulation may help to achieve a stable design whereas the deterministic design is unstable.

A GAUSSIAN PROCESS-DRIVEN WORST REALISTIC IMPERFECTION METHOD FOR BUCKLING ANALYSIS OF CYLINDRICAL SHELLS

Shaojun Feng[*1], Peng Hao[1] and Bo Wang[1]*

[1]*Dalian University of Technology*

ABSTRACT

Thin shells are very efficient structures that can support very high buckling loads and hence their buckling and post-buckling behaviors have presented scientific and engineering challenges for decades. Extensive theoretical studies connect initial post-buckling behavior with imperfection sensitivity. It is necessary to accurately analyze the capability before optimizing the structure. However, the significant discrepancy in loading capability between the theoretical and experimental results severely limits the design of the structure.

We propose a Gaussian process-driven worst imperfection method to generate simulated geometric imperfections and find the lower limit of buckling capability. First, we utilize the nested stochastic Kriging to estimate the global trend and envelopes of the geometric imperfections. Second, the expansion optimal linear estimation and direct weighting construction method are used to expand limited data, which allows the simulated geometric imperfections to have the same characteristics as the initial data. Third, two magnitude-based constraints are provided, which can make the simulated geometric imperfections more consistent with the realistic data and can represent more design space. Finally, for the cylindrical shells, the data pre-processing method is further provided in this paper. Two numerical examples with assumed geometric imperfections are used to validate the proposed method, and the minimum buckling capacity of a cylindrical shell with 8 realistic geometric imperfections data is estimated. The results show that the proposed method can achieve the best performance in terms of accuracy, efficiency, and robustness.

A DATA-DRIVEN OPTIMIZATION FRAMEWORK FOR A HIGH-ORDER HYBRID SCHEME TOWARDS IMPLICIT LARGE EDDY SIMULATIONS OF COMPRESSIBLE FLOW

*Yiqi Feng**[1], Zihao Wang[1], Felix S. Schranner[1], Josef Winter[1] and Nikolaus A. Adams[1]*

[1]*Technical University of Munich*

ABSTRACT

Simulating compressible turbulent flows entails dealing with a broad range of genuine (e.g. shocks, high gradients) as well as non-genuine (e.g. turbulence) subgrid-scales and their intricate interactions. The challenge lies in developing a numerical scheme that physically consistently recovers or models such widely varying flow features, and ensures numerical stability, computational efficiency as well as generalization robustness, simultaneously. A hybrid scheme has been demonstrated to be an effective method towards simulating compressible flows with turbulent structures [1,2]. The scheme employs sensors to adaptively choose from different high-order numerical schemes, each fit to optimally address specific flow characteristics. However, the existing method of parameter fitting relies on expert insight, spectral analysis, or partial numerical experiments, which may not fully account for the complex nonlinear interactions among the whole scales during simulation. In this study, we present an innovative data-driven multi-objective optimization method for designing a hybrid scheme suited for implicit large eddy simulation of complex compressible flows. The scheme is optimized to achieve a balance between three objectives: limited numerical dispersion, realistic scale dynamics and kinetic energy conservation. We employ a multi-objective Bayesian optimization framework with an expected hypervolume improvement acquisition function to perform the optimization as proposed in [3]. The results demonstrate that the scheme converges to an optimal solution with only a very limited number of evaluations. The proposed hybrid scheme is validated on basis of flow configurations involving a wide range of characteristic single- and two-phase flow characteristics. The hybrid scheme is benchmarked to established higher order non-linear schemes, clearly indicating the superior performance of the high-order hybrid scheme for LES of compressible flows.

TOWARDS HIERARCHICAL VERIFICATION BY UTILIZING SYMMETRIES

Jim Ferguson[*1]*

[1]*Los Alamos National Laboratory*

ABSTRACT

Verification & Validation represents a portion of testing and strengthening the credibility of codes and establishing a sense of the numerical uncertainty of simulations. Verification focuses on mathematical accuracy, and typically leaves comparison with experiments to validation. Extending verification results towards simulations that analysts and experimentalists care about requires losing analytical rigor but gaining relevance. In this presentation we discuss anchoring complex but relevant simulations to simpler ones whose accuracy is easier to test. To do this we rely on the tight coupling between known solutions and their related symmetries. As we move away from analytic solutions, using the solution's symmetry as a guide, we move toward complex simulations of interest to analysts. Simultaneously, this should help the analyst see that if a code doesn't perform well on certain simpler tests then simulation results of interest should be analyzed cautiously.

Analysing complicated simulations often pushes analysts outside the realm where their intuition has been developed and may be reliable. This requires significant trust in a code's accuracy across many physics disciplines. Understanding the numerical space over which rigorous analytic solutions for testing codes exists is important for supporting trust-worthy assessments. Analytic solutions in any dimension or geometry rely on symmetries. Symmetries over manifolds are the subject of Lie groups. Numerical methods involving Lie group have recently been developed, called Lie Group Integrators, and promise to improve numerical methods along symmetries of a numerical manifold.

At a more fundamental level to code verification, little attention has been given to understanding where test solutions come from, and what different tests should tell code developers and code users. Different tests typically evolve along different orbits of a symmetry. Comparing code results against different analytic solutions thus says something about a code's performance along specifics orbits. Understanding the space of orbits and how a code performs near each should be helpful to understanding how a code performs away from those orbits. Of course, analyst's complicated simulations are not bound to a specific orbit, but it is hoped that understanding the numerical uncertainty of a code in the space between orbits will better help analysts understand the numerical uncertainty in their results.

NUMERICAL STUDY OF THE BUBBLE RISING IN ELASTOVISCOPLASTIC FLUIDS USING THE GEOMETRIC VOLUME OF FLUID ALGORITHM

Ahmad Fakhari[1] *and Célio Fernandes**[2]

[1]*Airflow Sciences Corporation*
[2]*University of Porto*

ABSTRACT

This investigation delves into the dynamics of air bubble motion within liquids, a phenomenon of paramount significance in diverse domains such as heat transfer and material quality. Our endeavor entails the formulation of an innovative interface capturing technique tailored for simulating multiphase viscoelastic fluid flows. The algorithm we propose leverages a geometric volume of fluid methodology known as isoAdvector, steering away from conventional reliance on volume fraction gradients by incorporating a reconstructed distance function (RDF) to precisely ascertain interface curvature.

To fortify the precision and robustness of our approach, a piecewise linear interface construction (PLIC) scheme is integrated with RDF-based interface reconstruction. The culmination of these efforts is the development of the Multiphase Viscoelastic PLIC-RDF isoAdvector (MVP-RIA) algorithm. Numerical validation involved simulations of the buoyancy-driven rise of a bubble in an elastoviscoplastic liquid characterized by the Saramito-Herschel-Bulkley constitutive equation.

Our observations unveil a nuanced interplay of forces within very small air bubbles in elastoviscoplastic fluid, where the dominance of elasticity and capillary forces constrains bubble deformation. As the bubble volume expands, lateral stretching assumes a more pronounced role, culminating in the emergence of distinctive bifurcated tails. Ultimately, the bubbles adopt highly elongated shapes with sharper tails.

MECHANOBIOLOGY OF BONE ADAPTATION IN BAREFOOT RUNNING

Julie Kim[1], Thor Besier[1], Piaras Kelly[1] and Justin Fernandez[1]*

[1]University of Auckland

ABSTRACT

INTRODUCTION
Computational bone remodelling has been explored in many human activities, yet there are few examples of its application in the foot, which is a key joint that interacts the most with our environment primarily through gait. In this study we present the extension of a continuum level bone remodelling algorithm to include the ‘Mechanostat’, and its importance on realistic bone adaptation and numerical convergence. We present the model in the application of foot bone adaptation in barefoot runners. Bone density and trabecular architecture formation are contrasted with CT evidence to evaluate the model.

METHODS
A finite element foot model was developed from MRI scans. The model was segmented in the software Mimics, meshed in Hypermesh, and solved using Abaqus. Plantar fascia was represented by linearly elastic connectors whose stiffness was 200N/mm. The bones were modelled as linearly elastic isotropic materials with Young’s Modulus of 7300MPa and Poisson’s Ratio of 0.3, and the lumped soft tissue surrounding the bone was a linear elastic model with Young’s modulus of 0.15MPa and Poisson’s ratio of 0.45 [1]. OpenSIM was used to compute the Achilles tendon force. Plantar pressure measured during gait and Achilles tendon force were applied to load the foot. A continuum damage mechanics model [2] with an ability to evolve the setpoint value following the cellular accommodation theory [3] was employed to predict the osteogenic responses. An adult model was customised to temporal hopping data and then used to predict heel bone adaptation of a change in running strike pattern from classical rearfoot to forefoot running. The Abaqus model predicted the bone density and structural changes in the heel bone (calcaneus).

RESULTS AND DISCUSSION
The model predicted the formation of a cortical bone layer like that observed in adult CT and predicted future temporal bone density consistent with measured DEXA scans. The model predicted higher heel bone density in forefoot strike runners despite the heel not actually touching the ground during running. This is likely due to higher Achilles tendon force and is consistent with measurements in the running literature. The ‘Mechanostat’ adaptation improved convergence of the model and ensured that the bone reached a saturation point and did not continue to adapt unconstrained.

MATRIX ANALYSIS OF MOLECULAR STRUCTURES: FROM LINEAR ANALYSIS TO BUCKLING

Andrés Fernández San Miguel[1], Iván Couceiro Aguiar*[1], Luis Ramírez[1] and Fermín Navarrina Martínez[1]*

[1]*Universidade of A Coruña*

ABSTRACT

One of the great successes in the field of engineering, whether aeronautical, civil, or mechanical, was the development of the Finite Element Method, thanks to which problems of solid mechanics, fluids and even fluid-structure interaction can be solved with great precision. In its origins, the method was applied mainly to macroscale problems, while at the atomic scale the use of Molecular Dynamics has been the more usual way.

As an alternative to the Molecular Dynamics method, we propose a new formulation that allows obtaining the stiffness matrices directly from the force-field, without resorting to simplifications other than those used in its parameterization. The formulation allows both first order analysis, linear instability, and geometric nonlinear analysis.

In the case of first-order analysis, we applied this formulation to the vibrational analysis of different simple molecules [1,2], also including the parameterization of its force constants [2]. In turn, it has been applied to the study of the mechanical behavior of protein structures, such as coronavirus spikes or viral capsids.

The formulation has also allowed the study of linear buckling of structures such as carbon nanotubes and graphene sheets, allowing the development of equivalent continuous models of increasing interest in materials science [3]. Moreover, the inclusion of geometrical nonlinearities has allowed the study of nonlinear phenomena such as buckling in nanotubes both as monolayer and multilayer or in fullerenes.

TOPOLOGY OPTIMIZATION OF TRUSSES AND FRAMES ACCOUNTING FOR STABILITY AND INITIAL POST-BUCKLING RESPONSE

Federico Ferrari[1] and Ole Sigmund*[1]

[1]*Technical University of Denmark*

ABSTRACT

Sizing and topology optimization (TO) with maximum stiffness or stress reduction objectives often leads to designs that are highly sensitive to imperfections, and prone to geometric instabilities. Therefore, recent works have focused on introducing stability constraints, or on optimizing some nonlinear response functions, such as complementary work, end compliance, etc., achieving important results both in terms of computational efficiency and design novelty [1,2].

However, stability constraints only increase the initial buckling strength of the design, without giving any control neither on its imperfection sensitivity, nor on its actual buckling mechanism. Also, the optimization of non-linear response functions is almost always limited to the pre-buckling regime. To control the buckling mechanism, the post-buckling behavior must be investigated, and this requires computationally expensive path-following procedures which are often complicated by the interaction of nearly simultaneous buckling modes, frequently occurring for optimized designs.

An appealing alternative is offered by the asymptotic post-buckling (APB) theory [3], which provides an accurate approximation of the nonlinear response, close to a buckling point. Requiring one eigenvalue buckling analysis, and a few linear analyses, APB is a cheap computational tool for post-buckling simulation but is seldomly used for optimal design [4], and essentially missing in TO.
In this talk we apply APB theory to the optimization of the initial post-buckling behavior of trusses and frames. We consider compliance minimization problems, with constraints on the initial post-buckling coefficients, to ensure the systems' post-buckling stability. We also show how the APB theory can be used to generate an approximation of some non-linear response functions in the post-buckling regime. Basing the discussion on these simple structural models, we will review the points of cautions one needs to consider in the finite element implementation, discussing the suitability of the approach to large-scale problems, and more advanced continuum modelling.

FAST PREDICTION OF CLUSTER INTERACTION TENSORS THROUGH DATA-DRIVEN SURROGATE MODELING

Bernardo P. Ferreira[*1], Max S. Kukkola[2] and Miguel Bessa[1]*

[1]*Brown University*
[2]*Delft University of Technology*

ABSTRACT

One of the pressing challenges in computational solid mechanics is performing fast mechanical simulations of the multiple length scales of materials. Accomplishing this goal is essential to perform feasible multi-scale coupled analyses of materials and generate large material (synthetic) datasets required to train data-driven surrogate models [1].

In this context, Liu and coworkers [2] proposed the Self-consistent Clustering Analysis (SCA), a reduced-order method that achieves a striking balance between accuracy and efficiency. The core idea of the model reduction lies on a clustering-based domain decomposition performed in a preliminary offline-stage (learning). Similar to mesh-based simulations, the solution precision and computational cost depend on the number of clusters. As expected, the computation cost of the so-called Cluster Interaction Tensors (CITs) increases significantly with the number of clusters, thus raising a bottleneck in the learning process. In addition, such tensors are also recomputed during the online-stage (prediction) in the recently proposed extension called Adaptive Self-consistent Clustering Analysis (ASCA) [3], which further stresses the need of speeding up their computation.

In this contribution, we take advantage of a data-driven surrogate modeling approach to predict CITs directly from the clusters support functions. Deemed as key aspects, the efficient generation of a large representative training dataset and the choice of a suitable model architecture are discussed. Several comparisons between the predictions and the complete computation of the CITs demonstrate the performance of the data-driven model in terms of accuracy and computational time. Finally, the efficacy of the new approach is assessed in the multi-scale analysis of heterogeneous materials.

HOMOGENIZATION STRATEGY FOR THE PHASE-FIELD MODEL FOR PRESSURIZED FRACTURES

Eduarda Ferreira[*1], Hugo Leão[1], Roque Pitangueira[1] and Lapo Gori[1]*

[1]Federal University of Minas Gerais

ABSTRACT

Phase field model (PFM) for fracture is a relatively recent study and it has already been proven to be a propitious approach for modeling complex fractures. The PFM, based on a variational formulation, is able to automatically identifying multiple crack emerging and propagation, as well as representing bifurcation, nucleation and branching phenomena. For these reasons, the classic formulation has been extended to represent a variety of multiphysics problems, including hydraulic fracturing. Most hydraulic fracturing applications deal with materials that are heterogeneous at a certain scale. Adding the heterogeneous nature of the materials with the great difference of scales involved in the global problem make the study of hydraulic fracture from a multiscale approach an interesting topic to be explored. However, there are few proposals in the literature for applications of the PFM for fracture in the context of a multiscale analysis, especially considering this model at more than one scale of observation, which indicates a gap in knowledge. In this respect, the purpose of this work is to extend a proposal found in the literature for the computational homogenization of the phase-field [1] to problems involving pressurized fractures [2]. Micro and mesoscale will be considered. The microscale is designed to represent the composite material as a heterogeneous medium formed by components with different mechanical properties. The mesoscale is treated as an equivalent medium with homogenized properties. Both scales are modeled by a PFM that considers the pressure load on the fracture surface. Based on this proposal, it is be possible to verify the impact of the transition of the field variables and dual internal variables of the PFM from one scale to another and follow the evolution of the fracture process on two scales. All computational implementation and numerical simulations will be developed in the open-source software INSANE.

TOPOLOGY OPTIMIZATION FOR FIBER ORIENTATION IN FRACTURED CONCRETE

Andre Luis Ferreira da Silva[*1], Luís A. G. Bitencourt Jr.[1] and Emilio Carlos Nelli Silva[1]*

[1]Universidade de São Paulo

ABSTRACT

Concrete is widely used in civil engineering due to its compression strength. However, it is prone to cracking under tension, necessitating reinforcements to mitigate this vulnerability. The addition of fibers in the concrete has been used to improve the concrete resistance under tension solicitation after cracking occurrence. However, the orientation of these fibers plays a crucial role in the structure's mechanical behavior, making it possible to reduce the amount of fibers used to reinforce the concrete. The optimized fiber orientations are addressed in this work using the Topology Optimization.

The concrete behavior is simulated using a Continuum Damage Mechanics Theory (CDMT)-based model with a rate-independent formulation, distinguishing between tensile and compressive responses.

The methodology integrates an implicit-explicit integration scheme to improve computational efficiency. By focusing on the fracture mechanics model, we seek to minimize structure compliance, indirectly extending the lifespan of the reinforced concrete. We present the methodology, results, and conclusions, highlighting contributions to the field of concrete reinforced with fibers.

COUPLED TWIN CONICAL FUNNELS OR CONICAL HOSES: AN INTERNAL PROCESS OF DYNAMIC FLOW DISTRIBUTION

Ricardo Tomas Ferreyra[*1]*

[1]*Universidad Nacional de Córdoba*

ABSTRACT

The analytical derivation of internal dynamic hoses of conical type for conical flow takes place from the Laws of Continuity, Momentum and Energy. This analytical derivation is the objective of this article. From the physical laws of fluid mechanics, some evidence is obtained for two non-classical analytical boundary conditions necessary for this phenomenon. After these two new boundary conditions and since supersonic and hypersonic solid cones are related to theoretical and industrial interest, new analytical regions are established and characterized in the graph of cone angle, shock angle and Mach number of free flow.

EVOLVING DYNAMICS FOR THE ANALYSIS OF COMPLEX CRATERS

Ricardo Tomas Ferreyra[*1] and Michael Shpekin*[2]

[1]*Universidad Nacional de Córdoba*
[2]*Kazan Federal University*

ABSTRACT

In this work, dynamics evolution models are developed for the analysis and interpretation of processes, properties and temporal distribution of the matter involved in the formation of complex craters. The laws of fluid dynamics are applied as a tool for the development of the analytical model that allows subsequent analysis. The high energy process that is analyzed and described is explained through the evolution of dynamic balances associated with new energy balances in stages and related to a sequence of configurations that constitute patterns and geometries that evolve together with the dynamics of the formation of a complex crater. Then, the described dynamics involves considering stages, times, shapes, speeds, energies, impacts, frictions, rebounds and mass losses to develop the new model. As a consequence, at least three emergent physical phenomena are identified: a traveling piston (matter in motion in the process of melting), concentric rings and a raised central formation. Physical laws and phenomena are combined to obtain an energy distribution. Finally, a dynamic and thermodynamic balance is carried out in perspective and applied to known craters that are representative of the formation of complex craters and a good correlation is verified with the quantitative results predicted by the developed model

PREGNANCY BEFORE THE ONSET OF LABOR: A HOLISTIC BIOMECHANICAL PERSPECTIVE

Daniel Fidalgo[*12], Renato Jorge[21], Marco Parente[21], Erin Louwagie[3], Ewelina Malanowska[4], Kristin Myers[3] and Dulce Oliveira[1]*

ABSTRACT

The success of pregnancy and vaginal delivery is highly dependent on the complex interaction between the uterine body, cervix, and fetal membrane [1]. Usually, this interaction is synchronized, following a specific sequence in normal vaginal deliveries: (1) cervical ripening, (2) decidual activation/rupture of fetal membrane, and (3) uterine contractions [2]. Serious complications during vaginal delivery may occur when this sequence is not followed, such as difficult labor progression [2]. Understanding the phenomena occurring during the late stages of pregnancy is essential to offer clinical guidance and solve these problems.

This work analyzes the complex interaction between the cervix, fetal membrane, and uterine contractions before the onset of labor using a complete third-trimester gravid model of the uterus, cervix, fetal membrane, and abdomen. Through a series of numerical simulations, we investigate the impact of (i) initial cervical shape, (ii) cervical stiffness, (iii) cervical contractions, and (iv) intrauterine pressure on the resultant cervical shape and fetal membrane stress during uterine contractions.

The findings reveal several key observations: (i) maximum principal stress values in the cervix decrease in more dilated, shorter, and softer cervices; (ii) reduced cervical stiffness produces increased cervical dilation, larger cervical opening, and decreased cervical length; (iii) the initial cervical shape impacts final cervical dimensions; (iv) cervical contractions increase the maximum principal stress values and change the stress distributions; (v) cervical contractions potentiate cervical shortening and dilation; (vi) larger intrauterine pressure (IUP) causes considerably larger stress values and cervical opening, larger dilation, and smaller cervical length; (vii) the biaxial strength of the fetal membrane is only surpassed in the cases of the (1) shortest and most dilated initial cervical geometry and (2) larger IUP.

This is the first numerical study embracing a complete full gravid uterine and cervical model, uterine and cervical contractions, and a diversity of features associated with pregnancy. We hope to gain more insight into what conditions may influence a successful vaginal delivery and clarify the complex interaction between the cervix, fetal membrane, and body of the uterus, which is not entirely understood.

NEW FORMULATIONS FOR DIGITAL TWINNING IN BIOFLUIDS

C. Alberto Figueroa[*1], Jesse Capecelatro[1], Abhilash Malipeddi[1], Haizhou Yang[1] and Krishna Garikipati[2]*

[1]*University of Michigan*
[2]*University of Southern California*

ABSTRACT

In biofluids, Digital Twinning relies on leveraging medical images and pressure and flow data to perform customized, subject-specific predictions. Flows in blood vessels and lymphatic systems include complex structured fluids, composed of a liquid phase (plasma) and a disperse phase, which includes cells and other particles such as thrombus. In this work, we present two novel numerical formulations for digital twinning in biofluids, implemented in the open-source framework CRIMSON [1].

In the first application, we are concerned with the study of conditions in which the complex interactions between plasma and suspended particles is required. We recently developed a volume-filtered Eulerian-Lagrangian strategy that uses a finite element method (FEM) to solve for the fluid phase coupled with a discrete element method (DEM) for the particle phase [2].

In a second application, we are concerned with the diagnosis of vascular disease in the catheterization laboratory. Here, images and other hemodynamic data are acquired in real time, and the cardiologist must decide in just a few minutes whether the blockage in the vessels is severe enough to warrant intervention. This application relies on computational tools to accurately estimate pressure gradients and other parameters within minutes. This goal can only be achieved via suitable reduced order models. Our group has recently developed a machine learning approach for calculating pressure gradient indices in image-based vascular models [3].

ABSTRACT

The construction of mechanical models based on experimental or simulation data is becoming increasingly important in engineering practice. On the one hand, the mechanical models identified from experimental measurements can be used for analysis and simulation. On the other hand, the models used in modern simulation software often need to be further reduced and reconstructed from the simulation results because the original system operators are difficult or impossible to access. Moreover, the identified mechanical system should be able to represent the system behavior for different load cases and time schemes, which means that the original system properties and structural characteristics should be preserved. The recent non-intrusive methods, such as operator inference, often either do not satisfy the latter condition or do not provide a complete system representation due to the specific second-order ODE structure of the governing system of equations. In our work, we propose a methodology for identifying and reducing mechanical systems from data by solving an optimization problem using the capabilities of machine learning techniques. We are able to identify all system operators and preserve their original mathematical properties by including a reasonable parameterization of the system operators in the optimization problem. For linear mechanical systems, this ensures stability and interpretability of the resulting surrogate model. In addition, we study systems with nonlinear material behavior and the possibility of applying non-intrusive reduction methods to them. Numerical experiments are performed using simulation data from finite element software.

A VERSATILE COMPUTATIONAL FRAMEWORK FOR CONTINUUM-KINEMATICS-INSPIRED PERIDYNAMICS USING HYPER-DUAL NUMBERS

Soheil Firooz[*1], Ali Javili[2] and Paul Steinmann[1]*

[1]*Friedrich-Alexander-Universität Erlangen-Nürnberg*
[2]*Bilkent University*

ABSTRACT

Continuum-kinematics-inspired peridynamics (CPD) has been recently proposed as a novel reformulation of peridynamics that is characterized by one-, two- and three-neighbor interactions.
CPD is geometrically exact and thermodynamically consistent and does not suffer from zero-energy modes, displacement oscillations or material interpenetration. In this presentation, we introduce a computational framework furnished with automatic differentiation for the implementation of CPD. Thereby, otherwise tedious analytical differentiation is automatized by employing hyper-dual numbers (HDN). This differentiation method does not suffer from round-off errors, subtractive cancellation errors or truncation errors and is thereby highly stable with superb accuracy being insensitive to perturbation values. The proposed computational framework is compact and model-independent, thus once the framework is implemented, any other material model can be incorporated via modifying the potential energy solely. Finally, to illustrate the versatility of our proposed framework, various potential energies are considered and the corresponding material response is examined for different scenarios.

MODEL PARAMETER IDENTIFICATION IN SIMULATIONS OF THE WEST AFRICAN MONSOON WITH THE USE OF SURROGATE MODELS

Matthias Fischer[*1], Carsten Proppe[1], Peter Knippertz[1] and Alexander Lemburg[1]*

[1]*Karlsruhe Institute of Technology*

ABSTRACT

Numerical simulations of the West African monsoon (WAM) system are subject to substantial uncertainties and challenging to assess due to complex interactions within the circulation system, in particular with respect to clouds. In a previous study, we identified major uncertainty contributors in WAM simulations using the ICON (Icosahedral Nonhydrostatic) model, operationally employed by the German weather service (DWD) [1]. We selected six model parameters with significant uncertainty impacts and 15 Quantities of Interest (QoIs) characterizing the WAM system, including averaged temperature, precipitation, cloud cover, jet speeds and latitudes. We developed surrogate models via universal kriging to establish a relationship between the model parameters and the QoIs. In global sensitivity analyses (GSA), we quantified the uncertainty contributions of these parameters to the QoIs.

In this talk, we will present methods to identify optimal model parameters by incorporating reanalysis data as a reference for the QoIs and output fields. Our analysis is divided into two categories: (1) optimizing QoIs using obtained surrogate models, and (2) optimizing output fields based on grid-point data. These tasks are approached as multi-objective optimization problems, where multiple QoIs or output fields are optimized simultaneously. We tackle this through two novel strategies: (a) assigning weights with uncertainties to QoIs or output fields based on expert opinion and (b) independently varying these weights to assess their impact on the optimal model parameters.

This approach not only integrates expert judgment into model optimization but also enables a dynamic assessment of how weight selection influences the optimal parameters. Our findings reveal a high sensitivity of the optimal parameter set to the assigned weights, highlighting the critical role of weights in model optimization.

ARTIFICIAL INTELLIGENCE IN DAM ENGINEERING

Leandro Flach[*1]

[1]*Klohn Crippen Berger*

ABSTRACT

Artificial intelligence has been evolving at an incresing rate. Early adopters are already benefiting from it, and most companies consider implementing artificial intelligence strategic to increase profits and remain competitive. This paper highlights the challenges and opportunities that artificial intelligence presents to dam engineering.

Lots of data are gathered daily by instruments and inspections. Assessing them timely is important to understand the current condition of a dam. Furthermore, the earlier an anomaly is detected, the more likely it is to keep it under control. Artificial intelligence can quickly process large amounts of data and give dam engineers the information they need to find the best solution.

The optimal operation of a gated spillway must consider deterministic and stochastic values. The former are current, whereas the latter are forecast. Many scenarios should be frequently analysed to define what the best gate operation is at each stage. Artificial intelligence allows to consider all of them and select the one that maximises benefits while safeguarding dam safety.

Ground conditions interpretation is time-consuming and is usually carried out once the site investigation is finished. Artificial intelligence can expedite the process, so the remaining part of the campaign can be adjusted based on a preliminary assessment of gathered data. Moreover, the complexity of the generated ground model can be increased to better represent reality.

Those are just a few examples of why artificial intelligence has arisen so much appetite. Dam design, construction, and operation are complex to the point that can overwhelm humans. The challenges that artificial intelligence adoption presents must be overcome for dam engineering to benefit from the opportunities it offers.

ISOTHERMAL, LINEAR THERMOMECHANICAL COUPLING OF DIFFUSIONAL PHASE TRANSFORMATIONS AND CONSTITUTIVE LAWS TO PREDICT DAMAGE AT SMALL SCALES

Wolfgang Flachberger[*1], Swaroop Gaddikere-Nagaraja[1], Thomas Antretter[1] and Silvia Leitner[2]*

[1]Montanuniversity Leoben
[2]MCL Leoben

ABSTRACT

This work presents a Lagrangian formulation for the coupling of diffusional phase transformations and continuum mechanics using the finite element method (FEM). The emphasis on the Lagrange formalism is due to its convenience in automatically deriving variational forms, especially for coupled problems. Although the derived variational form can be used with any Galerkin-type numerical method we present a specific mixed finite element method that employs less comon basis functions such as the "discontinuous Galerkin" and the "Raviart-Thomas" element. The mixed FE approach has beneficial features such as better stability properties and less degrees of freedom in comparison to the usual Galerkin elements. The approach is used to investigate the impact of mechanical stresses on segregation and other damage mechanisms observed at the small scales. The model is characterized by sharp transitions between phases (sharp interface model) which is in strong contrast to other state-of-the-art methods for describing diffusional phase transformations like the Phase Field Method (PFM). It will however be shown that the presented model can actually be interpreted as a limiting case of Cahn Hilliard diffusion (PFM). A binary system is studied whose behaviour is described by four differential equations which are solved by an implicit, fully coupled scheme. The diffusion model is used to predict both the phase growth as well as damage relevant phenomena such as segregation of components at grain boundaries. Furthermore, the diffusion is coupled with a constitutive model for the mechanical material behaviour. The coupling is done in both ways considering the influence of diffusion on mechanics via phase-dependent material parameters as well as by considering the influence of stresses and strains on the diffusion. This enables a detailed investigation of the many phenomena that are observed in nonequilibrium systems.

ABSTRACT

Several Hyper-Reduction (HR) approaches, such as e.g., the Energy Conserving Sampling and Weighting (ECSW) [1], have been proposed to reduce the computational cost of nonlinear structural Finite Element (FE) analyses. However, many HR approaches are typically intrusive, posing challenges when it comes to integration into existing commercial software. Recently, several data driven methodologies have been proposed to generate Non-Intrusive Reduced Order Models (NIROMs) of nonlinear dynamic FE problems. NIROMs can be obtained via surrogate modelling by learning the dynamic on the reduced space, or via system identification by approximating nonlinear operators [2]. While being non-intrusive, they typically suffer from limitations such as overfitting, a reduced capacity to extrapolate and violation of key physics properties resulting in unstable behaviour.

This work proposes a data-driven, physics-augmented artificial neural network approach based on the Input Convex Neural Network (ICNN) architecture [3] for nonlinear structural FE formulations. The proposed approach combines stability-preserving properties of HR approaches with the non-intrusive properties of data-driven approaches. The resulting NIROM possesses the necessary stability-preserving properties to be successfully employed in dynamic numerical simulations. The proposed approach is validated on a nonlinear structural FE model of a cantilever beam undergoing nonlinear geometrical and material behaviour whilst subjected to different dynamic loads. A Proper Order Decomposition reduced order basis is generated using a set of displacement field snapshots obtained from different dynamic loading conditions, whereas reduced internal force snapshots are used to train the proposed network. The proposed ICNN-based architecture guarantees the a-priori enforcement of physical constraints and therefore provides stable and consistent predictions, unlike e.g., Fully-Connected NN approaches. The obtained results highlight the efficiency of the proposed approach for dynamic structural FE problems and showcase its potential as well for parametric and multiphysics applications.

COMPUTATIONAL MODELING OF EXPLOSIVELY DRIVEN FLYER PLATE EXPERIMENTS IN ALEGRA

Anna Flessner[1], Adam Bouma[1] and Mikhail Mesh[1]*

[1]*Sandia National Laboratories*

ABSTRACT

The Light Initiated High Explosive (LIHE) facility at Sandia National Laboratories conducts experiments that utilize LIHE to evaluate the response of structures to shock loading. One version of the experiment consists of accelerating a thin metal flyer plate into a target material, delivering a prescribed impulsive load to the target.

During the experiment, the flyer plate is accelerated by the detonation of silver acetylide silver nitrate (SASN) explosive applied to the flyer plate surface. SASN is a highly sensitive primary explosive and can be simultaneously initiated over the sprayed flyer plate surface by an intense flash of light.

The impulse delivered to the target material is a direct function of the SASN explosive deposition on the surface of the flyer plate, the flyer plate material/thickness, and the initial air gap between the flyer plate and impact surface of the target material. By tailoring these parameters, the experiment can be designed to deliver the desired impulse to the target material.

As the LIHE flyer plate technique has matured, work has been done in parallel to build high-fidelity computational models to better inform the design of experiments. A 2D axisymmetric finite element model of the flyer plate experiment was developed in ALEGRA, an arbitrary Lagrangian-Eulerian multi-physics code. The model accounts for the detonation of the explosive, expansion of the detonation products, and the motion and mechanical deformation of the flyer plate. The ALEGRA simulations show good agreement with provided experimental data for the flyer plate velocity as it accelerates, impacts the target material, and rebounds. This work summarizes the development of the ALEGRA computational model and the results.

NUMERICAL ANALYSIS OF SOIL EROSION WITH MATERIAL POINT METHOD AND NON-CONFORMING RIGID LINE MODELING

Anthony Flores[1], Luis Zambrano[1] and Bill Davids[1]*

[1]*University of Maine*

ABSTRACT

Soil erosion poses challenges in engineering that require mitigation to ensure the safety of structures, protect natural resources, and plan sustainable projects. The analysis of soil erosion from an engineering perspective is complex as it is composed of the soil-water or soil-air interaction, where each component is dependent on mechanical parameters that have been empirically quantified, lacking theoretical soundness due to the complexity of the phenomena described. One of these parameters is the soil frictional stress, which is a crucial input for measuring both local and global scour, influenced by the velocity gradient of water flow, and it lacks an analytical solution, necessitating numerical methods. While widely used, the conventional finite element method (FEM) has limitations in capturing long deformations and post-failure behavior. Furthermore, it often relies on aggressive and expensive algorithms.

A bidirectional contact algorithm between the rigid element and the particles has been integrated into the Anura 3D software. The Material Point Method (MPM) has been selected due to its ability to simulate large deformations while effectively tracking the behavior of individual particles. A simplified 2D analysis of an open sea where water particles engage with a soil layer has been considered. A rigid line element moving rotationally is proposed to simulate the water wave, with its lower edge serving as the center of rotation. This algorithm enables the creation of rigid 1D-line elements not conforming with the background mesh. Contact detection is then carried out through a distance field assigned to each material point, considering a radius of influence for each material point based on its density. Subsequently, a Lagrangian correction is applied to the rigid body, followed by an Eulerian correction to the material points, ultimately proceeding with the standard MPM cycle.

A model with a soil and a liquid layer has been developed to test the contact algorithm. The model included a rigid body that was a mechanical simulation of waves in the liquid.

ABSTRACT

Ischemic strokes are a significant cause of mortality and long-term disability in patients with atrial fibrosis. However, the underlying mechanisms are not understood and there are no predictive tools for clinical decision support, even if atrial fibrosis can be assessed non-invasively with imaging modalities like late gadolinium enhancement magnetic resonance imaging (LGE-MRI). Fibrotic remodeling modifies myocardial structure impairing LA electrical propagation, myocardium mechanics, and slowing down atrial blood flow. In addition, fibrotic patches release inflammatory cytokines and tissue injury factors that can activate the coagulation cascade.

To evaluate the role of these effects and their potential interactions, we perform multi-physics simulations, coupling electrophysiology, biomechanics, hemodynamics, and the coagulation cascade. We significantly reduce the computational cost of these simulations with two innovations. First, we introduce a multi-fidelity approach leveraging the low molecular diffusivity of coagulation species, which accelerates the simulation of reaction advection equations by over one order of magnitude. Second, the resulting modular multi-physics solver is implemented to run in graphics processing units (GPUs), achieving an additional speedup of almost two orders of magnitude. Overall, these innovations reduce the cost of the multi-physics simulations to ~ 1h per cardiac cycle, reducing the gap between the time associated to clinical diagnosis tests and the time to run patient-specific simulations.

We use these multi-physics simulations to analyze patient-specific models with different fibrosis burdens based on LGE-MRI scans. Fibrotic regions are modeled by locally modifying the myocardial mechanical properties and releasing pro-coagulatory tissue factor in the neighboring endocardium. To elucidate the interplay between these effects, the following conditions are considered per patient-specific model: no fibrosis, 5X increased passive stiffness and 2X reduced cardiomyocyte contractility (mechanical disruption), tissue factor release in fibrotic patches with normal mechanical properties (pro-coagulatory disruption), and both mechanical and pro-coagulatory disruption. These simulations will shed light onto

the complex nexus between fibrosis and stroke. Furthermore, their reduced computational cost is poised to create paradigm changes in clinical diagnosis support and personalized therapeutic planning.

DYNAMICS OF THE RELIABILITY OF AN AERIAL SYSTEM OPERATING IN ADVERSE CONDITIONS

Eduardo Fogliato[1]*

[1]La Universidad de la Defensa Nacional

ABSTRACT

Aerial systems must comply with basic capabilities to ensure the continuity of their operation under acceptable conditions and particularly in adverse situations. This is how, within a dynamic framework, reliability and degradation models are essential for prediction and decision making. Its application and execution provides results that, compared with historical measurements, allow the evaluation of the prediction and, if satisfactory, allows for an acceptable state of security based on the predictive tool which, by its nature, provides probable results in a simple way, early and continuous.
The necessity to know the system degradation´s speed on one hand and when to provide the necessary logistical support to restore it on the other hand, is a frequent problem in the aeronautical sector that occurs mainly for safety reasons for both the operator and the its human and material environment.
In this context, we recognize unavoidable and at the same time contributing aspects, which interact with each other and where we distinguish various operating variables, both endogenous and exogenous to the system, which by themselves generate a possible set of desired values for efficient, effective and safe work that allow the aerial system maintenance. From there, we also analyze the different responses in relation to their recovery capacity and they are quantified in this work in probabilistic terms. It should be noted that, even moving in a region where the quality is desired, the demanding uninterrupted operation of the system is associated with failure and degradation which requires periodic restoration of high, medium and low frequency (corrective, restorative and preventive) facilitated by the developed model. However, the sustained activity of the system causes a growing accumulation of tensions that occur in order to renew the daily availability of the system, causing an essential effort that is also increasing to sustain the permanent functioning of the system. The result is that the system degrades to such an extent that it limits the extent of its activity over time.
In this paper we propose models for the timely prediction of restoration moments, which maximize the useful life of the system conceived from its endogenous and exogenous variables. Finally, real cases with different responses are analyzed in an environment associated with countries where resources are not abundant or in systems that for functional reasons are self-sufficient degenerative or, at the same time, operate in adverse environments.

LANDSLIDE RUN-OUT SIMULATIONS WITH DEPTH-AVERAGED MODELS AND INTEGRATION WITH 3D IMPACT ANALYSIS USING THE MATERIAL POINT METHOD

Marco Fois[1], Carlo de Falco[1], Andi Makarim Katili[2], Antonia Larese[3] and Luca Formaggia[1]*

ABSTRACT

Landslides pose a significant threat to human safety and the well-being of communities, making them one of the most challenging natural phenomena. Their potential for catastrophic consequences, both in terms of human lives and economic impact, is a major concern. Additionally, their inherent unpredictability adds to the complexity of managing the risks associated with landslides. It is crucial to continuously monitor areas susceptible to landslides. In situ detection systems like piezometers and strain gauges play a vital role in accurately monitoring internal pressures and surface movements in the targeted areas. Simultaneously, satellite surveys contribute by offering detailed topographic and elevation data for the study area. However, relying solely on empirical monitoring is insufficient for ensuring effective management of hazardous situations, especially in terms of preventive measures. The substantial economic costs and the impracticality of conducting realistic experiments underscore the growing necessity of developing numerical simulations to better understand and address landslide phenomena. This study provides advanced simulations of mudflows and fast landslides using particle depth-averaged methods, specifically employing the Material Point Method adapted for shallow waters (Depth Averaged Material Point Method). The numerical method has been parallelized for enhanced efficiency and validated through benchmark tests and real-world cases. Furthermore, the investigation extends to coupling the depth-averaged formulation of shallow water with a three-dimensional formulation in order to have a detailed description of the impact phase of the sliding material on barriers and membranes. The multidimensional approach and its validation on real cases provide a robust foundation for a more profound and accurate understanding of the behavior of mudflows and fast landslides.

ADAPTIVE MESH ALGORITHM FOR FRICTIONAL CONTACT PROBLEMS BASED ON A POSTERIORI ERROR ANALYSIS

Ilaria Fontana[*1] and Daniele Antonio Di Pietro*[2]

[1]*Northwestern University*
[2]*University of Montpellier*

ABSTRACT

The finite element method is a widely adopted computational tool for solving problems formulated as partial differential equations in computational mechanics. For instance, engineering teams often perform finite element numerical simulations to analyze the behavior of large hydraulic structures. The nonlinear behavior of concrete dams, particularly within their weakest zones, such as the concrete-rock contact in the foundation or the interfaces between blocks, significantly influence their stability. A mathematical approximation representing the behavior of these zones consists in the unilateral contact conditions with friction, expressed in terms of normal and tangential components of displacement and surface stress at the interface level.

This presentation concentrates on frictional unilateral contact problems within a framework encompassing both Tresca and Coulomb friction conditions. Numerically, we adopt a finite element discretization with weak enforcement of nonlinear contact conditions à la Nitsche. This choice enables an easy implementation of the contact conditions in a weak sense without the introduction of additional unknowns such as Lagrange multipliers. For this problem, we present an a posteriori error analysis based on equilibrated stress reconstruction, providing a guaranteed fully-computable upper bound of the error that distinguishes the different components of the error through some local estimators [1], in the spirit of [2]. The key concept behind these estimators is to provide an equilibrated stress reconstruction with continuous normal trace across the edges of the mesh, locally in equilibrium with the volumetric and surface forces. Inspired by [3], we propose a practical method to achieve this reconstruction by assembling solutions of problems locally defined on patches around mesh vertices using the Arnold-Falk-Winther mixed finite element space.

We use then the local estimators to introduce a fully-automated adaptive algorithm for the refinement of the mesh with a stopping criterion for the linearization algorithm. Numerical compare this adaptive algorithm with a uniform approach, showing that the former provide better convergence rate for the error measured in the H1-norm and energy norm.

[3]Polytechnic University of Milan

ABSTRACT

The de Rham complex unifies the treatment of the classical differential operators in vector calculus, in particular the gradient, curl and divergence in three-dimensional space. When the complex is equipped with inner products we obtain the Hodge-Laplacian, generalizing the usual scalar/vector Laplacian. Thus, the study of cochain complexes is strongly linked to certain processes in continuum mechanics governed by partial differential equations.

Recent work has established that various coupled problems can also be cast in the context of (double) cochain complexes. The Hodge-Laplacian on the mixed-dimensional de Rham complex describes coupled problems where the coupling takes place across manifolds of various dimensions [1]. On the other hand, the Čech-de Rham complex is a cochain complex where the coupling is on an equidimensional overlap of domains. It has been shown that Hodge-Laplacians on the Čech-de Rham complex corresponds to models of coupled problems common in applications [2].

A cochain map between the mixed-dimensional de Rham complex and the Čech-de Rham complex can therefore be seen as a link between mixed-dimensional and equidimensional representations of the same physical problem. The construction of the aforementioned cochain map have been made for a class of mixed-dimensional geometries [3]. Additional properties of such a cochain map will lead to an approximation theory between mixed-dimensional and equidimensional models.

A DEPTH AVERAGED MATERIAL POINT METHOD FOR FAST FLOW-LIKE LANDSLIDES AND MUDFLOWS

Luca Formaggia[*1], Marco Fois[1], Carlo de Falco[1] and Simona Perotto[1]*

[1]*Politecnico di Milano*

ABSTRACT

Among the most dangerous natural phenomena for the safety of people, landslides are one of the most problematic: not only because of their potentially catastrophic nature in terms of human and economic loss, but also because of their intrinsic unpredictability.

In this work, we are interested in the development of efficient tools for the simulation of landslide evolution immediately following the phase of initiation of the landslide front. The basic mathematical model used to describe gravity-driven free surface flows is the depth-integrated equations derived from the Navier-Stokes equation for an incompressible fluid. We propose a semiconservative variant of the Depth-Averaged Material Point Method (DAMPM), which is a depth-integrated version of the Material Point Method (MPM). Numerical test are carried out to verify the effectiveness of the procedure both on synthetic and real case scenarios.

SYMMETRY FOR OPEN SETS WITH ORDERED NONLOCAL CURVATURE

Animesh Biswas[1], *Mikil Foss**[1] *and Petronela Radu*[1]

[1]*University of Nebraska-Lincoln*

ABSTRACT

This talk will focus on a geometric problem involving nonlocal mean curvature defined via an integrable kernel. In the classical setting, it is well known that a smooth boundaryless surface with constant mean curvature must be a sphere. Li and Nirenberg studied the problem where the mean curvature is instead assumed to be monotone (ordered) in a given direction. Under certain geometric and regularity assumptions, they showed there must be a hyperplane, orthogonal to that direction, across which the surface is symmetric. Thus, if the mean curvature is ordered in all directions, the surface is a sphere. I will present an analogous result where the curvature is measured with a nonlocal operator and the surface is the boundary of an open set.

NUMERICAL MODELING OF DEEP EARTHQUAKES CONSIDERING PHASE TRANSFORMATION AND THERMAL EFFECTS

Craig Foster[*1], Sheng-Wei Chi[1], S Sindhusuta[1], Ashay Panse[1], Javad Mofidi Rouchi[1], Yanbin Wang[1] and Timothy Officer[1]*

[1]*University of Illinois at Chicago*

ABSTRACT

The causes of deep earthquakes, those below approximately 60 km, remain poorly understood. High pressures prohibit the frictional sliding that dominates shallower earthquakes. Roughly, these earthquakes are split between intermediate-depth earthquakes, those between 60 and 350 km depth, and deep-focus earthquakes, those below 350 km. These two types of earthquakes seem to be clustered distinctly by depth and may have different mechanisms.

One of the leading hypotheses, especially for deep-focus earthquakes, is that of transformational faulting. Under high temperatures and pressures, minerals in the subducting slab change phase to denser and weaker structure. The densification can remove some of the pressure on the material and, combined with weakening, allow for sliding. High strains along the band can start to create transformation in narrow bands. Thermal effects can also locally enhance phase transformation, creating a runaway reaction that could lead to a macroscale event.

We create an enhanced finite element model to model these processes and see if macroscale fault generation is possible by this mechanism. Phase transformation is modeled as a rate process that is a function of temperature and mean stress, following [1]. Under the correct softening conditions, the phase transformation can localize into narrow bands. These bands are modeled using an enhanced strain finite element.

We first model small laboratory experiments [2] to see if local inclusions can perturb the stress field enough to incite this process. We then upscale the model to examine fault-scale scenarios, to see if large-scale earthquakes can be generated at depth. These simulations will eventually be compared to catalogs of deep earthquakes to see if they match the characteristics of observed events.

THE HUNTER, THE RANCHER, THE RENAISSANCE MAN: A TRIBUTE TO MY BELOVED FRIEND TINSLEY ODEN

*John Foster**[1]

[1]*The University of Texas at Austin*

ABSTRACT

Over the last eight years of his life, I spent considerably more time at "Oden Ranch" with Tinsley than on campus. We would traverse the ranch's expansive terrain, covering more than 10 miles of dirt, rock, and hilly roads in his well-worn Ford F250, which spanned nearly 800 acres. As we attended to ranch duties, I was captivated by his tales of adventure. His stories ranged from hunts in the Arctic Circle to expeditions in Africa and South America, not forgetting the countless autumn deer hunts on the ranch. He had an incredible memory for the names and personalities of guides and guests who joined him on these adventures.

Though Tinsley was globally recognized for his professional achievements, I will always cherish his genuine affection and kindness towards everyone he met, especially those who shared his passion for the outdoors, myself included. In this talk, I aim to recount some of the stories he shared with me, as well as those we forged together. These narratives will be accompanied by photographs and, quite likely, some tears, as I pay homage to my dear friend.

ADVANCES IN A 10-NODE COMPOSITE TETRAHEDRAL FRAMEWORK FOR SHOCK AND MESH ADAPTIVITY

James Foulk[1], Jesse Thomas[1], Scott Miller[1], David Noble[1], William Scherzinger[1], Michael Veilleux[1] and Alejandro Mota[1]*

[1]*Sandia National Laboratories*

ABSTRACT

We have extended the recently reformulated 10-node composite tetrahedral finite element for solid mechanics. We generalized the gradient operator and mass matrix to curved domains through analytical expressions weighted by subtetrahedra Jacobians. Optimal integration weights were constructed to increase the accuracy of Gaussian quadrature. We preserved the variational structure of the formulation through a new five-field functional with additional, independent fields for the Jacobian and the pressure. A deleterious soft mode, common to both the quadratic and composite tetrahedral element with constant pressure formulations was effectively stabilized through a novel convex energy penalty function.

In recent work, we probed the viability of the formulation for shock. We investigated a new, nonlinear, symmetric stabilization scheme for structured and unstructured meshes. The new scheme enables the large volumetric strains inherent in shock environments and does not affect prior work focused on large, unconfined, plastic deformations.

Here we extend the requisite stabilization schemes to mesh adaptivity. We focus on new methodologies for mapping the stabilization energy to a stressed reference configuration and examine the impact on the solution. We explore problems of increasing complexity for metals that span convergence for Taylor bar impact to resolving Richtmyer-Meshkov instabilities.

ABSTRACT

Surface insulation resistance (SIR) serves as an IPC J-STD-001H prescribed method of obtaining objective evidence that manufacturing processes for high performance/harsh environment electronic products result in acceptable levels of residues such that performance under anticipated operating conditions is not adversely affected. Despite this methodology providing potential insight into the underlying physical phenomena occurring within the system, evaluation of the cleanliness and reliability of a manufacturing process via SIR testing currently relies upon a binary pass/fail paradigm based upon whether the measured current was above a scientifically arbitrary threshold value at any time during the test window. Sandia National Laboratories, in collaboration with university and industry partners, has engaged in a systematic investigation of SIR towards an understanding of how the underlying mechanisms manifest in the observed time-series data. The explored parameter space included (a) design geometry of the test patterns, (b) materials selection in the test board construction, (c) chemistry and concentration of contaminants on the test board and (d) environmental conditions of the test chamber. Additional characterization techniques —electrochemical impedance spectroscopy, capacitance-voltage, more—were conducted before, after and/or in parallel to complement the SIR measurements. Results were interpreted through multivariate statistical analysis and within the context of analytical and equivalent circuit models. Future work seeks to enhance applicability to industry processes through the investigation of increasingly relevant test pattern designs, materials selection, and investigated contaminants.

A DEEP MATERIAL NETWORK USING MICROPOLAR MECHANICS

Noah Francis[*1], Dongil Shin[2], Ricardo Lebensohn[3], Fatemeh Pourahmadian[1] and Rémi Dingreville[2]*

[1]University of Colorado Boulder
[2]Sandia National Laboratories
[3]Los Alamos National Laboratory

ABSTRACT

The deep material network (DMN) is a recent paradigm that combines homogenization techniques with neural networks to rapidly predict the response of composite materials with high accuracy. These reduced order models have analytical formulas at their core, making them capable of extrapolating to other constitutive equations after training only once on linear elastic data. Thus far, the approaches to DMN use classical continuum mechanics to construct the network. Here we study the DMN idea extended to micropolar mechanics, which generalizes the classical continuum to include not only the three displacement degrees of freedom at every point, but three additional microrotation ones too. In the micropolar setting, intrinsic length scale effects representing the microstructure of the material arise naturally. These length scales are not captured in the classical models, so it is of interest to have a DMN sensitive to these effects. The homogenization building block of the micropolar DMN is derived via asymptotic homogenization applied to a simple micropolar laminate. This formula is a function of the normal vector of the laminate plane and the volume fraction; both of which will serve as network parameters to be learned in the training process. The training data is generated using linear elastic micropolar fast Fourier transform (FFT) direct numerical simulations (DNS). Then, using a nonlinear micropolar constitutive model, the micropolar DMN is shown to extrapolate accurately without retraining. The reference DNS used as our metric for accuracy is a nonlinear extension of the micropolar FFT DNS.

UTILIZING MACHINE LEARNING FOR CRACK GROWTH RATES PREDICTIONS IN AN AERONAUTICAL ALUMINUM ALLOY

Yuval Freed[*1]

[1]*Israel Aerospace Industries*

ABSTRACT

Recent progress in computational capabilities introduces a new era where data-driven methodologies play a pivotal role in accurately simulating intricate engineering phenomena. These methodologies, harnessing the power of machine learning, offer mathematical approximations that act as surrogate models. Their strength lies in their ability to replace convoluted explicit mathematical relationships with models demanding significantly reduced computational resources.

This study addresses the formidable challenge of predicting the crack growth behavior of aluminum 7075-T6, a commonly used material in the aviation industry. The inherent complexity of crack growth in this alloy stems from several influencing factors, rendering explicit mathematical equations inadequate for comprehensive descriptions. Notably, the presence of "waviness" behavior within the linear Paris law region and the pronounced impact of variables such as the R-ratio and specimen thickness contribute to the intricate nature of crack growth predictions.

To overcome these challenges, we explore four distinct machine learning regression algorithms: Random Forest (RF), Gaussian Process Regression (GPR), K-Nearest Neighbors (KNN), and Kernel Regression (KR). These algorithms are studied for their efficiency in capturing the patterns inherent in the crack growth behavior of aluminum 7075-T6. The performance evaluation involves a meticulous assessment of their predictive capabilities under various conditions.

The key objective is to identify the most promising algorithm among the four, capable of providing accurate and reliable predictions for the crack growth in aluminum 7075-T6 across diverse fatigue stress spectra. By systematically comparing and contrasting the performance of these machine learning algorithms, we aim to shed light on the most suitable approach for tackling the complex task of crack growth prediction in this critical aviation material. This research not only contributes to the understanding of material behavior but also holds the potential to enhance the reliability and safety of aeronautical structures through more informed predictions of crack growth rates.

POLYMORPHIC UNCERTAINTY QUANTIFICATION IN STRUCTURAL DYNAMICS

Steffen Freitag[*1], Marc Fina[1], Maximilian Schweizer[1] and Werner Wagner[1]*

[1]*Karlsruhe Institute of Technology*

ABSTRACT

The reduction of material consumption required to build engineering structures leads to an increasing design of lightweight structures. Optimization approaches can be used to minimize the amount of construction material. However, it is important to investigate the structural performance of lightweight structures under dynamic loads with respect to the structural reliability and serviceability. This requires to quantify the uncertainty of the structural loads and the structural parameters. In this contribution, a concept is presented to consider aleatory and epistemic uncertainty [1] in order to compute the responses of structures under dynamic loading. Stochastic and non-stochastic uncertainty models, such as random variables, intervals and fuzzy numbers, are combined, which leads to a polymorphic uncertainty quantification of the structural performance by means of probability boxes or fuzzy random variables. To compute the uncertain structural responses, a nested loop of Monte Carlo simulations and interval analyses is required, which may be time consuming in case of computational expensive simulation models, e.g., finite element simulations and low probabilities to be computed. To reduce the computation time, surrogate modeling approaches for the finite element simulation model or methods where the failure probability is estimated by the standard deviation are helpful, see e.g. [2]. It is important to capture the time-variant structural behavior within the surrogate modeling approach in case of dynamic loads. The resulting polymorphic uncertain structural responses, such as time series of stresses and accelerations or its maximal quantities, computed by the surrogate model are finally evaluated by means of statistical measures, such as mean values, standard deviations or quantile values. Or they are used to calculate imprecise probabilities of the structural failure with respect to safety and serviceability. Academic examples are presented and the developed approach is applied to a footbridge structure considering the dynamic loads of moving pedestrians, see [3].

CODE-VERIFICATION TECHNIQUES FOR INTEGRAL EQUATIONS

Brian Freno[*1]

[1]*Sandia National Laboratories*

ABSTRACT

Code verification is an important step towards establishing the credibility of the results of computational physics codes. Through code verification, the correctness of the implementation of the numerical methods is assessed. The discretization of differential, integral, or integro-differential equations incurs some truncation error, and thus the approximate solutions produced from the discretized equations will incur an associated discretization error. If the discretization error tends to zero as the discretization is refined, the consistency of the code is verified. This may be taken a step further by examining not only consistency, but the rate at which the error decreases as the discretization is refined, thereby verifying the order of accuracy of the discretization scheme. The correctness of the numerical-method implementation may then be verified by comparing the expected and observed orders of accuracy obtained from numerous test cases with known solutions.

Exact solutions are limited and may not sufficiently exercise the capabilities of the code. Manufactured solutions are a popular alternative, permitting the construction of problems of arbitrary complexity with known solutions. Through the method of manufactured solutions (MMS), a solution is manufactured and substituted directly into the governing equations to yield a residual term, which is added as a source term to coerce the solution to the manufactured solution.

Integral equations yield an additional challenge. While analytical differentiation is straightforward, analytical integration is not always possible. Therefore, the residual source term arising from the manufactured solution may not be representable in closed form, and its implementation may be accompanied by numerical techniques that carry their own uncertainties. Furthermore, in many applications, singular integrals appear, which can further complicate the numerical evaluation of the source term. Therefore, many of the benefits associated with MMS are lost when applied to integral equations in a straightforward manner.

Integral equations incur numerical error from three sources: domain discretization, solution discretization, and numerical integration. Domain-discretization error arises from the approximation of curved surfaces with planar elements. Solution-discretization error arises from the approximation of the solution in terms of a finite number of basis functions, or alternatively the approximation of the underlying equation operators in terms of a finite amount of solution queries. Numerical-integration error arises from the approximate evaluation of integrals, usually with quadrature.

We present our approaches to code verification of integral equations, which isolate and measure these different sources of numerical error. We demonstrate their effectiveness for cases with and without coding errors.

A NEW CONCEPT FOR EMBEDDING SUB-STRUCTURES VIA LEVEL-SETS

Thomas-Peter Fries[1], Jonas Neumeyer[1] and Michael Wolfgang Kaiser[1]*

[1]*Graz University of Technology*

ABSTRACT

A new concept for including sub-structures such as fibres and membranes into bulk materials is proposed and generalized from [1, 2]. The bulk domain is equipped with level-set functions whose isosurfaces and/or isolines represent the geometries of the embedded sub-structures. Each level-set function represents an infinite set of continuously embedded, homogenized sub-structures, implied by each of the infinite level sets. This enables a new concept for advanced, anisotropic materials such as biological tissues, layered rocks, composites, and textiles. Mechanical models are proposed which consider the physics on the individual level sets including the generalization into the whole bulk domain [1, 2]. The bulk models for the sub-structures are coupled to classical homogenous and isotropic mechanical models resulting in a new class of models. For the numerical analysis, the bulk domain is meshed using classical, higher-order elements. It is noteworthy that these elements do by no means align to the embedded level sets which is otherwise characteristic for a fictious domain method. However, the present approach does not come with the usual challenges of FDMs. That is, boundary conditions and numerical integration are done as in the classical FEM and there is no need for stabilization. The numerical approach may be traced back to [3] in the context of transport applications and was called Bulk Trace FEM in [1]. Numerical results confirm the success of the proposed sub-structure models in various contexts, even enabling optimal, higher-order accurate results when smooth solutions are expected.

ABSTRACT

Numerical simulations serve as invaluable tools to study complex subsurface systems and support decision-making. Achieving accurate and reliable simulations for various applications—ranging from carbon storage to geothermal energy production—is contingent upon modeling the concurrent interplay of different physical processes. This includes evaluating hazards such as excessive subsidence or induced seismicity. The core challenge stems from the complex interplay and strong non-linearity intrinsic to these processes. Hydrodynamical properties, for example, are tightly coupled with mechanical configurations, making it challenging to solve with decoupled approaches. As a result, there is a need for robust numerical models capable of reliably predicting the complexities inherent in subsurface systems.

In this work, we propose low-order continuous finite elements to simulate solid matrix deformations, and a cell-centered finite volume discretization to solve both the solid matrix and fracture fluid mass balance equations. Frictional contact is addressed using the augmented Lagrange multiplier method following a conformal approach. A single grid is utilized for both mechanical and flow processes, employing piecewise-constant basis functions for fluid pressure and Lagrange multipliers. The implementation of the augmented Lagrangian method follows a Uzawa procedure—a dual-loop algorithm solving the weak form in terms of displacements and pore pressure, holding the Lagrange multipliers constant in the inner loop and updating them in the outer loop. This method can be viewed as a sort of Lagrange multiplier formulation regularized by penalty functions and it offers distinct advantages. Unlike traditional penalty methods, it avoids increasing ill-conditioning of the linear systems, ensuring numerical stability and converging precisely to the exact solution for a finite value of the penalty coefficient. Additionally, this approach generates a smooth energy functional and transforms the problem into a fully unconstrained one, eliminating the need for an active set strategy typically required when employing the Lagrange Multiplier method.
To validate our approach, synthetic numerical tests demonstrate robustness and accuracy. Furthermore, we apply this methodology to address a real-world problem, demonstrating its practical applicability.

ABSTRACT

Several approaches have been suggested to enhance high-performance computing of granular flows via the Discrete Element Method (DEM). However, the number of published works on this subject (e.g., [1]) is relatively limited, especially when contrasted with the widespread application of DEM in both research and industry sectors. This scarcity in literature can be attributed to the intrinsic complexity of granular media at the grain scale, which are dynamic and disorganized systems, posing significant challenges to effective parallelization. In our work, we introduce a method that leverages a fundamental constraint of DEM simulations, transforming it into a potential for efficient and adaptable parallel processing on distributed memory systems. Specifically, the "numerical sound speed," determined by the standard particle diameter and the time step, imposes a maximum limit on the speed at which disturbances can travel through the discrete material. We demonstrate how this numerical phenomenon, often considered minor in most applications, can be repurposed as a novel criterion for dividing the spatial domain. This approach fosters a parallelization strategy well-suited for DEM. Our methodology is detailed through its practical integration into the DEM'ocritus software [2,3]. We evaluate its effectiveness via benchmark tests on assemblies of up to 15 million particles. These tests focus on scenarios pertinent to geomechanics and the process industry.

INTERPOLATION-BASED IMMERSED BOUNDARY FINITE ELEMENT AND ISOGEOMETRIC METHODS FOR MULTI-MATERIAL AND MULTI-PHYSICS PROBLEMS

Jennifer Fromm[*1], John A. Evans[2] and Jiun-Shyan Chen[1]*

[1]*University of California, San Diego*
[2]*University of Colorado Boulder*

ABSTRACT

Immersed boundary methods are high-order accurate tools used to model geometrically complex problems in computational mechanics. While traditional finite element methods require the construction of high-quality boundary fitted meshes, immersed boundary methods instead embed the computational domain in a structured background grid. Interpolation-based immersed boundary methods augment existing finite element software to non-invasively implement immersed-boundary capabilities through extraction. Extraction, which has previously been applied to implement isogeometric analysis (IGA) in finite element codes, interpolates the structured background basis as a linear combination of Lagrange polynomials which can be easily integrated by existing methods. This work extends the previously introduced interpolation-based immersed IGA method [1] to multi-material and multi-physics PDEs, utilizing enrichment schemes analogous to those used in traditional immersed boundary methods like XFEM and XIGA. Beginning from level-set descriptions of domain geometries, Heaviside enrichment is implemented to accommodate discontinuities in the solution field across material interfaces. This allows for image based analysis, which is illustrated in this work by analysis of Micro-CT images of a composite sample. Adaptive refinement, used to both improve interface geometry representations and to resolve large solution gradients near interfaces, is applied with truncated hierarchically-refined B-splines (THB) [2]. Multi-physics problems typically have unique discretization requirements for each field, and fields must be coupled. Extraction allows users to interpolate a variety of discretizations with a single unifying Lagrange basis. Interpolation also provides a straightforward coupling method, both at interfaces and within domains. This work provides numerical examples illustrating optimal convergence rates for this method in both 2D and 3D for PDEs representing heat conduction, linear elasticity, and thermoelasticitiy. We present the utility of this method with an image-based analysis of a composite sample, where in addition to circumventing typical meshing difficulties, our method offers a dramatic reduction in degrees of freedom when compared to classical boundary fitted finite element methods.

MONOLITHIC AND PARTITIONED FEM FOR FSI: ALE DIVERGENCE-FREE HDG FLUID SOLVER + TDNNS STRUCTURAL SOLVER

Guosheng Fu[*1]*

[1]*University of Notre Dame*

ABSTRACT

We present novel (high-order) finite element schemes for the fluid-structure interaction (FSI) problem based on an arbitrary Lagrangian-Eulerian divergence-free hybridizable discontinuous Gakerkin (ALE divergence-free HDG) incompressible flow solver, a Tangential-DisplacementNormal-Normal-Stress (TDNNS) nonlinear elasticity solver, and a generalized Robin interface condition treatment. Temporal discretization is performed using the high-order backward difference formulas (BDFs). Both monolithic and strongly coupled partitioned fully discrete schemes are obtained. Numerical convergence studies are performed for the flow and elasticity solvers, and the coupled FSI solver, which verify the high-order space-time convergence of the proposed schemes. Numerical results on classical two dimensional benchmark problems also showed good performance of our proposed methods.

PHASE-FIELD MODELING OF CRYSTALLITES GROWTH AND POLYCRYSTALLINITY EFFECT ON SOLID-STATE SINTERING

Wenjie Fu[*1], Yongxin Gao[1], Arkadz Kirshtein[2] and Qingcheng Yang[1]*

[1]*Shanghai University*
[2]*Tufts University*

ABSTRACT

Crystallite growth and polycrystallinity are crucial determinants of the properties and performance of sintered materials. Understanding their intricate interplay is essential for optimizing manufacturing processes and tailoring material properties to specific applications. In this study, we present a comprehensive phase-field modeling approach to investigate the dynamics of crystallite growth and the influence of polycrystallinity on solid-state sintering.

The phase-field method has emerged as a powerful computational tool for simulating microstructural evolution in materials science. By employing a diffuse interface approach, it enables realistic representation of complex interfaces and morphological changes during sintering. Initially, we validate the recently proposed interracially consistent phase-field model of solid-state sintering by comparing it with experiments involving single-crystal powder materials. Subsequently, we utilize this model to simulate the microstructure evolution of polycrystalline powder particles. We elucidate the mechanisms governing crystallite growth and analyze the effects of grain boundary structure and orientation on sintering kinetics. Our simulations reveal the role of grain boundaries as diffusion pathways and their impact on mass transport during densification.

Overall, our phase-field modeling approach provides valuable insights into the fundamental mechanisms governing crystallite growth and polycrystallinity effects on solid-state sintering. By integrating computational simulations with experimental observations, we aim to facilitate the design and optimization of advanced materials with tailored microstructures and enhanced performance across a wide range of applications.

ABSTRACT

The development of phononic crystals offers a potential solution for precise control of acoustic/elastic waves. Designing phononic crystals with desired characteristics has become a research focus in recent years. However, the precision of altering acoustic and mechanical waves remains a significant challenge for existing inverse design methods. The rapidly advancing field of machine learning is revolutionizing the design of these materials. As an important branch of machine learning, reinforcement learning is being employed to solve mechanical problems more intelligently through the interaction of an agent with its environment. In this paper, we demonstrate the successful application of machine learning in designing 2D phononic crystals with the desired band structure. We first employed the meshless generalized finite difference method to solve the dispersion equation for a periodic structure. To achieve a desired frequency range with a wider first-order bandgap width, we utilized a modified reinforcement learning algorithm incorporating particle swarm optimization to effectively estimate the shape parameters. This parallel technology offers computational cost savings, is independent of the initial state and target, and is effective and stable. This enhanced reinforcement learning-based interactive design approach can be easily applied to other reverse engineering problems.

ABSTRACT

Data-driven constitutive modeling with neural networks has received increased interest in recent years due to its ability to easily incorporate physical and mechanistic constraints and to overcome the challenging and time-consuming task of formulating phenomenological constitutive laws that can accurately capture the observed material response. However, even though neural network-based constitutive laws have been shown to generalize proficiently, the generated representations are not easily interpretable due to their high number of trainable parameters. Sparse regression approaches exist that allow for obtaining interpretable expressions, but the user is tasked with creating a library of model forms which by construction limits their expressiveness to the functional forms provided in the libraries. In this work, we propose to train regularized physics-augmented neural network-based constitutive models utilizing a smoothed version of L0-regularization. This aims to maintain the trustworthiness inherited by the physical constraints, but also enables interpretability which has not been possible thus far on any type of machine learning-based constitutive model where model forms were not assumed a-priory but were actually discovered. During the training process, the network simultaneously fits the training data and penalizes the number of active parameters, while also ensuring constitutive constraints such as thermodynamic consistency. We show that the method can reliably obtain interpretable and trustworthy constitutive models for compressible and incompressible hyperelasticity, yield functions, and hardening models for elastoplasticity, for synthetic and experimental data.

TOPOLOGY OPTIMIZED-MECHANICAL UNFEELABILITY REVERSAL

Garuda Fujii[*1]*

[1]*Shinshu University*

ABSTRACT

Mechanical unfeelability cloak is a metadevice that can realize mechanical unfeelability which is an analogy of optical invisibility to elasto-mechanics. A mechanical unfeelability cloak, usually surrounding an obstacle that is stiffer than a host material, reproduces a displacement field as if no obstacle is present inside the host structure despite the obstacle is actually present. It is very difficult to apply transformation theory, one of the most common approaches when designing cloaking devices that manipulate different physics, to elastic mechanics because the governing equation is not form-invariant, then, the approach for designing a mechanical unfeelability cloak is very limited. Mechanical unfeelability cloaks are usually composed of mechanical metamaterials which realize anisotropic mechanical properties by tuning the artificial microstructures. Some different schemes have been also proposed based on isotropic bulk materials for mechanical unfeelability cloaking without using mechanical metamaterials. Topology optimization is one of the promising approach to design a mechanical unfeelability cloak, some attempts have been proposed using density based topology optimization and level set-based topology optimization. Recent development of the topology optimization enables not only designing elastic structures for cloaking but also adding an mechanical function to optimum structures such as an mechanical cloak-concentrator. In this work, we propose new multifunctional mechanical structures performing for both cloaking and reversing stress inside. The aim is to minimize the stress in the same direction as the external load as the first objective function, and to make the sign of the objective function negative in order to reverse the stress. To suppress the displacement caused by the reversal system, the difference between cloaked displacement and that of a host homogeneous structure is minimized as the second objective function. Radial Basis Function (RBF) parametrized-level set method is employed as a structural modeling to reduce the number of design variables without sacrificing the accuracy of finite element analyses. A covariance matrix adaptation evolution strategy (CMA-ES) is employed to explore the optimal set of design variables because of its robustness to difficult properties such as multimodality, interdependence between design variables, etc. CMA-ES is a multi-point search that adapts its distribution parameters for sampling, i.e. the shape, size and center of the distribution of candidate solutions generated based on normally distributed-random numbers. The use of CMA-ES makes designers free from guessing the appropriate initial solution and adjusting strategy parameters.

A MICRO- AND MACROSCOPIC HYBRID TRAFFIC SIMULATION MODEL FOR HIGHWAY MERGING SECTION

Hideki Fujii[*1] and Yo Imai*[1]

[1]*The University of Tokyo*

ABSTRACT

A hybrid traffic simulation model is defined as a combination of multiple traffic models with different resolutions, which are dynamically switched to each other. The proposed model couples a microscopic and a macroscopic model. Macroscopic models aggregate the behavior of many vehicles into macroscopic variables, e.g., density, traffic volume, and mean speed, and update these variables at long intervals. For this purpose, a model that regards the fluid as a continuum is used [1]. Meanwhile, microscopic models individually determine each car's behavior through a series of rules [2]. Here, a traffic flow is considered as the sum of car behaviors as particles.
A microscopic model is suitable for high-resolution simulations where vehicle properties are heterogeneous, or flow characteristics vary from lane to lane, etc. However, they are computationally expensive since detailed vehicle behaviors must be updated at short intervals. On the other hand, a macroscopic model is computationally inexpensive and suitable to simulate large-scale traffic flow. However, it cannot capture individual car behavior. In a dynamic hybrid model, the application domains of micro- and macroscopic models can be switched during the simulation to achieve overall speed-up while keeping a high resolution of the area of interest.
The contribution to the research field is to model traffic flow phenomena at multiple resolutions and to propose methods to combine them. This presentation reports the results of improving the dynamic hybrid model already proposed by the authors. The model is also applied to an expressway merge section to evaluate its accuracy and computational efficiency.

COORDINATE TRANSFORMATION BASED ON SPH(2) FOR EFFICIENT FREE SURFACE FLOW SIMULATION

Shujiro Fujioka[1], Kumpei Tsuji[2], Naoto Mitsume[3] and Mitsuteru Asai[1]*

[1]*Kyushu University*
[2]*Tohoku University*
[3]*Tsukuba University*

ABSTRACT

The original SPH with fixed kernel functions guarantees accuracy in interpolation and numerical differentiation, only when particles are regularly and uniformly distributed. Therefore, the modified gradient operators are often used, where the first-order accuracy is preserved even when the particles are randomly distributed. On the other hand, there have not been much discussion on second-order derivatives (including Laplacian operators) and gradient models with higher-order accuracy. Hence, we proposed a class of SPH model, which we refer as "SPH(2)" [1], that satisfies second-order accuracy for both first- and second-order derivatives.

In this study, we utilize the SPH(2) for coordinate transformations that require first- and second-order derivatives including cross-derivatives. These transformations may help to reduce the heavy computations of particle methods, for example, in coastal engineering applications. We intend to develop to a "sigma-coordinate system", which changes the vertical resolution depending on the ocean depth, at the end, and as a first step, we generalize the vertical coordinate transformation in this study. The coordinate transformations for the ellipsoidal particle model [2] and the bottom boundary-fitted particle method [3] were performed using the SPH(2) operators to demonstrate the effectiveness of the proposed method.

EARLY FORECASTING OF TSUNAMI WAVEFORM WITH BAYESIAN SCENARIO-SUPERPOSITION

Saneiki Fujita[*1], Reika Nomura[1], Shuji Moriguchi[1], Yu Otake[1], Randall J. LeVeque[2] and Kenjiro Terada[1]*

[1]*Tohoku University*
[2]*University of Washington*

ABSTRACT

Early tsunami warning plays an important role in disaster mitigation, and various methods that can forecast tsunami waveforms and/or inundation have been developed. Based on the lesson learned from past devastating tsunami events (e.g., the 2011 Tohoku tsunami event), researches have focused on improving the accuracy and immediacy of tsunami forecasting. In addition to such efforts, a probabilistic forecasting model will prevent under/overestimation of arrival wave heights since it can simultaneously provide prediction reliability. According to this background, we have proposed the early tsunami forecasting method based on the Bayesian theorem (Nomura et al., 2022). However, since the previous method only detects the “best-fit scenario” from a precomputed database by comparing the true waveforms, it cannot provide an accurate prediction if similar scenarios are not included in the database.

This study proposes an improved early tsunami forecasting method by introducing the scenario superposition concept based on the Bayesian theorem. This time, we focus on the Shikoku region (Japan) as a target site, which is threatened by the tsunami triggered by the Nankai Trough subduction zone. By GeoClaw software (Clawpack Development Team, 2021), we generate both training and test data consisting of synthetic tsunami wave heights. The test data is then input as an unknown tsunami event in the Bayesian technique which sequentially estimates/updates each training data-specific weight. Based on the evaluated weights, the scenario superposition is achieved by a linear combination of each hypothetical scenario in the precomputed database. It can be said that the present method is superior to the previous one because waveforms that have a much larger/smaller amplitude than all the trained scenarios, is predicted by not only interpolation but also extrapolation. Additionally, a probability distribution for the weight parameters is simultaneously obtained, which enables quantifying and visualizing the prediction reliability. We use the proposed and previous methods to forecast waveforms of test data and compare their results. Consequently, it was found that the proposed method could accurately predict waveforms, which could not be predicted by the previous method, within a 10-minute observation duration.

THE METHOD OF FUNDAMENTAL SOLUTIONS USING ADAPTIVE SOURCE POINT SELECTION FOR TWO-DIMENSIONAL ELASTIC WAVE ANALYSIS

Akira Furukawa[*1]*

[1]*Hokkaido University*

ABSTRACT

The method of fundamental solutions (MFS) [1] is a numerical simulation method of mesh-free type and widely used for solving problems related to elastic deformation, vibration, and wave propagation. MFS uses fundamental solutions as a basis function and its approximate solutions are expressed by the linear combination of these fundamental solutions and approximation coefficients. In MFS, the source points of fundamental solutions are placed at arbitrary positions in the complementary domain of analysis one.

Compared with finite difference method (FDM) and finite element method (FEM), MFS requires fewer unknowns, because it does not require mesh generation of analysis domains and boundaries. Moreover, the numerical implementation of the MFS is simpler than that of boundary element method (BEM), because MFS can avoid the singular integration over the boundary. However, the accuracy of MFS is affected by the location of the source points. Thus, making the selection of suitable source point locations is a crucial task.

In this study, we develop a MFS which includes adaptive source point selection using orthogonal matching pursuit (OMP) [2]. OMP, a sparse modeling technique, can select appropriate basis functions from underdetermined system of equations. In our proposed method, we prepare source points whose number is more than that of equations and select adequate source points using OMP. We solve two-dimensional elastic wave problems using our proposed MFS and discuss its advantages and disadvantages.

ABSTRACT

With the drastic development of additive manufacturing technologies in recent years, the high manufacturability of these techniques has garnered attention for enabling topology optimization with high design flexibility. However, when performing additive layer manufacturing, constraints such as overhang limitations, minimum thickness, and curvature exist, making it challenging to generate structures obtained directly from topology optimization calculations.
Focusing on overhang constraints, various methods have been proposed to reduce support material or aim for support-free structures[1-3]. Among these, approaches have been suggested considering the gradient of design variables, extracting angles from it, and applying constraints, as well as those leveraging the characteristics of mesh.
This study proposes a novel approach to consider constraints by developing a topology optimization design method based on image processing techniques. The angle information is extracted using the Sobel Filter, a form of image processing technology. Penalties are imposed on surfaces that do not satisfy stackable angles, and an objective function is defined to minimize these penalties. We formulate the multi-objective optimization problem, considering both stiffness and manufacturability.
We have successfully obtained optimized structures with higher performance and manufacturability by introducing this optimization problem as a post-process of conventional topology optimization problems. This paper presents numerical examples to demonstrate the validity and effectiveness of the proposed methodology.

STUDY ON THE MECHANICAL ASYMMETRY OF A NON-RECIPROCAL GEL USING COMPUTATIONAL HOMOGENIZATION

Takuma Fuse[1], Seishiro Matsubara[1], So Nagashima[1] and Dai Okumura[1]*

[1]*Nagoya University*

ABSTRACT

Recently, mechanical asymmetry triggered by a specific loading direction has received attractive attention in the solid mechanics community. Materials exhibiting this asymmetry are expected to promote the development of asymmetric systems such as energy harvesting and material transport. A non-reciprocal gel (NR gel) developed by Ishida et al.[1] is a hydrogel containing magnetically oriented metal nanosheets, which can be regarded as a homogeneous material. The compressive load induces the buckling of nanosheets and results in the asymmetry of the macroscopic elastic response – the elastic modulus in the tensile direction is ten times larger than that in the compressive direction. Understanding the relationship between mechanical asymmetry and nanosheet buckling will facilitate the design of NR gels, leading to their application in various engineering fields.
In this study, we investigate influential factors that characterize the relationship between mechanical asymmetry and nanosheet buckling. The unit cell of NR gel is modeled as an elastic bilayer consisting of hydrogel and nanosheet, whose Young's modulus ratio and thickness ratio are parameterized. In the eigenvalue buckling analysis, the energetically preferred wavelengths for nanosheet buckling are computed for each parameter. The microscopic responses of NR gel are analyzed by the post-buckling analysis for the unit cell with the preferred wavelength and converted to macroscopic responses by the computational homogenization. We show that the microscopic responses are in good agreement with the analytical solution for layered composites[2]. We also find that the mechanical asymmetry of the macroscopic responses is pronounced as the Young’s modulus ratio increases or the thickness ratio decreases. We further analyze the in-plane spacing between nanosheets, which may also contribute to the mechanical asymmetry of a NR gel.

ADVANCED MULTISCALE MODELLING OF PLANT FIBER-REINFORCED BIOCOMPOSITES: BRIDGING THE GAP IN PREDICTIVE ANALYSIS FOR SUSTAINABLE CONSTRUCTION MATERIALS

Markus Königsberger[1], Valentin Senk[1], Markus Lukacevic[12], Sebastian Pech[1] and Josef Füssl[1]*

[1]TU Wien

[2]Christian Doppler Laboratory for Next-Generation Wood-Based Biocomposite

ABSTRACT

This study presents a novel approach in the predictive modelling of plant fibre-reinforced biocomposites, a sustainable and cost-effective alternative to conventional building materials. Biocomposites, consisting of natural cellulose fibres bonded with low CO2 footprint polymers like lignin [1], offer significant environmental advantages. However, their complex microstructure, characterised by variable fibre types, lengths, orientations, and mechanical interactions with the polymer matrix, has historically limited their use in load-bearing structural elements.

Our research addresses these challenges by developing advanced micromechanics-based multiscale modelling tools. These tools facilitate the comprehensive characterisation of 3D stiffness and, to some extent, the strength of natural fibres and their composites [2]. At the microscale, we consider various fibre orientations and aspect ratios, effectively representing biocomposite microstructures with diverse fibre configurations. Additionally, we incorporate a spring-type interface model within the continuum micromechanics framework to account for the typically weak fiber-matrix bond. This multiscale model is validated through uniaxial tensile tests on various plant fibre composites, accurately predicting the stiffness changes due to fibre alignment and interface compliance variations.

Furthermore, our approach employs nonlinear plasticity, XFEM, and cohesive zone models to simulate failure mechanisms, including matrix softening, fibre breakage, and fibre-matrix de-bonding, in a unit cell with periodic boundary conditions. This enables precise predictions of nonlinear macroscopic behaviour, validated against experimental data for both short- and long-fibre composites.

Our research paves the way for the practical application of lightweight biocomposite structures in real architectural contexts. The integration of these models with finite-element simulations and a 3D sketching tool provides a novel platform for material-informed computational design [3]. This study not only offers novel tools with respect to modelling and simulation of biocomposites but also contributes to the broader goal of developing sustainable construction materials.

ADVANCING STRUCTURAL SAFETY THROUGH INTEGRATED YIELD AND BUCKLING INDICATOR OPTIMIZATION

Christoffer Fyllgraf Christensen[*1], Fengwen Wang[1], Jonas Engqvist[2], Ole Sigmund[1] and Mathias Wallin[2]*

[1]*Technical University of Denmark*
[2]*Lund University*

ABSTRACT

This study addresses the challenge of identifying and preventing failure in engineering structures by combining yield stress and buckling indicators in topology optimization to enhance structural integrity and safety. Our approach integrates two key aspects: the inclusion of yield stress limits derived from homogenization-based analysis and the implementation of predictive buckling indicators within the structural design. Employing a novel framework, we incorporate local yield-based stress constraints based on a density-dependent von Mises yield surface alongside global and local buckling criteria. This methodology ensures that the resulting designs adhere to critical material yield behaviors crucial for practical applications. Additionally, our study embeds buckling indicators in the multiscale designs. Based on an adapted Willam-Warnke stress criterion presented by Christensen et al. [1], these indicators are engineered to visibly exhibit non-critical local buckling under load conditions just below global critical buckling. Inspired by the work of da Silva et al. [2], the blueprint design and a variant, where the predetermined indicator region is omitted, are considered. The result is an innovative safety feature, signaling the need for load reduction or maintenance. Experimental testing validates the correlation between the numerical simulations and the physical behavior of the printed structures, confirming the feasibility of our approach. Our research bridges the gap between theoretical optimization models and practical applications. By combining yield stress considerations and buckling indicators, we not only ensure adherence to material and mechanical performance but also introduce a novel safety paradigm in engineering design. The integrated approach contributes significantly to structural safety, offering built-in early-warning failure prediction capabilities and paving the way for more reliable and safer structural implementations.

ABSTRACT

Many metal additive manufacturing (AM) technologies, such as laser powder bed fusion (LPBF), rely on the stacking of thin powder layers with a rigid blade or a roller. The spreading step is critical because defects in the powder bed (i.e., low packing density, poor surface uniformity, particle segregation, etc.) often result in defects in the final product (i.e., lack of fusion, porosity, etc.). Currently, the lack of understanding of the spreading process, which depends, among other factors, on the powder properties and spreader geometry, results in a trial-and-error approach to ensure a quality powder bed which is not cost effective. Discrete Element Method (DEM) simulations can help us understand the mechanisms at play during the spreading process and select the best operating parameters (i.e., spreader geometry, spreader speed, layer thickness, etc.) for a given powder feedstock.

In this work, we first present Lethe, an open-source DEM software capable of simulating the spreading of multiple powder layers, with periodically moving spreaders, powder dispenser platform and build-plate, all in a single simulation. We then use this software to run large-scale DEM simulations, evaluating the influence of the operation parameters and of the DEM parameters related to the feedstock (i.e., surface energy, restitution coefficient, friction coefficients, etc.) on the powder bed quality. Finally, through a collaboration with the National Research Council of Canada, we use an experimental set-up that replicates the whole spreading process while allowing freedom on operating parameters. This experimental set-up measures the relative density of the powder bed in between each layer. Using DEM simulation, we replicate these experimental results to assess the role of the powder property on the bed density and to gain insight into the physical mechanism affecting the bed quality in certain operating conditions. This paves the way for a digital twin for powder spreading that could swiftly identify powder bed quality from the powder property and the operating parameters.

VARATIONAL PRINCIPLES FOR COUPLED CHEMO-MECHANICS IN ELASTIC AND DISSIPATIVE SOLIDS

Swaroop Gaddikere Nagaraja[*1], Wolfgang Flachberger[1] and Thomas Antretter[1]*

[1]*Montanuniversitaet Leoben*

ABSTRACT

Variational principles for coupled chemo-mechanical problems in elastic and dissipative solids at infinitesimal strains are outlined in the present work. In doing so, it is seen that the gradient of the primary fields additionally enter the energetic and dissipative potential functions, resulting in additional balance equations. The governing balance equations of the coupled problem are derived as Euler equations of the incremental variational principles, formulated in continuous-and discrete-time/space settings. Furthermore, the variables governing the inelastic process are locally condensed which yields a reduced global problem that is solved in a discrete-space-time setting. The symmetric structure of the proposed framework with respect to the primary and state variables is an advantage, and this is exploited in the numerical treatment within the finite element paradigm. The framework is applied to Cahn-Hilliard- type diffusion and Allen-Cahn-type phase transformation in elastic and dissipative solids. The applicability of the proposed framework is demonstrated by means of two- and three-dimensional representative numerical simulations.

DENDRITE INHIBITION STRATEGY USING HETERO-EPITAXIAL RESIDUAL STRESSES IN THIN FILM DEPOSITION MECHANICS

Musanna Galib[1], Jian Liu[1] and Mauricio Ponga[1]*

[1]*The University of British Columbia*

ABSTRACT

Dendrite formation is a long-standing problem for the commercial application of rechargeable metal anode batteries. The well-controlled coating on anodes can solve the problem of instability and uncontrolled reactions between electrodes and electrolytes. Understanding the effects of pre-stressed (residual stress) electrodes with artificial solid-electrolyte inter-phase layer (thin film) on dendrite formation is crucial for the successful application of stable anodes. In this work, using DFT-informed continuum modeling and phase-field modeling, we studied the impacts of residual stresses on the surface evolution of atomic/molecular layer deposited (ALD/MLD) Al2O3 and alucone coating on Zn anodes. During the thin film deposition process, the induced stress arises from two sources, namely, the residual stress during fabrication and the mechanical stress associated with the volume expansion. Of the two, residual stress has largely been considered to have a negligible effect without any rigorous evidence being put forward. Epitaxial stresses are one of the major sources of residual stress in the hetero-epitaxial thin films, which are sensitive to the misfit in crystal lattices existing between film and substrate. The epitaxial stresses influence defect formation in most thin-film systems. We critically assessed alucone and alumina-coated Zn surfaces to depict a prospective methodology to reduce the dendrite growth using the developed hetero-epitaxial residual stress. We used DFT-informed misfit strain analysis in the phase field model to understand the significant consequences of residual stress, such as microstructural changes and deformation in the materials.

ABSTRACT

The use of the compositional reservoir simulation has become an important tool to accurately predict the oil and gas recovery in complex petroleum reservoirs, and in the modelling of complex phenomena such the enhanced oil recovery processes. Although the compositional model based on Equations of State (EOS) produces a much better description of the fluid flow behavior when compared with the simpler “black oil” model, its use can be very computationally demanding, due to the solution of a large system of Partial Differential Equations (PDEs) composed by the component mass conservation, Darcy’s low and the fugacity constraints. Besides, to properly model the fluid flow in geologic complex heterogeneous and anisotropic reservoirs including “Y” faults and pinchouts and to properly represent inclined wells the use of unstructured computational meshes can be of utmost importance. In this context, to solve the system of PDEs we have used the classical IMPEC (Implicit Pressure Explicit Composition) strategy along with the Peng-Robinson’s Equation of State to model the phase behavior during the fluid flow in the reservoir. To approximate the pressure equation, we have used the Multipoint Flux Approximation with a Diamond Stencil (MPFA-D) finite volume method and the second order Monotone Upstream-centered Scheme for Conservation Laws (MUSCL) for the solution of the component transport equations along with an adequate multidimensional limiting strategy to suppress spurious numerical oscillations. For the time integration we have used the third order Runge–Kutta method. To evaluate our formulation, we have solved some benchmark problems found in literature with very promising results when compared to other classical schemes particularly for problems involving unstructured and non k-orthogonal meshes and full tensor rock permeabilities.

SIMULATION-BASED INFERENCE OF DYNAMICAL SYSTEMS WITH MODEL UNCERTAINTY

Nick Galioto[*1] and Alex Gorodetsky*[1]

[1]*University of Michigan*

ABSTRACT

Accounting for model uncertainty during the estimation of dynamical systems is important for generating reliable and generalizable predictions. For state-space systems, quantification of model uncertainty can be achieved through the estimation of an added process noise term in the system dynamics [1]. Within a Bayesian framework, the inclusion of process noise in the model formulation has shown to improve the likelihood smoothness and yield inherent regularization during estimation [2]. The cost of adding process noise, however, is that the system states become uncertain and must be marginalized out when evaluating the likelihood, requiring costly integration. The cost can be mitigated with recursive filtering algorithms, but these algorithms require inversion of covariance matrices, resulting in a computational complexity that scales cubically with the state and measurement dimensions. As a result, the filtering algorithm is unsuitable for even moderate dimensions.

Simulation-based inference (SBI) methods offer an alternative means for constructing an approximate likelihood at a potentially lower computational cost. These methods circumvent the challenge of computing costly or intractable likelihoods by using outputs from a model simulator to estimate a surrogate density function that can be evaluated efficiently, e.g., a neural network. In this talk, we consider two SBI methods for likelihood approximation: the sequential neural likelihood and the Bayesian synthetic likelihood. We present the advantages and disadvantages of each approach in comparison to the filtering-based approximation and discuss the feasibility of extending each algorithm to problem settings with model uncertainty. Then, we benchmark each algorithm on noisy, single-trajectory data from the Lotka-Volterra predator-prey model. In this comparison, we analyze the differences in cost and effective sample size between the methods for posterior sampling.

REDUCED-ORDER PHASE-FIELD MODELING FOR CONTROLLED MICROSTRUCTURE IN ADDITIVE MANUFACTURING

Zhengtao Gan[*1]

[1]*The University of Texas at El Paso*

ABSTRACT

One of the significant challenges associated with Laser Powder Bed Fusion (L-PBF) is the evolution of microstructures (i.e., crystalline grain structures), which has a significant impact on the final material properties. To address this challenge, our study presents a physics-guided and machine-learning-aided approach for optimizing scan paths to achieve the desired microstructure outcomes, particularly focusing on the generation of equiaxed grains which are desirable for enhanced material properties. We utilize phase-field (PF) modeling, a physics-based computational method, to gain insights into microstructure evolution. The high computational costs associated with PF modeling can be mitigated by employing machine learning reduced-order or surrogate models. We will introduce two approaches for accelerating phase field models. The first one is a physics-embedded graph network, which leverages an elegant graph representation of the grain structure and embed the classic PF theory (e.g., Allen-Cahn equation) into the graph network. The second approach is by training a surrogate machine-learning model using a three-dimensional (3D) U-Net convolutional neural network. This approach enables the learning of microstructure evolution in a supervised manner, with the machine learning model being able to predict crystalline grain orientations with high accuracy based on the initial microstructure and thermal history. The training data pivotal for our machine-learning model is generated from single-track, single-layer PF simulations, under various process parameters. We aim to capture the essential characteristics of grain structures in a compact representation. The developed approach effectively minimizes computational demands, yielding a structured and accessible search space for optimization. Leveraging the reduced-order models, we implement a reinforcement learning strategy, finely tuning the laser tool path to precisely attain the desire crystalline microstructure.

ADVANCING THE DESIGN OF COMBINED PILED-RAFT FOUNDATIONS: AN INTEGRATED APPROACH OF SUPERVISED MACHINE LEARNING AND ANALYTICAL METHODS

David Sharvit[1], Ty Phuor[2], Pavel Trapper[1] and Avshalom Ganz[2]*

[1]Ben-Gurion University of the Negev
[2]Ariel University

ABSTRACT

The Combined Piled-Raft Foundation (CPRF) is recognized as a highly economical and effective foundation system for towering structures. However, its intricate design process is often marked by time-intensive challenges. Addressing this, several closed-form approximate solutions have been proposed in the past. Nonetheless, the reliability of these solutions, particularly for preliminary design stages, remains a topic of debate.

In this study, we rigorously evaluate the applicability and accuracy of three prevalent approximate solutions in the analysis of CPRF systems. These methods include the Poulos-David-Randolph method (PDR), the equivalent pier method (EP), and the equivalent raft method (ER). Our evaluation is grounded in a comparative analysis with a benchmark 3D finite element model. This comprehensive assessment involved 700 cases across varying CPRF configurations, encompassing 20 distinct dimensional parameters such as pile length, diameter, spacing, as well as the width and length of the raft.

The crux of our study lies in the application of supervised machine learning techniques. These advanced methodologies were employed to ascertain the validity domain of each evaluated method. The primary objective was to delineate the specific conditions under which each method can be applied with utmost accuracy. Our findings aim to streamline the design process of CPRFs, thereby enhancing both the efficiency and the reliability of foundation designs for tall buildings. This study stands at the intersection of traditional analytical approaches and cutting-edge machine learning applications, heralding a new paradigm in engineering practices.

EFFECTS OF VOID SHAPE AND DISTRIBUTION ON DUCTILE FRACTURE BASED ON UNIT-CELL CALCULATIONS

Baisen Gao[*1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

Ductile fracture in porous metallic materials is primarily governed by void behavior according to the previous studies. In this study, we explore the effect of initial void shape and distribution on ductile failure under various stress states based on unit-cell calculations. The credibility of our numerical findings is validated through mechanical tests conducted on additively manufactured specimens.
A proportional loading is applied on the unit cell to matin a constant loading state during the deformation. Different criterions are employed to identify the strain localization and void coalescence behavior [1]. Spherical, oblate, and prolate voids serve are employed as the initial shapes for single-voided unit cells, allowing us to identify void growth, strain localization, and void coalescence varying stress triaxialities. Additionally, we also investigate the effect of void distribution effect on ductile fracture with multiple regularly or randomly distributed voids.
Our numerical results show that the geometric asymmetry resulting from the initial void shape induces anisotropic deformation and failure. Strain localization for the spherical void occurs earlier than for other void shapes at high stress triaxiality, instead of occurring between the prolate void and the oblate void for void coalescence. A greater thickness enhances deformation capacity and delay void coalescence under high stress triaxiality. The conclusion also corroborated by calculations through multiple-voided unit cells. Furthermore, simulations of multiple-voided unit cells reveal that ductile fracture can be influenced by adjusting void distributions and loading conditions. Void clusters may promote the fracture occurrences, even as the initial void fraction decreases. Controlling the main loading direction on components emerges as a strategy to govern fracture behavior through adjusting defect distribution.

Our numerical findings offer valuable insights into specific mechanical and tomographic experiments involving additively manufactured components [2]. Additionally, our investigation illustrates on the potential for manufacturing more fracture-resistant components through additive manufacturing, underscoring the significance of defect engineering in metallic material fracture control.

IMPLEMENTATION OF EXTRINSIC COHESIVE ZONE MODEL (ECZM) IN 2D FINITE-DISCRETE ELEMENT METHOD (FDEM) USING NODE BINDING SCHEME

Ke Gao[1]*

[1]*Southern University of Science and Technology*

ABSTRACT

The combined finite-discrete element method (FDEM) has been widely used for rock fracturing simulations. Conventionally, FDEM is realized using the intrinsic cohesive zone model (ICZM); however, it has the drawback of artificial compliance and high computational expense. As a complement, the extrinsic cohesive zone model (ECZM) is seen to be realized in FDEM recently, whereas the node splitting scheme utilized is cumbersome. Here, within the framework of ICZM-based FDEM, we propose a node binding scheme to efficiently bind the pre-discretized finite elements and thus guarantee the continuum behavior of materials in the elastic stage. The yield surfaces, controlled by ECZM, are dynamically embedded by invoking the pre-inserted cohesive elements. The effectiveness and efficiency of the proposed approach are validated and tested by performing a suite of numerical experiments. Compared with ICZM-based FDEM, the proposed approach can correctly capture material deformation and reduce the computation cost. In contrast to the existing ECZM-based FDEM, the proposed approach can overcome the frequent and complex element topology updating. This work provides a novel perspective that fully inherits the advantages of both ICZM and ECZM, but circumvents their shortcomings, which guarantees a more efficient and effective simulation of brittle material evolution from continuum to discontinuum.

TOPOLOGY OPTIMIZATION METHOD OF SKIN-TO-SKELETON CONNECTION AREA'S DISTRIBUTION DESIGN FOR ALLEVIATING STRAIN CONCENTRATION AND SUPPRESSING WRINKLES OF FLEXIBLE SHEETS

Zhaodong Wei[1], *Renjing Gao**[1] *and Shutian Liu*[1]

[1]*Dalian University of Technology*

ABSTRACT

Morphing wing can get over the limitation of traditional aircraft's fixed shape and achieve the best aerodynamic efficiency. However, the phenomenon of excessive strain in local area of flexible skin surface and skin bump due to aerodynamic loads frequently occurs in the morphing process of wings. How to alleviate strain concentration of the skin and suppress skin wrinkles are crucial considerations in the morphing process of the flexible sheet. In this paper, we propose a strategy to improve the uniformity of the strain distribution and suppress skin wrinkles through rationally distributing the connection areas between the skin and skeleton of the sandwich-flexible-sheet, and develop a topology optimization method for determining the optimal distribution of the connection areas. In this method, the connection areas between the skin and the support skeleton are considered as the virtual adhesion layer comprising of adhesion materials. Based on the topology optimization idea, the distribution of connection areas is described by allocating the presence and absence of the adhesion material. The optimization model is established with minimizing the globe stress of the skin as the objective function, the volume fraction of the design domain and the normal deflection of the maximum displacement points in the skin wrinkles areas as constraints. The effectiveness of the proposed method is verified through examples involving tensile and rotational states of the sandwich-flexible-sheet with Ω-shaped honeycomb skeleton structure, and the results show that the optimization method can significantly improve the strain distribution of the skin and mitigate the degree of wrinkles. Finally, a variable-sweep structure for unmanned aerial vehicles (UAVs) is designed to explore the practical value of the proposed method.

A FINITE ELEMENT-INSPIRED HYPERGRAPH NEURAL NETWORK: APPLICATION TO FLUID FLOW AND FLUID-STRUCTURE INTERACTION SIMULATIONS

Rui Gao[*1], Indu Kant Deo[1] and Rajeev Jaiman[1]*

[1]*University of British Columbia*

ABSTRACT

An emerging trend in deep learning research focuses on the applications of graph neural networks (GNNs) for mesh-based continuum mechanics simulations. Most of these learning frameworks operate on graphs wherein each edge connects two nodes. Inspired by the data connectivity in the finite element method, we present a method to construct a hypergraph by connecting the nodes by elements rather than edges. A hypergraph message-passing network is defined on such a node-element hypergraph that mimics the calculation process of local stiffness matrices. We term this method a finite element-inspired hypergraph neural network, in short FEIH(phi)-GNN. We further equip the proposed network with rotation equivariance, and explore its capability for modeling unsteady fluid flow systems. The effectiveness of the network is demonstrated on flow around bluff and streamlined bodies. Stabilized and accurate temporal roll-out predictions can be obtained within the interpolation Reynolds number range. The network is also able to extrapolate moderately towards a higher Reynolds number domain out of the training range. Adopting the arbitrary Lagrangian-Eulerian formulation, we further construct a quasi-monolithic framework that enables the modeling of fluid-structure systems, and applied such a framework to two prototypical cases, namely the flow around an elastically mounted cylinder, and the flow around a hyperelastic plate attached to a fixed cylinder. The proposed framework tracks the interface description and provides stable and accurate system state predictions during roll-out.

INTEGRATING MECHANICS, PIEZOELECTRICITY AND ELECTROCHEMISTRY

Tianhan Gao[1] and Wei Lu*[1]

[1]*University of Michigan*

ABSTRACT

Lithium metal battery provides the highest possible theoretical capacity. However, one of the biggest challenge in realizing lithium metal battery is dendrite growth during lithium deposition, which leads to internal short circuit and safety hazard when it pierces through the separator. Dendrite penetration is also the key barrier for achieving fast charging in current lithium ion batteries. We show a new mechanism of stopping dendrite formation by using the mechanical deformation of a piezoelectric film or coating. A local over-potential appears when a piezoelectric separator film is deformed by any surface protrusion. This piezoelectric over-potential reduces the driving force of lithium diffusion toward any protrusion, resulting in a flat lithium metal surface. We developed a computational framework that integrates mechanics, piezoelectricity and electrochemistry [1-3]. With this framework, we have investigated the electrodeposition of lithium ions on a lithium metal surface through a porous piezoelectric film. Simulations show how dendrites forms and grows during regular lithium ion deposition, while a piezoelectric film completely stops any dendrite nucleation.

IMPEDANCE INHOMOGENEITY INDUCED BY THE SIO ADDITION IN SIO/GR COMPOSITE ANODE

Xiang Gao[1] and Jun Xu*[1]

[1]*University of Delaware*

ABSTRACT

Silicon/Carbon (Si/C) composite anode materials have emerged as promising candidates for high-energy-density lithium-ion batteries (LIBs), boasting advantages such as high capacity, cost-effectiveness, and abundance. However, the integration of Si-based materials into conventional C anodes introduces heterogeneous interactions between electrochemical and mechanical behaviors, owing to substantial volume changes and chemical potential variations. One significant consequence of these interactions is the impedance inhomogeneity, which adversely affects the discharging capacity of Si-based LIBs. In an effort to comprehensively understand this phenomenon and its underlying mechanisms, an electrochemo-mechanical coupled model is established, incorporating detailed particle geometries on the anode side. The model is employed to investigate polarization components and their evolution during the charging/discharging process. Various influencing factors, such as SiO weight percentage (wt.%), electrode thickness, and SiO distributions (both in terms of distribution uniformity and direction), are systematically discussed. This study offers an efficient computational approach to analyze battery polarizations, deepening the understanding of the inhomogeneous evolution of these polarizations in Si/C composite anodes. Ultimately, these insights guide the design of anodes for next-generation high-energy-density LIBs.

EVOLUTION OF MICROSTRUCTURE GRAINS IN THREE-DIMENSIONAL PHASE FIELD DURING WIRE ARC ADDITIVE MANUFACTURING PROCESS

Xiang Gao[*1] and Zhao Zhang*[1]

[1]*Dalian University of Technology*

ABSTRACT

In the WAAM process, the growth and evolution of grains are affected by the morphology of the melt pool, and the microstructure of the components are influenced by the growth of grains and the evolution between columnar and equiaxed grains significantly. Based on the double ellipsoidal heat source, the morphology of the melt pool under different heat source parameters was studied. A three-dimensional phase field model containing a heterogeneous nucleation model was developed to study the microstructure evolution under different process conditions in the WAAM process. The results indicate that the depth of the molten pool increases with the increasing of arc power and the decreasing of arc scanning speed. The size and growth direction of grains are mainly controlled by the morphology of the melt pool. The interior and top of the component are composed of columnar grains and equiaxed grains, respectively. With the unidirectional travel direction deposition strategy, the bending degree of columnar grains increases with the decreasing of arc scanning speed. The increasing of arc power and the decreasing of speed lead to grain coarsening. With the bidirectional travel direction deposition strategy, the growth direction of columnar grains changes, resulting in the formation of bent columnar grains.

MULTISCALE MODELING OF HYDROGEN TRANSPORT IN STEELS AND ITS RESULTING EMBRITTLEMENT EFFECT

Xiaosheng Gao[*1], Guanyue Rao[1] and Chuanshi Huang[2]*

[1]*University of Akron*
[2]*Dassault Systèmes*

ABSTRACT

A multiscale modeling approach is adopted in this study to understand the hydrogen embrittlement (HE) mechanisms and to predict failure of engineering components subjected to complex stress state and under the influence of hydrogen environment. Firstly, molecular dynamics simulations of the body-centered cubic (BCC) iron are conducted on an atomistic scale to examine the effect of hydrogen on the fracture behavior with the focus on the influence of grain boundaries (GB). An increase in dislocation nucleation at the crack tip region due to the presence of hydrogen contributes to the so-called hydrogen enhanced localized plasticity (HELP). It is observed that change in atomic structure leads to localized dislocation pile ups and void formations, which facilitates fracture and embrittles the material. Various GB types and orientations as well as mixed mode loadings are considered to assess the impact of grain boundary energy and mode mixity on the hydrogen effect on crack propagation. Next, the effect of stress state on ductile failure under the influence of hydrogen is studied at the microscale by incorporating the hydrogen diffusion process and the HELP effect into a finite element program and performing a series unit cell analysis. It is shown that localized plastic deformation plays a major role in increasing the local hydrogen concentration due to the newly generated trapping sites and the HELP effect promotes material failure by accelerating void growth. The fracture process is strongly affected by the stress state subjected by the material unit characterized by the stress triaxiality and Lode parameter. Lastly, a numerical framework is developed at the macroscale by incorporating hydrogen transport in steels and the resulting HELP and HEDE (hydrogen enhanced decohesion) mechanisms into a phase field model to simulate hydrogen embrittlement and crack propagation in engineering components. The results show that both HELP and HEDE reduce the specimen’s load carrying capacity. With properly chosen model parameters, the numerical model can predict crack propagation and ductile to brittle transition due to the presence of hydrogen.

GENERALIZED WEAK-FORM FREE ELEMENT METHOD FOR SOLVING MECHANICS PROBLEMS

Xiao-Wei Gao[1]*

[1]*Dalian University of Technology*

ABSTRACT

In this study, two generalization methods are proposed for extending the Weak-form Free Element Method (WFrEM) to solve heat conduction, solid and fluid mechanics problems by using general iso-parametric elements with and without internal nodes. The first generalization is performed based on the interface force/flux equilibrium of all elements around the collocation point as done in FEM and the second one is fulfilled by setting up a control volume within a free element as done in FVM.
These generalizations can break through the restriction of FrEM on using elements having at least one internal node. Besides, the free element control volume method presented in this study can overcome the difficulty in FVM that high-order solution schemes cannot be easily formed.

In the generalized WFrEM, also called the extended WFrEM, the meshes used in the standard FEM as well as the polygon/polyhedron elements can also be naturally used.

Detailed formulations of the generalized WFrEM for solving heat and mechanics problems are given in the study and a number of numerical examples will be analyzed to verify the correctness and stability of the proposed method.

Keywords: Generalized weak-form free element method, Extended weak-form free element method, Free element control volume method, Free Element Method, Heat conduction, Mechanics.

ABSTRACT

During the last three decades, the adjoint method has been widely used for aerodynamic design problems, since the calculation cost of the gradient for objective function is of the same order of magnitude of single flow solution, essentially independent of the number of design variables. For unsteady flow problems involving moving and deforming boundaries, the arbitrary Lagrangian Eulerian (ALE) formulation is particularly useful, as it combines the advantages of the Lagrangian and the Eulerian approaches and possibly reduces their drawbacks. And it can be easily combined with discrete adjoint method to solve unsteady aerodynamic optimization problems. However, if local modification of connectivity occurs, the discrete adjoint formulation is unavailable. In this paper, an accurate and efficient discrete adjoint method is presented for aerodynamic design optimization on three-dimensional dynamic meshes with local grid topology modification. The key issue here is the interpretation of local topology modification in the adjoint framework. An interpolation-free conservative ALE scheme, proposed by Guardone et al. [Arbitrary Lagrangian Eulerian formulation for two-dimensional flows, Journal of Computational Physics 230, (2011)], is applied to interpret the local topology modification as continuous deformation of the corresponding elements. Therefore, the discrete adjoint formulation can be naturally applied to these elements, analogous to the fixed-connectivity case. To avoid manual implementation of discrete adjoint, automatic differentiation (AD) is used to construct the duality-preserving discrete adjoint for the complete unsteady simulation. The advantages of the present method are as follows: (1) The present method can be used to arbitrary mesh movement or deformation, not only the case of small boundary displacement or the movement of multiple rigid bodies. (2) Most of the necessary terms in adjoint formulation are created by AD tool, so large part of discrete adjoint implementation is automatic and lengthy development time is avoided. (3) The adjoint formulation here is the exact adjoint of the tangent model, which is featured of exact duality preserving in the complete optimization problem. So the gradient of object function in adjoint model is perfect consistent with that obtained in tangent model or other exact numerical differentiation methods in machine precision. This feature also affords a convenient verification of discrete adjoint code. (4) Applying the AD tool selectively can dramatically improve the performance of AD based adjoint implementation, achieving similar efficiency to hand-coded version. Several three-dimensional design problems are presented to demonstrate the effectiveness of the proposed method.

A MECHANICAL-ELECTRIC COUPLING MODEL FOR SUPERCONDUCTING CORC CABLES

Yuanwen Gao[*1], Jiangtao Yan[1] and Shilin Zhang[1]*

[1]*Lanzhou University*

ABSTRACT

The conductor on round core (CORC) cable is new type supercondcuting cable, which is one of the best candidates for the next generation nuclear fusion magnets due to its simple preparation process, high current carrying and low AC loss. CORC cable in the preparation and operation process will be affected by mechanical force, thermal and electromagnetic load, will produce axial tensile, transverse compression and torsion and other different deformation. Therefore, the analysis on the mechanic-electric behavior is the key link of cable design and preparation. In this study, a coupling mechanical-electromagnetic model is established for CORC cable, and the influence of mechanical strain on its critical current is considered. The behavior of critical current degradation and AC loss of CORC cable under different deformation modes is discussed. The effects of cable winding angle, types gap, and the material properties of the cable core structure on the mechanical-electric behavior of CORC cable are further parameterized studied, and some experimental phenomena are explained. All the results indicate that the model has a good prediction accuracy for different deformation mode. For example: for the torsion case: compared to the previous model, the error between the simulation results and the experiment is reduced from 46% to less than 10%.

A FRACTURE MECHANICS-BASED APPROACH FOR CYLINDRICAL CAVITY EXPANSION IN THE ELASTOPLASTIC MEDIUM

Yue Gao[1], Zhanli Liu[1], Zhuo Zhuang[1] and Emmanuel Detournay[2]*

[1]*Tsinghua University*
[2]*University of Minnesota*

ABSTRACT

Cylindrical cavity expansion problems in the elastoplastic medium are common in geomechanics, including mining and petroleum engineering. The elastoplastic constitutive model is often used to analyze these problems, leading to a continuum solution. However, localized deformation caused by softening is generally observed in geomaterials, and hence the fracture mechanics-based method becomes an alternative approach to the problem.

In this approach, instead of assuming the existence of a plastic zone surrounding the cavity, a group of evenly distributed shear fractures initiates and propagates from the cavity boundary in the elastic medium. The Mohr-Coulomb criterion is enforced over the shear fractures to establish the relationship between the normal and shear stresses on the fracture surface. The minimum plastic dissipation criterion is adopted to determine the fracture propagation direction. The problem is discretized by the displacement discontinuity method, and then solved numerically by an optimization algorithm [1-3].

The numerical simulation solution converges to the traditional plastic constitutive model as the number of shear fractures increases, where the convex hull of the fracture tips is interpreted as the plastic zone. Additionally, the external loading and radial displacement over the cavity boundary also converge to the solution obtained by the traditional elastoplastic solution. This fracture mechanics-based approach provides us with a novel tool for investigating the softening and localization behavior of the elastoplastic medium.

SYMMETRY-ENFORCING NEURAL NETWORKS FOR CONSTITUTIVE MODELING

Kevin Garanger[*1] and Julian Rimoli*[1]

[1]*University of California, Irvine*

ABSTRACT

The use of machine learning techniques to homogenize the effective behavior of arbitrary microstructures has been shown to be not only efficient but also accurate. In a recent work, we demonstrated how to combine state-of-the-art micromechanical modeling and advanced machine learning techniques to homogenize complex microstructures exhibiting non-linear and history dependent behaviors [1]. The resulting homogenized model, termed smart constitutive law (SCL), enables the adoption of microstructurally informed constitutive laws into finite element solvers at a fraction of the computational cost required by traditional concurrent multiscale approaches. In this work, the capabilities of SCLs are expanded via the introduction of a novel methodology that enforces material symmetries at the neuron level, applicable across various neural network architectures. This approach utilizes tensor-based features in neural networks, facilitating the concise and accurate representation of symmetry-preserving operations, and is general enough to be extend to problems beyond constitutive modeling. Details on the construction of these tensor-based neural networks and their application in learning constitutive laws are presented for both elastic and inelastic materials. The superiority of this approach over traditional neural networks is demonstrated in scenarios with limited data and strong symmetries, through comprehensive testing on various materials, including isotropic neo-Hookean materials and tensegrity lattice metamaterials. This work is concluded by a discussion on the potential of this methodology to discover symmetry bases in materials and by an outline of future research directions.

PHYSICS-INFORMED NEURAL NETWORKS FOR BLOOD FLOW INVERSE PROBLEMS

Jeremias Garay[*1], Jocelyn Dunstan[1], Sergio Uribe[2] and Francisco Sahli Costabal[1]*

[1]*Pontifical Catholic University of Chile*
[2]*University of Monash*

ABSTRACT

Physics-informed neural networks (PINNs) [1] have emerged as a powerful tool for solving inverse problems, especially in cases where no complete information about the system is known and scatter measurements are available. This is especially useful in hemodynamics since the boundary information is often difficult to model, and high-quality blood flow measurements are generally hard to obtain. In this work, we use the PINNs methodology for estimating reduced-order model parameters such as the ones used in the Windkessel model [2], and the full velocity field from scatter 2D noisy measurements in the ascending aorta. The results show robust and accurate parameter estimations when using the method with simulated data, while the velocity reconstruction accuracy shows dependence on the measurement quality and the flow pattern complexity. In conclusion, the presented methodology allows for solving clinical-relevant inverse problems in hemodynamics and complex coupled physical systems.

ABSTRACT

Modeling the coupled constitutive response and evolution of voids during plastic flow is critical for both component manufacturing and lifetime estimation purposes. To this end, we propose a new homogenized constitutive equation for modeling the stress-driven response of a rate-dependent, plastically anisotropic FCC single crystal with voids that deforms by plastic flow. The approach combines an analytically-based micromechanical component, which ensures theoretical consistency, with a data-driven symbolic regression component, which captures analytically intractable mechanisms. This hybrid approach also uses a systematic strategy to
identify problem-specific physics-informed solution requirements before conducting the data-driven component. The data-driven component consists of a physics-informed genetic programming-based symbolic regression (P-GPSR) algorithm that can exploit these solution requirements in conjunction with data. Here, the problem is contextualized as a multiform optimization problem in which the same set of data-driven components are embedded in a new gauge function and a new strain rate function. This contextualization helps mitigate potential overfitting and also expands the available training data to include both an effective stress measure and strain rate. This is also a multiobjective optimization problem, and the genetic algorithm benefits from a supplementary search and selection step that mitigates challenges satisfying competing objectives. Notably, the P-GPSR produced constitutive equations are theoretically consistent and the physical significance of all terms is known.

COMPRESSIVE STOCKING OPTIMIZATION FOR LYMPHEDEMA TREATMENT AT LOWER-LIMB

Aratz Garcia Llona[*1], Miquel Aguirre[23], Francesc Verdugo[4] and Stéphane Avril[1]*

[1]*École des mines de Saint-Étienne*

ABSTRACT

The lymphatic system is the responsible to collect the lymph and return to the bloodstream. Lymphedema is disease that causes swelling in the body's tissues due to accumulation of lymph, which usually takes places in the extremities. It may occur due to genetic reasons or as a result of damage to the lymphatic system, such as after cancer treatment. This research focuses on the treatment of lymphedema at lower-limb through compression stockings, which is a widely applied measure to reduce the volume of edemas [1].

Despite effective at a clinical level, the use of off-the-shelf stockings with predefined sizes, reduces the efficiency. With the long-term aim of designing patient-specific stockings, this study aims to develop real-time simulation tool to predict the most suitable stocking for a given patient. For such purpose, the use of standard Finite Element techniques falls short, as large models are needed which implies high computational cost.

For this purpose, a solution based on Reduced Order Model (ROM) is developed to compute, in real-time, the tissue hydrostatic stress distribution at the location of the lymphatic system [2]. Hydrostatic stress is a compressing pressure that squeeze lymphatic vessels (hypertension), which improves lymph circulation and increase the drainage capacity.

Starting from CT-scan of patients, the geometry is registered through a reduced number of parameters applying Free-Form Deformation algorithm. These parameters are the inputs of the ROM together with material properties. The ROM requires to solve a high number of FE models defined through the mentioned parameters to create a training dataset. Such pre-processing step is carried out through Gridap [3], an open source finite element method library written in Julia.

This method enables to design the most efficient compressive stockings considering the particularities of each patient, which improves the drainage of lymph at lower-limb. It provides the required compressive pressure applied by the stocking which is an important fact to design the patient-specific stockings.

ROTOR-STATOR DESIGN TO TRANSPORT COMPRESSIBLE TURBULENT FLOW UNDER THE TOPOLOGY OPTIMIZATION METHOD

Luis Fernando Garcia Rodriguez[*1], Diego Hayashi Alonso[1] and Emilio Carlos Nelli Silva[1]*

[1]*University of São Paulo*

ABSTRACT

The energy consumed by a compressor heavily depends on the design of the rotor-stator coupling. Both components play distinct roles: the rotor for compression and the stator for directing the flow. Simultaneous analysis of both components is required to avoid miscalculations arising from aerodynamic effects, such as tip vortexes [1]. The interaction between the rotor and stator in fluid leads to pressure fluctuations and is imperative to comprehensively characterize and control these fluid excitations, which are compressible due to rapid changes in flow density, direction, and velocity. Therefore, the current research develops a rotor-stator design considering the flexibility of the topology optimization method, which has shown efficient and innovative designs for the transport of incompressible flow at rotor-stator systems [2]. This research novelty relies in the transport of compressible turbulent steady-state flow under a multi-reference frame domain that separates the rotating part from the stator section. The primal state equations are solved using the rhoSimpleFoam solver from OpenFoam, and the adjoint system is solved using automatic differentiation from FENICS (dolfin-adjoint) [3]. The IPOPT optimizer is used, and a material density-based distribution is employed to define the permeability of the cell's domain. The method is validated through a sensitivity analysis, and 2D rotors-stator couplings are optimized under different rotations, showing the importance of optimizing both systems under a multi-reference frame approach successfully.

ENHANCING FLUID MECHANICS ANALYSIS: APPLYING ORDER-TRUNCATED IMAGINARY ALGEBRA FOR EFFICIENT SENSITIVITY ANALYSIS IN FLUID SIMULATIONS

Manuel Garcia Ruiz[*1] and Alexandra Vishnevskaya*[1]

[1]*Angelo State University*

ABSTRACT

Sensitivity analysis in fluid mechanics plays a critical role in understanding and predicting how changes in specific parameters or conditions affect the behavior of fluid flow systems. Fluid mechanics, with its inherent complexity due to the behavior of fluids under various conditions, benefits greatly from such analysis.
Sensitivity analysis is used to understand fluid behavior: fluid systems can be susceptible to parameter changes like velocity, pressure, temperature, and viscosity. Sensitivity analysis helps predict how small changes in these parameters can lead to significant variations in fluid behavior.
Hypercomplex differentiation has been successfully used to calculate high-order derivatives of nonlinear problems [1]. In our approach, we apply Order-Truncated Imaginary (OTI) algebra for conducting sensitivity analysis on fluid simulations. This method enables high-order differentiation and is computed as a postprocessing phase, thus not interfering with the finite element simulation [2]. The process begins by determining the solution at each node for a specific time step, achievable through various simulation software. Following this, we compile the global tangent matrix. Subsequently, we establish a system of equations and calculate the imaginary components of the solution, which contain the derivatives with respect to design parameters. OTI algebra facilitates the assessment of sensitivities in fluid dynamics problems as a postprocessing activity, eliminating the need for additional computational resources in the finite element analysis. High-order derivatives of the fluid velocity were computed using the presented methodology. Results showed excellent agreement when compared to known analytical solutions.

NUMERICAL AND EXPERIMENTAL ANALYSIS OF PEEL FAILURE PROGRESSION IN ADHESIVE JOINTS OF GFRP VIA T-PEEL TEST

Eusebio Garcia Vasquez[*1], Jose A. Manzo Preciado[1], Jairo A. Paredes[2] and Julio A. Rodriguez Gonzalez[1]*

[1]*Centro de Ingeniería y Desarrollo Industrial*
[2]*Universidad Nacional de Colombia*

ABSTRACT

This paper focuses on numerically modeling peel failure in adhesively bonded fiberglass reinforced composite (FRP) joints, employing T-peel tests to investigate the influence of fiber orientation, adhesive thickness, and substrate thickness on peel strength. The applied methodology, utilizing the serial/parallel mixing theory as a constitutive law manager, is complemented by the integration of constitutive models capturing damage in both the adhesive and substrate. This cohesive approach enables a nuanced representation of the interaction between these materials, specifically modeling the substrate-adhesive interface.

To validate results, a design of experiments is carried out that examines the thickness of the adhesive, the number of substrate sheets and different fiber orientations. The validity of our approach is confirmed by obtaining accurate comparisons with experimental results.

The applied approach, which employs a numerical modeling based on serial-parallel mixing theory and constitutive damage models, results in a robust tool for adhesive bond design and optimization, as it accurately predicts peel failure propagation and also provides a deeper understanding of the failure mechanism by providing a stress distribution along the substrate-adhesive interface.

STOCHASTIC DESIGN OF MULTI-MATERIAL WELLBORE PLUG PLACEMENT PROCESSES

Carlos Garcia Verdugo[*1], Eilis Rosenbaum[2], Matthew Grasinger[3] and John Brigham[1]*

[1]*University of Pittsburgh*
[2]*National Energy Technology Laboratory*
[3]*Air Force Research Laboratory*

ABSTRACT

Plugging orphaned and abandoned wells with a combination of bentonite clay gel and cement slurry has emerged as a cost-effective strategy for preventing the migration of unwanted fluids and ensuring zonal isolation. Despite the efficacy of this approach, challenges persist, such as the potential loss of the bentonite component of the plug and unexpected leakage. Prior work has shown the capability of the Lattice Boltzmann Method (LBM) to estimate the resulting plug positioning and other important factors when placing layered multi-material plugs comprised of bentonite clay gel and cement slurry (Garcia, et al. 2023). The current research builds upon this previous work by expanding the plug placement analysis, and ultimately design approach to incorporate the ubiquitous uncertainty that exists in plug placement processes, including variability in wellbore conditions (e.g., borehole diameter) and process parameters (e.g., pumping velocity). As previously, the LBM is used as the deterministic solver to simulate the effects of the rheological properties of cement slurry and bentonite clay gel, as well as wellbore condition in wellbore plugging operations, due to its capability to capture the complex fluid interactions inherent in multi-material systems. The LBM is then combined with a Monte Carlo approach that uses response surface modeling for computational efficiency to evaluate the effects of uncertainty in the system parameters on the plug placement process. In addition to the details of the analysis strategy, results will be presented examining the effects of the rheological properties of cement slurry and bentonite during realistic plug placement scenarios accounting for uncertainty. Moreover, this analysis will be used to explore the design elements of the plugging process (e.g., material properties, pumping velocity, etc.) that are needed to ensure reliable plug placement to achieve zonal isolation.

VIRTUAL ELEMENT APPROXIMATION OF EIGENVALUE PROBLEMS

Daniele Boffi[1], Francesca Gardini[2] and Lucia Gastaldi[2]*

[1]King Abdullah University of Science and Technology
[2]University of Brescia

ABSTRACT

Virtual Element Methods (VEM) for the approximation of PDE eigenvalues problems has been adopted and analyzed by several authors, starting from standard elliptic problem, including hp VEM, nonconforming VEM, and mixed schemes, the Steklov eigenvalue problem, plate models, linear elasticity, to transmission problems.
An important feature of VEM, as compared to standard FEM, is that suitable stabilizing forms, depending on appropriate parameters, have to be introduced in order to guarantee consistency and stability of the approximation. Indeed, as it is well known, the matrices assembled for the discretization are computed by the use of suitable projection operators. This is due to the virtual nature of the basis functions corresponding to the degrees of freedom at the interior of the elements. The lack of knowledge of such basis functions is compensated by adding appropriately chosen stabilization terms. Typical theoretical results state that, for given choices of the stabilization parameters, the discrete solution converges to the continuous one with optimal order asymptotically in h or p. It is implicitly understood that the convergence behavior depends on the choice of the parameters.
Recently, it was observed [1,2] that in the case of eigenvalue problems, the presence of the stabilizing partameters may introduce artificially additional eigenmodes and we have to make sure that they will not pollute the portion of the spectrum we are interested in.
In [1] we presented a systematic study of the eigenvalue dependence on the parameters. If the discrete eigenvalue problem can be written in the form $Au = \lambda Mu$, with A and M depending linearly on the stabilizing parameters α and β, respectively, then the quick and easy recipe is to pick a sufficiently large α and a small (possibly zero) β.

CONSISTENT, ACCURATE UNSTEADY ADJOINTS FOR MESH AND MODEL ADAPTIVITY

Vikram Garg[*1] and Roy Stogner*[2]

[1]*O-Logic*
[2]*Idaho National Labs*

ABSTRACT

We present general, automated adjoint techniques and implementations for implicit unsteady solvers. Particular attention is paid to the correctness and consistency of the adjoint error estimate, which reveals a non-intuitive adjoint weighting for implicit-Euler timesteppers. The unsteady adjoint is used to drive mesh adaptivity between timesteps, while an adaptive time solver is used to adapt timesteps, providing a spatio-temporal adaptive numerical scheme. Numerical experiments illustrate the role of the adjoint solution in revealing and resolving non-local sources of error for both the space and time discretization.

INFERENCE OF FOKKER-PLANCK EQUATIONS FOR THE DYNAMICS OF POPULATIONS

Krishna Garikipati[*1], Siddhartha Srivastava[1], Saem Han[2], Chengyang Huang[2] and Xun Huan[2]*

[1]*University of Southern California*
[2]*University of Michigan*

ABSTRACT

The population dynamics of a wide range of systems from human agents to biological cells evolve in response to internal rules. One common approach to them is via Markov Decision Processes, which address these problems by considering agents that take actions following a probabilistic policy function to make transitions between states. Also included in this framework is the notion of a reward function that the agents maximize by choosing an optimal policy. Such a description can be arrived at by algorithms of inverse reinforcement learning, which, however depend on the specification of the transition probability function. While the transition function may be constructed empirically, it may miss important mechanistic information and not generalize well. This has led to interest in obtaining the transition function by first inferring a partial differential equation--typically one that has the form of an optimal transport problem--from the data. When applied to real data that is multi-modal, represents high-dimensional probability densities, and furthermore is sparse, the optimal transport form may be difficult to learn. Here, recent advances in learning complex, push-forward maps of distributions assume importance. They allow the identification of optimal transport forms underlying non-Gaussian distributions. Furthermore, with the Fokker-Planck equation, they also allow the inference of the potential and diffusivity in parametric form. This is of special interest in the setting of cell dynamics where the potential field can arise from chemokine gradients and diffusivity models the random migration of cells. We will discuss recent advances in the inference of high-dimensional Fokker-Planck equations for this class of problems.

EFFECTS OF DIFFERENT ARCHITECTURAL CHOICES FOR AUXETIC METAMATERIALS ON IMPACT MITIGATION

Til Gärtner[1,2], S.J. van den Boom[2], J. Weerheijm[1] and L.J. Sluys[1]*

[1]Delft University of Technology
[2]Netherlands Institute for Applied Scientific Research (TNO)

ABSTRACT

For the mitigation of high-velocity impacts in military or space context, such as bullet and fragment impacts on personal protective equipment or space debris endangering satellites at orbital velocities, auxetic (negative Poisson's ratio) materials are claimed to offer distinct advantages. These materials provide enhanced indentation resistance, shear resistance, fracture toughness, and energy adsorption [1]. Auxetic materials are rare in nature and must be artificially designed. The process of designing materials with desired static properties is well understood in the linear regime. However, there has been little attention given to the behavior of architected materials under finite deformations at high deformation rates, which are expected during impact events. The resulting microstructural changes and how they affect the desired properties are not yet well understood.
A design and optimization process of these metamaterials, informed by their behavior in high-velocity impact, is necessary to enable the development of lightweight protective structures. Computational tools are needed to help engineers design these structures with the challenges of high-velocity impact scenarios in mind and to ensure a fast and reliable design process. For these tools a solid understanding of the material behavior under large deformations and high rates, including the highly dynamic and nonlinear effects in the heterogenous metamaterials, is crucial. A solid numerical representation of lattice structures is essential in achieving this understanding.
This research examines the effects of changes to the geometry due to large deformations at high strain rates in architected auxetic lattice materials. It presents the modelling of these lattice structures as an assembly of nonlinear beams in both static and dynamic conditions. We discuss the changes in the internal structure of different architectures and the subsequent response to localized high velocity impacts. To ensure a fair comparison, we first design various auxetic architectures with the same initial linear properties. We then illustrate the differences in the evolution of these properties under simple deformation modes and relate them to the observed variations in the impact mitigation performance of the studied architectures. We also illustrate the geometrical features of these architectures and their influence on the response. Finally, we demonstrate the performance of the nonlinear computational model through relevant numerical examples.

LAGRANGE MULTIPLIER APPROACHES FOR THE FINITE ELEMENT APPROXIMATION OF INTERFACE PROBLEMS

Lucia Gastaldi[*1], Daniele Boffi[2] and Luca Heltai[3]*

[1]*University of Brescia*
[2]*King Abdullah University of Science and Technology*
[3]*Università di Pisa*

ABSTRACT

This talk is devoted to the finite element approximation of boundary value problems with interfaces. We shall consider a simple second order elliptic equation with discontinuous coefficients and present the most common approaches for its finite element discretization. One main feature of these methods consists in the construction of the mesh which can befitted or unfitted. In the first case the mesh is constructed such that the elements are not cut by the interface, so that the resulting approximation has optimal rate of convergence according to the regularity of the solution.
Unfitted meshes are independent of the position of the interface, leading possibly to non optimal rate of convergence of the approximation. In particular, we shall present methods based on the introduction of a Lagrange multiplier to enforce weakly the transmission conditions across the interface using unfitted meshes. These approaches can be efficiently extended to the finite element approximation of fluid-structure interaction systems.

EFFICIENT NUMERICAL SCHEMES FOR DEPTH-INTEGRATED LANDSLIDE RUNOUT MODELS

Federico Gatti[1], Carlo de Falco[2], Simona Perotto[2] and Luca Formaggia[2]*

[1]*Consiglio Nazionale delle Ricerche - Istituto di Matematica Applicata e Tecnologie Informatiche "E. Magenes" (CNR-IMATI)*
[2]*Politecnico di Milano*

ABSTRACT

The development of landslide early-warning systems is of paramount importance for cities located in mountainous areas.
Landslide dynamic encompasses various velocity scales and mechanical behaviors, presenting challenges in numerical modeling. In this work, we focus on landslide runout phase. While the comparison of the horizontal propagation length scale of the landslide with
the vertical one suggests the use of depth-integrated models, the different behavior of various types of landslide, such as debris flows and mudflows, entails the need to define more detailed mathematical models.

Two numerical frameworks are proposed: one for homogeneous moving slides, such as mudflows, and the other for landslides with significant solid-liquid interactions. These schemes adopt adaptive mesh refinement and domain partitioning on hierarchical quadtree meshes, enhancing scalability and efficiency. These numerical schemes can be seen as modifications of the standard two-step Taylor-Galerkin (TG2) scheme on quadtree meshes. We propose modifications aimed at ensuring well-balancing property and overcoming the numerical stiffness coming from diffusion-reaction terms, while guaranteeing scaling performances proper of the TG2 scheme. To ensure the well-balancing property we resort on a novel implementation of the path-conservative strategy in TG2 scheme and employ either second-order operator splitting methods or implicit-explicit additive Runge-Kutta scheme to face numerical stiffness coming from the finite-element discretization of diffusion-reaction terms.

Numerical experiments demonstrate the effectiveness of the schemes in terms of time-step selection, parallel performance, accuracy, and ability to deal with real topographies.

SOLVING DISTRIBUTIONALLY ROBUST SHAPE DESIGN PROBLEMS BY LEARNING SHAPE DERIVATIVES

Long Chen[1] *and Nicolas R. Gauger**[1]

[1]*University of Kaiserslautern-Landau (RPTU)*

ABSTRACT

Recently, a robust design optimization framework based on distributionally robust optimization (DRO) was proposed in [1]. DRO aims to minimize the worst-case expected performance in a set of distributions that is informed by observed data with uncertainties. It allows a new perspective to the formulation of robust design optimization problems, which is classically based on the mean-variance (standard deviation) optimization formulation pioneered by Taguchi [2]. Notably, DRO allows data-driven and statistically principled ways to quantify the trade-offs between robustness and performance, which contrasting the classical robust design formulation that captures uncertainty only qualitatively.

This study focuses on the solution of distributionally robust shape design problems in which the function and gradient evaluations are expensive. To accelerate the solution of the min-max design problems, we present a computational framework that learns not only the forward solution of an engineering problem, but also the respective first-order information, in our case, the shape derivatives. We will present computational results on complex engineering design problems, where the data for the training are obtained using the open-source software SU2.

A MULTISCALE IMMERSED BOUNDARY FRAMEWORK FOR ACOUSTIC STREAMING

Khemraj Gautam Kshetri[1], Amneet Pal Singh Bhalla*[2] and Nitesh Nama[1]

[1]*University of Nebraska-Lincoln*
[2]*San Diego State University*

ABSTRACT

Key Words: Acoustic Streaming, Immersed Boundary, Multiscale Methods

The integration of acoustics and microfluidics (“microacoustofluidics”) has shown great promise for precise manipulation of fluids and particles at microscales. Microacoustofluidic systems typically entail propagation of high-frequency acoustic waves through viscous fluids. Owing to the dissipation of the acoustic wave in viscous fluids, the fluid response is characterized not only by a high-frequency response of the fluid, but also by a slow mean flow, referred to as acoustic streaming. This nonlinear interaction of acoustic waves with viscous fluids can be harnessed to realize acoustically propelled microswimmers that can offer precise, tunable motion at microscales [1]. However, while acoustic streaming flows have been extensively studied, the understanding of immersed moving objects within streaming flows remains a work in progress.

In this work, we present an immersed boundary formulation to model the motion of acoustically propelled microswimmers. We leverage an explicit time scale separation approach to split the problem into a periodic first-order problem that models the fluid’s high-frequency response, and a second-order time-averaged problem that describes the fluid’s mean response [2]. Notably, the second-order system is solved in terms of fluid’s mean Lagrangian velocity that significantly facilitates its coupling to the immersed object. The proposed formulation is numerically implemented within the open-source Immersed Boundary Adaptive Mesh Refinement (IBAMR) framework [3]. In addition to the details of the formulation and its implementation, we present numerical test cases to highlight the salient features and capabilities of our implementation.

ENHANCED HYDRODYNAMIC DIFFUSION IN DENSE BINARY ACTIVE SUSPENSIONS

Zhouyang Ge[*1], Shervin Bagheri[2] and Gwynn Elfring[1]*

[1]*The University of British Columbia*
[2]*KTH Royal Institute of Technology*

ABSTRACT

Active suspensions are fluids loaded with microscale energy-injecting particles such as cells, bacteria or active colloids. Because they are intrinsically out-of-equilibrium, active suspensions can display a number of fascinating phenomena, including enhanced diffusion, "bacterial turbulence", and even a "superfluidic" rheology.

Here, we numerically study the effect of incorporating passive particles into a dense active suspension using the Fast Stokesian Dynamics method. Specifically, we focus on individually immotile active particles, whose collective dynamics arise from the activity-induced many-body hydrodynamic interactions. In the absence of Brownian motion, both active and passive particles fluctuate vigorously in space, displaying pronounced hydrodynamic diffusion. The rotational diffusivity of all particles decreases monotonically with the fraction of passive ones; however, surprisingly, the translational diffusivity is nonmonotonic and can be significantly enhanced. This suggests a hydrodynamic coupling of the translational and rotational dynamics, which we find can be attributed to local ordering of the active particles as a result of hydrodynamic interactions. Using a toy model, where passive particles are treated as defects in a lattice of aligned force dipoles, we reveal a simple mechanism by which spatial correlations and inactivity give rise to enhanced diffusion. Our results uncover an unexpected effect of passive particles on the dynamics of active suspensions, providing new possibilities to enhance mixing and modulate mass transport in active fluids.

THE THERMO-MECHANICAL INTERACTIONS OF FAULT FRICTION

Bruce Gee[*12], Mengsu Hu[2] and Michael Manga[3]*

[1]University of California, Berkeley
[2]Lawrence Berkeley National Laboratory
[3]University of California Berkeley

ABSTRACT

The frictional behaviour of rocks and fault surfaces is important to a wide range of geological processes such as earthquake nucleation and induced seismicity. The frictional properties of rocks depend on many parameters including velocity, stress, temperature, chemistry, and material properties. The frictional behaviour is complex – for example, some rocks have been shown to transition from velocity-strengthening to weakening then back to strengthening as the rock temperature is increased [1]. In-situ fault conditions combine all these properties simultaneously leading to multi-physics behaviour that cannot be adequately studied at the laboratory scale.

While fault movement is a multi-physics phenomenon combining lubrication, chemistry, and deformation, here we focus primarily on the thermo-mechanical behaviour of fault movement. There is a strong two-way coupling behaviour as fault movement under large in-situ stresses induces significant flash heating of the fault surface [2]. The heating causes thermo-elastic expansion near the fault surface, which increases the contact stress, but the heating also softens and potentially melts the rock mass. The heating of the rock mass changes the stress state and frictional properties, which in turn changes the rate at which heat is generated.

In this study, we build a coupled numerical model to examine the in-situ thermo-mechanical behaviour of fault friction. We discuss the development of the numerical model and coupling methods, as well as the associated numerical challenges including contact, steep temperature gradients, large model scales, and convergence. We consider traditional friction models including the Coulomb and rate-and-state friction laws and compare them to more modern constitutive laws. We examine the thermo-mechanical effects and compare them to laboratory observations to determine which observed frictional effects can be attributed to coupled thermo-mechanical behaviours and which must be attributed to other factors. Last, we discuss the implications of geochemistry and lubrication on the coupled in-situ fault friction behaviour.

[4]*Oden Institute for Computational Engineering and Sciences*

ABSTRACT

The rapidly increasing demand for computer simulations of complex physical, chemical, and other processes places a significant burden on the shoulders of computational scientists and engineers. Despite the remarkable rise of available computer resources and computing technologies, the need for model order reduction to cope with these problems is an ever-present reality. Reduced-order models are imperative in making computationally tractable outer-loop applications that require simulating systems for many scenarios with different parameters and under varying inputs. They require that one numerically solves the differential equations describing the physical system of interest in low-dimensional reduced spaces, in contrast to the original full-order models. However, traditional model reduction techniques often fail to identify a low-dimensional linear subspace for approximating the solution to many physics-based simulations.

In this talk I will present a novel method for learning projection-based reduced-order models of physics-based dynamical systems using nonlinear manifolds. First, we learn the manifold by identifying nonlinear structure in the data through a general representation learning problem. The proposed approach is driven by embeddings of low-order polynomial form. The algebraic structure of the system that governs the problem of interest in the reduced space is revealed by means of a projection onto the nonlinear manifold. The matrix operators of the reduced-order model are then approximated, in a least-squares sense, using data-driven operator inference. Numerical experiments on a number of nonlinear problems demonstrate the generalizability of the methodology and the increase in accuracy that can be obtained over standard POD-based methods.

DATA-DRIVEN FUNCTIONAL NETWORKS FOR COMPLEX RESPONSE ANALYSIS

Charlotte Geier[*1] and Norbert Hoffmann*[12]

[1]*Hamburg University of Technology*
[2]*Imperial College London*

ABSTRACT

Network methods are a growing field of data-based approaches to the modeling and analysis of complex dynamical systems. These complex networks provide a complementary perspective to classical physics-based or neural network-based approaches, where the resulting model is often a black box. In this alternative approach to data-based modeling, networks formed by nodes connected via edges represent uni- or multivariate data sets. The complex network is obtained from measurement data using physics-based measures, such as recurrence properties. Network methods are popular in many disciplines, such as biology, climate research, and medicine. Examples of practical applications include determining coupling properties between different system components, tracking transient phenomena such as regime changes, and anomaly detection.

In this work, we use a recurrence-based network algorithm to generate a functional network from a synthetic data set of displacements of different model components. The underlying dynamical system is a classical model for a bladed disc, as in a wind turbine. The model consists of cyclically coupled nonlinear oscillators, which are known to exhibit complex dynamical behavior. In the functional network, each node represents a physical component of the model, and each edge represents a functional relationship between two elements. More precisely, the network nodes are connected based on a recurrence-based functional dependency obtained from the displacement time series, instead of their geometrical proximity or physical coupling.

The functional network reveals important information on the underlying dynamical system, such as the dimension of the dynamics in phase space. The network can also follow the propagation of an external disturbance through the system and track dynamical transitions stemming from changes in system parameters. These findings may provide a basis for a more efficient system analysis through better sensor placement based on determining relevant measurement locations. It can also help develop effective countermeasures against unwanted disturbances or vibrations in specific parts of the machine by exploiting the path the disturbance takes through the system. Additionally, early warning methods for critical transitions can be developed based on the functional network methods.

A NEW PARADIGM FOR ENGINEERING SIMULATIONS UNDER UNCERTAINTIES: TIME-SEPARATED STOCHASTIC MECHANICS

Hendrik Geisler[*1] and Philipp Junker*[1]

[1]*Leibniz University Hannover*

ABSTRACT

The widespread use of uncertainty quantification in engineering simulations is severely hindered by the lack of fast and accurate methods that can handle inelastic material behavior and local material fluctuations. Many existing methods in the framework of stochastic finite element methods can only be employed for linear elastic or simplified polynomial material models.

In contrast, the time-separated stochastic mechanics was directly developed for the fast and accurate uncertainty quantification of structures with inelastic material response.
The method is based on a separation of both of the system equations, i.e. the balance of linear momentum and the evolution equation for the internal variable(s), into stochastic but time-independent and deterministic time-dependent terms. This allows to approximate the stochastic behavior with a low number of fast deterministic FEM simulations and several fast matrix calculations. In comparison to classical Monte Carlo simulations a significant speed-up combined with a high accuracy can be be observed.

In this talk, we present the application of this promising new approach for the inclusion of stochasticity for a variety of different problems as viscoplastic materials, damage simulations and phase transformations.

LINEAR AND NON-LINEAR DIMENSION REDUCTION STRATEGIES FOR MULTI-FIDELITY SAMPLING UNCERTAINTY QUANTIFICATION: COMPLEXITY VERSUS PRECISION

Gianluca Geraci[*1], Andrea Zanoni[2], Xiaoshu Zeng[3], Matteo Salvador[2], Alison Marsden[2] and Daniele Schiavazzi[4]*

[1]*Sandia National Laboratories*
[2]*Stanford University*
[3]*University of Southern California*
[4]*University of Notre Dame*

ABSTRACT

Multi-fidelity sampling approaches are emerging as effective techniques for the evaluation of statistics of high-fidelity models, whenever the number of available evaluations is limited. In principle, these approaches work by leveraging the statistical correlation among quantities of interest generated by several data sources, and lead to a reduced estimator variance by combining the limited number of high-fidelity evaluations with a large number of low-fidelity model outputs (e.g., [1,2]). Unfortunately, for realistic applications in science and engineering, the correlation between low- and high-fidelity model outputs can be limited as a result of a different parameterization. For instance, the low-fidelity model can be formulated in terms of a simplified constitutive or closure model (e.g., Reynolds-Averaged Navier Stokes turbulence model) defined using a different number of parameters than the high-fidelity model (e.g., Large Eddy Simulation).

In recent studies [3,4], we have demonstrated that a shared input parameterization can be created by relying on low-dimensional manifolds. This shared parameterization is often capable of significantly increasing the correlation between models, thus enhancing the overall performance of multi-fidelity sampling strategies.

In this talk, we will consider both linear (Adaptive Basis, AB) and nonlinear (Auto-Encoders, AE) dimensionality reduction strategies to understand the computational trade-off between the complexity of identifying a shared manifold and the resulting correlation increase. We will also quantify the overall performance of the multi-fidelity estimators associated with these approaches. Finally, we will consider extensions of the estimators introduced in [3,4] that include the use of low-dimensional manifolds with dimensions greater than one, and the use of multiple low-fidelity models. We will illustrate the computational challenges associated with these extensions, and consider multiple test cases to compare and contrast strategies based on AB and AE.

INTELLIGENT DECISION SUPPORT SYSTEM FOR RAIL SANDING SYSTEM

Nima Gerami Seresht[1], Sadaf Maramizonouz[2] and Sadegh Nadimi[2]*

[1]Durham University
[2]Newcastle University

ABSTRACT

Low rail adhesion has a significant safety and financial impact on the railway industry and society (estimated at £350m/year in the UK). Currently, this phenomenon is managed by depositing dry sand through an onboard system that the operator subjectively controls while, inevitably, neglecting several efficiency factors. However, both contamination and sanding cause surface damage, wear, and fatigue of railway tracks. Additionally, if not adequately controlled, an excessive amount of sand can interface with the ability of track circuits to detect a train, called wheel-rail isolation, causing safety issues. Accordingly, a prominent need was identified by the research and industry communities for analysing the several parameters that affect the rail sanding systems' efficiency and determining optimal decisions regarding the application of these systems.

Whilst sanding parameters such as the location of the nozzle, frequency of application, and angle of attack have been extensively studied, the lack of understanding of the physical and chemical processes at rail-wheel interfaces has been acknowledged by industry experts to be of key importance and fundamental to overcoming the challenges. Additionally, accounting for the inherent subjectivity associated with the human decision-making process is essential for communicating the results of such analysis with train operators more effectively.

In this project, we have developed an intelligent and intuitive framework to support train operators in making rail sanding decisions in real time. Our framework, named INSURERS (INtelligent deciSion sUppoRt systEm for Rail Sanding), utilises a high-fidelity digital twin of rail sanding systems and combines it with advanced machine learning and granular computing techniques to deliver an intelligent and intuitive framework train operation in low adhesion conditions.

Our first contribution is utilising deep learning to replicate our high-fidelity discrete element modelling of rail sanding systems [1], which significantly reduces the simulation computational cost; hence, we realised the use of high-fidelity digital twin frameworks in real-time applications. Our second contribution is using granular computing to replicate human's subjective decision-making process. Human decisions are often made based on subjective assessment of their surrounding environment (e.g., "low" adhesion, "very low" temperature). Consequently, an intuitive decision-support system needs to replicate such subjective decision-making procedures [2]. Our future contributions will include the quantification of human factors and field measurement in the proposed framework.

FLEXIBLE MACRO-MICRO COUPLING FOR SPATIAL SIMULATION OF THE LIVER

Steffen Gerhäusser[*1], Lena Lambers[1], Luis Mandl[1], Ishaan Desai[1], Benjamin Uekermann[1], Matthias König[2] and Tim Ricken[1]*

[1]University of Stuttgart
[2]Humboldt-University of Berlin

ABSTRACT

Liver disease is one of the leading causes of death in the developed world. Because irreversible liver damage and end-stage liver disease may require high-risk surgery such as liver resection or transplantation, simulation-based risk assessment has enormous potential for clinical application [1]. For example, personalized drug dosing and pharmacokinetics can be simulated prior to actual treatment. Here, we present a flexible macro-micro coupling based on the interplay between the tissue and the cellular scale using FEBio, libRoadRunner and preCICE [2]. The deformation, flow and transport processes at the macro scale are represented by a system of coupled partial differential equations (PDEs) within the Theory of Porous Media (TPM). The described advection-diffusion system is extended by reaction terms that model cellular functions such as metabolism of the hepatocytes that form the tissue matrix. Each hepatocyte can be modeled as an individual microsimulation using ordinary differential equations (ODEs). Reproducible and efficient data communication between the domain-specific solvers FEBio (PDE) and libRoadRunner (ODE) can be achieved using the coupling library preCICE. The micro simulations are adaptively controlled by the MicroManager [3], a software tool of the preCICE ecosystem. libRoadRunner uses the Standard Biology Markup Language (SBML) as input format and provides a flexible model exchange to couple different systems on the micro scale. On the macro scale, generic software layers are used to maintain the flexibility of FEBio. We demonstrate the system using the example of the SPT model, which describes the conversion of a substrate (S) into a product (P) with the formation of a toxic by-product (T) as a showcase.

APPLICATION OF GPU PROCESSING TO THE ELASTIC-PLASTIC IMPACT CODE (EPIC)

Charles Gerlach[*1]*

[1]*Southwest Research Institute*

ABSTRACT

Graphics Processing Units (GPUs), specialized chips designed to help computers render large numbers of 3D geometries, have been increasing in computational power over the years. Because they are designed to do similar computations for millions of objects, the GPU has been optimized for the single-instruction-multiple-data (SIMD) computing model. As GPUs have become more powerful, they have been applied to many different computational mechanics problems. For some problems, like using the spectral method on crystal plasticity, the vast majority of the problem can be done on the GPU, leading to remarkable speed-ups compared to running on a general-purpose Central Processing Unit (CPU).

For Lagrangian Finite-Element problems, GPUs can be helpful for certain algorithms in the code, such as the strain/stress computations in the finite elements and meshless particles, but they will not be efficient for every algorithm. The Elastic-Plastic Impact Code (EPIC) is both a research and production Lagrangian Finite-Element code that has been primarily funded and used by various branches of the Department of Defense (DoD). EPIC has long used the Message-Passing Interface (MPI) for parallelism, and has more recently added OpenMP compiler directives (which also use the SIMD computing model). OpenMP can be used in conjunction with MPI to increase EPIC's scalability. Using GPUs via the OpenACC programming interface instead of OpenMP for the thread-based parallelism will open up further possible speedups of the stress/strain computations for both elements and particles, as well as the contact algorithm.

This presentation will show the relative speeds of doing the element, particle, and contact computations on CPUs and GPUs on various architectures.

MIMETIC SPECTRAL ELEMENT DISCRETIZATION OF CONTINUUM MECHANICS

Marc Gerritsma[*1] and Revanth Sharma*[2]

[1]*TU Delft*
[2]*TU Eindhoven*

ABSTRACT

In mimetic discretization methods we distinguish between conservation laws, definitions and constitutive laws. Since conservation laws and definitions are topological, we demand that these relations are discretized without any reference to discretization parameters such as the element size, time step or polynomial order used in the method. The metric-dependent part in which these numerical parameters do appear, stems from the constitutive relations, which, in turn, follow from the energy relations.
In this talk all physical variables will be interpreted as (co)vector-valued differential forms and duality will be employed to design a discretization which meets the above requirements.
As an example, the mimetic spectral element method is applied to an elasticity problem, [1,2] for which exact conservation will be demonstrated.

THE INTERNODES METHOD FOR THE SOLUTION OF PDES IN MULTIDOMAIN SETTINGS FEATURING NON-CONFORMING INTERFACES

Paola Gervasio[*1]*

[1]*Università di Brescia*

ABSTRACT

The Internodes method is an interpolation-based approach for dealing with the solution of PDEs in domains partitioned into non-overlapping subregions featuring non-conforming interfaces. The non-conformity could be of geometric type (non-watertight interfaces) and/or discretization type (when the mesh sizes and/or the local polynomial degrees inside the subdomains differ). The discretization inside each subdomain can be achieved by a Galerkin-based method, e.g., Finite Elements, Spectral Elements, or Isogeometric Analysis.

The method was introduced in [1] and its convergence was analyzed in [2] for hp−fem. In particular, when the mesh sizes in the two adjacent subdomains decrease uniformly, then the method achieves optimal convergence in the broken-energy norm with respect to the maximum mesh size, exactly as the well-celebrated Mortar method does. Moreover, it has been proved that Internodes is conservative, that is it preserves some quantities (typical of the continuous solution of the specific PDE) at the interface of the decomposition. For example, in the case of linear elasticity problems, it preserves the balance of the forces and the null total work at the interface. The Internodes method has been applied with success to multiphysics problems, contact problems, and, recently, in the context of Reduced Basis Methods [3].

In this talk, I will present the Internodes method and its applications in different contexts, as a result of the collaboration with many co-authors: Pasquale Africa, Guillaume Anciaux, Michele Bucelli, Agnese Dall'Olio, Simone Deparis, Davide Forti, Andrea Manzoni, Federico Marini, Alfio Quarteroni, Yannis Voet, Filippo Zacchei, Elena Zappon.

STABILITY OF NANOSCALE GAS BUBBLE TRAPPED BY A SURFACE DEFECT: A MOLECULAR DYNAMICS STUDY

Ali Ghamartale[*1], P. Amy Tsai[1] and Tian Tang[1]*

[1]*University of Alberta*

ABSTRACT

Surface defects are known to be able to trap and stabilize nanobubbles, which can impact applications in industry, such as improving the separation process [1] and reducing drag force [2]. The stability of nanobubbles is highly depend on thermodynamic conditions and fluid properties as well as surface characteristics such as wettability and defect shape. Although a few mechanisms, such as oversaturation and contact line pinning, have been proposed in the literature, there are controversial opinions which are rooted in the limited resolution of experimental approaches [3]. In this work, molecular dynamics simulations are performed to investigate how the stability of a nanobubble trapped in a surface defect (cavity) is affected by the shape of the cavity, surface wettability, and the gas type. For this purpose, the investigation considers two cavities with the same opening width and depth (one V-shaped and the other square-shaped), two types of silica-based surfaces with different levels of wettability (hydroxylated and methylated, the former having greater water wettability), and two types of gas (carbon dioxide and nitrogen). The results show that regardless of the cavity shape, the gas molecules have a higher probability to position close to the corners of the defects. The square-shaped cavity exhibits better capability in adsorbing and stabilizing the gas molecules. Both nitrogen and carbon dioxide are able to form hydrogen bonds with the hydroxylated silica, enhancing their stability near the surface. However, nitrogen shows stronger hydrogen bonding. Together, the highest nanobubble stability is observed for the nitrogen trapped in the square-shaped cavity of the hydroxylated silica. Results revealed from molecular simulations can be used to design surface features that are better at trapping and stabilizing nanoscale gas bubbles without changing thermodynamic conditions or fluid properties.

NEW PARADIGMS IN DATA ASSIMILATION

Roger Ghanem[1]*

[1]*University of Southern California*

ABSTRACT

Partial differential equation provide a map from initial/boundary conditions and parameters to field variables that vary at each point of space and time. This level of completeness, while suitable for understanding the behavior of physical processes, is often too detailed for the purpose of data-based inference. This is because, often, operational and experimental measurements pertain to patterns that form coherent structures that are not, themselves, constrained by the same physical laws as the field variables. This situation is increasingly common with modern sensing capabilities that are matched with flagship simulation resources.

In this talk I will describe a new paradigm for data assimilation that is adapted to this reality. The new methodology maintains a firm grounding in probabilistic concepts while permitting statistical conditioning on arbitrary observables and inferences about equally arbitrary quantities of interest. I will show examples from a variety of applications that include materials science and reactive flows.

ABSTRACT

A digital twin is a computational model of a physical system that continually updates its knowledge of the system by assimilating observational data, and in turn informs decisions and controls the system to achieve a desired goal, over a continually evolving time horizon. When the model takes the form of a system of PDEs, and when the data assimilation and optimal control problems must be solved under uncertainty, the computations underlying digital twins quickly become prohibitive. Efficient surrogates of the maps from parameters and decision variables to quantities of interest, which involve solution of the forward PDEs, is key to making digital twins tractable. Unfortunately, constructing such surrogates presents significant challenges when the parameter/decision dimension is high and the forward model is expensive, which limits the amount of available data.

Deep neural networks (DNNs) have emerged as leading contenders for overcoming the challenges of constructing infinite dimensional surrogate models. These have become known as neural operators. We show that black box application of DNNs for problems with infinite dimensional parameter fields leads to poor results when training data are limited due to the expense of the model. Instead, by constructing a network architecture that captures the geometry of the map---in particular its smoothness, anisotropy, intrinsic low-dimensionality, and input-output derivatives---one can construct a dimension-independent reduced basis neural operator that is accurate and optimization-aware using limited training data. We employ this reduced basis neural operator to make tractable the the solution of PDE-constrained Bayesian inverse problems and optimal control under uncertainty. Applications are shown to problems governed by wave propagation, hyperelasticity, and viscous flows.

TOWARDS REAL TIME BAYESIAN INVERSION AND PREDICTION OF MEGATHRUST TSUNAMIS

Stefan Henneking[1], Sreeram Venkat[1], Milinda Fernando[1] and Omar Ghattas[1]*

[1]The University of Texas at Austin

ABSTRACT

Tsunamis generated from megathrust earthquakes are capable of massive destruction. Efforts are proceeding to instrument subduction zones with seafloor acoustic pressure sensors to provide early warning for tsunamis. Our goal is to employ this pressure data, along with the coupled acoustic–gravity wave equations, to infer the spatiotemporal seafloor motion in a real time early warning system. The solution of this inverse problem then provides the boundary forcing to forward propagate the tsunamis toward populated areas along coastlines. Solution of the forward problem alone—the acoustic-gravity wave equations in a 3D compressible ocean—entails severe computational costs stemming from the need to resolve ocean acoustic waves with wavelength of order 150 m in a subduction zone of length ~1000 km and width ~200 km. This can require O(minutes) on a large GPU cluster. The inverse problem formally requires thousands of forward wave propagations; thus our goal appears to be intractable. We propose a novel approach to enable the accurate solution of this pair of inverse and prediction problems in real time, i.e., in a few seconds. The key is to exploit the structure of the parameter-to-observable map, namely that it is a shift-invariant operator, and its block Toeplitz structure permits fast FFT diagonalization. We discuss the Bayesian formulation, consistent discretization, and fast GPU solution. Application to inference of earthquake-induced tsunamis on the Cascadia subduction zone will be presented.

MESOSCOPIC SIMULATIONS OF PROTEIN-INDUCED MORPHOLOGICAL CHANGES IN ENDOPLASMIC RETICULUM

Emad Ghazizadeh[*1] and Wylie Stroberg*[1]

[1]*University of Alberta*

ABSTRACT

The endoplasmic reticulum (ER) represents a highly dynamic intracellular network, characterized by a complex arrangement of membrane tubules and sheet-like cisternae. This complex morphology is perpetually in flux, responding to environmental cues. Key to this adaptability are various proteins within the ER membrane, orchestrating its structure in response to internal and external signals. Among these proteins, Climp-63 plays a central role in shaping sheet-like membrane structures within the ER. Climp-63 achieves this by forming dimeric struts across the ER lumen, promoting the development of expansive cisternae. Within the ER lumen, the accumulation of unfolded proteins leads to increased pressure and subsequent expansion of the ER lumen. In a counterbalancing mechanism, Climp-63 dimers bind across the lumen, mitigating the expansion induced by elevated unfolded proteins. This equilibrium of ER membrane shape is contingent upon the dynamic interplay between Climp-63 concentration and the unfolded protein loads within the ER lumen, aspects that are not fully understood. This study aims to show mesh-free simulation of ER membrane under influence of protein-driven remodelling membrane and the unfolded protein loads using Mesoscopic Membrane-Protein (MesM-P) method providing experimental length and time scale which is unapproachable for all-atom and coarse-grained molecular dynamic method. The findings provide crucial insights into the adaptive nature of the ER, shedding light on its ability to swiftly respond to changing cellular conditions such as tubulation, protein oligomerization. Understanding these regulatory processes may have implications for unraveling broader cellular dynamics and may offer potential avenues for therapeutic interventions such as diabetes, cancer and aging in conditions influenced by ER dysfunction.

ABSTRACT

Global warming is impacting several crucial Earth systems, with the permafrost being among the affected components. To assess and predict the consequences of global warming, a numerical cryohydrogeological study on water and energy transfer in a forested, continuous permafrost site is conducted using the open-source fluid dynamics engine, OpenFOAM, with a parallel high-performance computing solver for the numerical simulation of permafrost dynamics. The numerical results reasonably replicate the measured soil temperature profiles and the dynamics of infiltrated waters observed in previous biogeochemical studies of the site of interest. However, these simulations can be enhanced by assimilating experimental measurements into the model through the development of a hybrid modeling approach. This approach aims to improve the physical simulation by incorporating data while maintaining the stability and the predictive capability of the dynamic model.

This work proposes a hybrid modeling process involving a spectral decomposition of the physical solution, combined with a deep neural network, to predict the augmented solution and correct the simulation. The final hybrid solution demonstrates a significant improvement in simulation accuracy when tested against future measurements, which were not part of the training set. Leveraging the resulting hybrid model, predictions are made regarding permafrost behavior in the coming years based on the currently accepted global warming scenarios.

QUANTIFYING UNCERTAINTY AND TUNING HYPERPARAMETERS OF THE UNSCENTED KALMAN FILTER USING A PHYSICS-AWARE LOSS FUNCTION FOR JOINT STATE AND PARAMETER IDENTIFICATION OF DYNAMICAL SYSTEMS

Esmaeil Ghorbani[1], Quentin Dollon[2] and Frederick Gosselin[1]*

[1]*Polytechnique Montréal*
[2]*Hydro-Quebec Research Institutes (IREQ)*

ABSTRACT

In this study, employing terminology akin to Physics informed neural networks (PINNs), we introduce a versatile physics-aware loss function designed for tuning the hyperparameters of the unscented Kalman filter (UKF). Selecting appropriate hyperparameters is vital for the performance of all Kalman filtering algorithms, a process that can be both time-consuming and challenging in various contexts. Our primary objective is to use the UKF to estimate the desired states and parameters of the underlying system based on a predefined parametric model. This is part of a larger project aiming to develop a data-driven digital twin for a hydro turbine. The innovative idea involves adjusting the hyperparameters in an external optimization loop, using a nonlinear mesh adaptive direct search algorithm (NOMAD) combined with a physics-aware loss function. A key benefit of this novel loss function is that it does not incorporate sensor data into the physics-aware loss function. Instead, it solely relies on estimated states and parameters to minimize the loss function and optimize the hyperparameters. Additional advantages include: 1) The UKF's ability to filter sensor data noise during the estimation process prevents fluctuations or overfitting in the tuning of hyperparameters; 2) The Physics-aware loss aids in quantifying the modelling and measurement uncertainty of the system, considering its underlying physics; 3) Since the loss function is uncorrelated to sensor data, the algorithm could function as a virtual sensor for systems with sparse sensor data; 4) The algorithm facilitates the identification of Multiphysics systems, especially when there's no direct measurement for specific physics aspects. For instance, it can identify the influence of an unobserved fluid state in fluid-solid interaction problems. We have selected various case studies to assess the performance of the loss function under extreme scenarios. These include systems with time-varying parameters, systems with large number of unknowns and sparse measurements, chaotic systems (like the Lorenz system), highly nonlinear systems (Bouc-wen model), and the wake oscillator problem in fluid-structure interactions. These extreme case studies are chosen in a way to demonstrate that our proposed loss function achieves better accuracy compared to traditional data-driven loss functions. We also compare the performance of the data-driven loss function with our new loss function and the results are presented.

OPTIMIZATION BASED SYNTHESIS WITH DIRECTED CELL MIGRATION

Soham Ghosh[*1] and Eric Havenhill*[1]

[1]*Colorado State University*

ABSTRACT

Collective behavior of biological agents such as herds of organisms and cells is a fundamental feature in the systems biology and in the emergence of new phenomena in the biological environment. Collective cell migration under a physical or chemical cue is an example of this fundamental phenomenon where individual cell migration is driven by the collective behavior of the neighboring cells and vice versa. The goal of this research is to discover the mathematical rules of collective cell migration using experimental data and testing the predictive nature of the models in independent experimental data. Such insight is made possible in this work with the hybrid use of dynamic mode decomposition (DMD) and optimal control theory. Both single and multi-cellular systems are simulated, including obstacle courses, using this framework. The results of this work show how cells collectively behave during their migration and also, opens the possibility of designing robotic cells for possible therapeutic purpose where the cell trajectory can be controlled.

CRYSTAL PLASTICITY PHASE FIELD MODEL WITH CRACK TIP ENHANCEMENT BY CONCURRENT ATOMISTIC-CONTINUUM MODEL

Somnath Ghosh[1] and Kishore Nair*[1]

[1]*Johns Hopkins University*

ABSTRACT

Crack propagation in polycrystalline metallic alloys is a complex multiscale process due to the interactions between cracks and dislocations. Dislocations nucleating from a crack tip contribute to the plasticity evolution in the vicinity of the crack, as well as to the crack propagation process. This paper systematically develops a method for enhancing the defect energy, accounting for crack-tip nucleated dislocations in the Helmholtz free energy density functional associated with the phase-field formulation of crack evolution in a coupled crystal plasticity finite element phase field (CPFE-PF) model. A concurrent crystal plasticity FE - molecular dynamics (CPFE-MD) model is developed to provide a basis and reference for this development. The CPFEM-MD model contains a crack in the MD domain. Dislocations emitted from the crack tip in the atomic domain are identified, transformed into dislocation densities across the interface into the continuum domain and subsequently propagated. The crack tip nucleated dislocation densities are subsequently used in the defect energy augmentation by modifying the accumulated slip to account for their contribution. A special method of identifying crack tips from the crack phase-field is proposed. The resulting CPFE-PF model thus captures the atomic scale mechanisms and shows a noteworthy deviation in the crack path and evolution of state variables near the crack tip in comparison with predictions without these contributions. State variables such as the effective plastic strain due to nucleated dislocations in the CPFEM-PF are validated by comparing them with predictions by the CPFE-MD model. A systematic study of the deformation mechanisms of Ti-6Al in the presence of a crack is conducted. The concurrent CPFE-MD model is used to create a database of the dislocation density and other state variables in the vicinity of the crack. A novel Bayesian inference methodology operates on this database to identify critical state variables that affect the crack tip nucleated dislocation densities. A genetic programming-based symbolic regression (GPSR) method is implemented to derive the functional form of the dislocation density evolution in terms of the critical state variables. Using the modified defect energy formulation, the evolution of crack and other state variables is compared. A significant deviation of the crack path and rate of propagation is observed. In conclusion, the overall framework and the derived functional form can be incorporated into any continuum crack model to account for the atomistic crack tip dislocation nucleation mechanism, independent of the microstructure and loading conditions.

DATA-DRIVEN BAYESIAN MODEL-BASED PREDICTION OF FATIGUE CRACK NUCLEATION IN NI-BASED SUPERALLOYS

Somnath Ghosh[*1] and George Weber*[2]

[1]*Johns Hopkins University*

[2]*NASA Langley Research Center*

ABSTRACT

This paper develops a probabilistic predictive model for crack nucleation in the Ni-based superalloy Ren\'e 88DT under fatigue loading. In this process, it fuses several statistical, data-driven methods operating on micromechanical and experimental data, as well as important mechanistic observations. The model systematically reduces a large set of experimentally obtained microstructural data and corresponding crystal plasticity-based micromechanical simulation results to a three-dimensional posterior probability density function (PDF) for crack nucleation. The framework identifies the three most important crack-delineating state variables in the microstructural material volume, viz. (1) the von Mises stress, (2) the maximum plastic slip rate, and (3) the plastic defect energy. This selection process is performed in a automated, data-driven manner without external intervention. It follows a statistically unbiased approach that makes an informed decision, while accounting for numerous experimental microstructures and mechanical simulations. The entire procedure, ranging from processing of experimental EBSD and SEM data, multiscale simulations for creating a database, to the development of the probabilistic crack nucleation model is implemented through an automated computational pipeline. Four serial, connected modules comprised this pipeline, viz.

- Collection of local microstructural data after fatigue loading and the cleaning and processing of EBSD data;
- Development of a concurrent multiscale model with the embedded image-based 3D microstructure in a self-consistent homogenized material;
- Multiscale simulations with different experimental microstructures to create a database of relevant micromechanical state variables;
- Formulation of a Bayesian crack nucleation model that identifies crack nucleation sites from the database of local state variable fields.

A simplified crack nucleation indicator is formulated to integrate the parallel slip concepts into a single scalar model.

OPTIMIZATION OF THE SPECIMEN GEOMETRY FOR ONE-SHOT DISCOVERY OF MATERIAL MODELS

[1]*ETH Zurich*
[2]*Weierstrass Institute for Applied Analysis and Stochastics*
[3]*Delft University of Technology*

ABSTRACT

We recently proposed an approach for Efficient Unsupervised Constitutive Law Identification and Discovery (EUCLID), which exploits machine learning tools such as sparse regression [1], Bayesian learning [2], or neural networks [3] to automatically discover material laws independent of stress data, but solely based on full-field displacement and global force data obtained from mechanical testing. The displacement field can be measured on the surface of a target specimen via digital image correlation (DIC).

An important feature of the approach is that, in principle, the discovery of the material law can be performed in a one-shot fashion, i.e., using only one experiment. However, this capability heavily relies upon the richness of the measured displacement data, i.e., their ability to probe the stress-strain space (where the stresses depend on the constitutive law being sought) to an extent sufficient for an accurate and robust discovery process. The richness of the displacement data and the robustness of the discovery process are in turn governed by the specimen geometry.

In the present study, we aim to optimally design the geometry of the target specimen via density-based topology optimisation approach. In this fashion, we perform automatic specimen design by maximising the robustness of the solution, i.e., the identified material parameters, given noisy displacement measurements from DIC. In this contribution, we shed light on the objective function, the topology optimisation framework, and a range of optimised topologies for orthotropic elasticity.

Keywords: Optimised specimen geometry; topology optimisation; discovery of material models; one-shot discovery.

UNFITTED HIGH-ORDER HYBRIDISABLE DISCONTINUOUS GALERKIN METHOD WITH EXACT NURBS GEOMETRIES APPLIED TO MICROFLUIDICS SYSTEMS

Matteo Giacomini[*1], Stefano Piccardo[2] and Antonio Huerta[1]*

[1]*Universitat Politècnica de Catalunya*
[2]*RMIT Europe*

ABSTRACT

The simulation of multi-fluid systems entails a series of numerical challenges related to the complex flow features that may arise from the interaction of different materials. Although high-order methods have demonstrated superior accuracy with respect to low-order methods, the difficulties to automatically generate high-order, curved meshes still limit their applicability in realistic scenarios. In this context, immersed boundary methods provide competitive solutions to handle complex geometries. In this talk, an unfitted, high-order hybridisable discontinuous Galerkin (HDG) method for two-fluid incompressible Stokes flows is introduced [1]. Boundaries and interfaces are described using NURBS curves embedded in a fixed Cartesian grid. The proposed immersed HDG method is suitable to exactly treat the geometry of the boundaries and the interfaces, circumventing the technical challenges of generating a high-order, curved mesh fitting the NURBS. Accuracy and consistency of the method are obtained by combining (i) the NURBS-enhanced finite element method (NEFEM) to perform numerical integration along immersed NURBS and in elements cut by NURBS curves [2]; (ii) a Nitsche's formulation to impose Dirichlet conditions on embedded surfaces; (iii) an automatic degree-adaptive procedure relying on the superconvergence property of the HDG postprocessed solution. Exploiting non-conforming meshes, exact NURBS geometry and high-order approximations, the method provides high-fidelity results on coarse meshes, independent of the geometric features of the domain, and maintains unknowns only on the mesh skeleton as in standard HDG [3], without introducing any additional degree of freedom on non-matching boundaries/interfaces. Numerical examples demonstrating the accuracy and robustness of the method will be presented, even in the presence of badly cut cells or faces, showcasing the suitability of the discussed approach to simulate microfluidics systems described using CAD geometries.

HYPER-DIMENSIONAL GAP FINITE ELEMENTS FOR THE ENFORCEMENT OF INTERFACIAL CONSTRAINTS

*Brian Giffin**[1]

[1]*Oklahoma State University*

ABSTRACT

In the classical theory of two-body contact, a single shared contact interface is considered between two continuum bodies, and is further discretized as such in the finite element setting. In general, however, the finite element mesh topology of two contacting bodies will be non-conforming at this shared interface, requiring the definition of a preferred or intermediate surface over which integral constraints may be evaluated. The specification of this interface is deemed to be somewhat arbitrary, but in practice the numerical solution of contact problems may exhibit sensitivity to the particular choice of intermediate surface. A further complication concerns the need to establish projective mappings between the discretized finite element surfaces and the chosen intermediate surface, particularly for the sake of evaluating the contact gap function between pairs of points on each of the two bodies.

As an alternative to the strategy previously described, a new methodology for the enforcement of contact constraints in the context of finite element analyses is proposed. The method entails an alternative representation of contact surface integrals by equivalently integrating over the interstitial – albeit degenerate gap volume between two contacting bodies. An auxiliary indicator field is defined on each body, and is used to represent the degenerate interstitial volume as a non-degenerate hyper-dimensional gap volume. Over this domain, the gradient of the continuously interpolated displacement field with respect to the indicator field yields the oriented displacement gap, which may be used in the formulation of contact inequality constraints. Discretization of the hyper-dimensional gap volume into conforming finite elements is explored, and is observed to offer several advantages over existing contact discretization methods: the proposed method does not require the computation of geometric intersections or projections; it exploits conventional Gaussian quadrature schemes to integrate the hyper-dimensional gap integrals with a sufficient degree of accuracy; and may be naturally and efficiently extended to represent contact between higher-order surfaces. The efficacy of the method is demonstrated on several benchmark problems. Continuing and future work is also discussed, with a focus on intended applications and extensions of the method.

PHYSICS GUIDED DATA-DRIVEN MODEL REDUCTION APPLIED TO C02 SEQUESTRATION

Eduardo Gildin[*1], Jungang Chen[1], Daniel Badawi Badawi[1] and Dimitrios Voulanas[1]*

[1]*Texas A&M University*

ABSTRACT

Meeting the net-zero emission paradigm will require a realignment of hydrocarbon production strategies with other forms of energy production (e.g., CCUS, H2, geothermal). Profiting from all these energy sources is only possible if accurate and timely prediction of behavior of fluids, including geomechanics issues in the subsurface, can be attained. Integrated reservoir studies are computationally expensive, especially for performance prediction and decision-making processes. Reduced-order modeling alleviates the computational burden of such simulations by running cheaper and faster models while preserving accuracy. This talk will show the developments of physics-based and Data-driven based proxy models for coupled flow and geomechanics in porous media. We high speedups and accuracy by by introducing several novel components to proxy modeling in porous media: (1) augment the state -space to yield a bi-linear system, and (2) introduce an autoencoder based on deep neural network to linearize physics reservoir equations in a reduced manifold by means of a Koopman operator, and (3) propose a physics-informed convolutional neural network (PICNN) time-varying well controls. While most of PICNNs in existing literatures worked on parameter-to-state mapping, our proposed network parameterizes the solutions with time-varying controls to establish a control-to-state regression. To capture the time-dependent relationship between inputs and outputs, the network is designed to mimic discretized state space equations. We train the network progressively for every time step, enabling it to simultaneously predict oil pressure and water saturation at each timestep. After training the network for one timestep, we leverage transfer learning techniques to expedite the training process for subsequent time step. We will show the performance of this new methodology starting with a small example involving a two-dimensional two-phase (oi and water) reservoir subject to a waterflooding plan with three wells (one injector and two producers). I will also note that our framework is extendable to other studies, especially in the case of CO2 storage processes. Our method achieves speedups of 1000X once properly trained.

ADVANCES ON THE USE OF CONDENSED HIGH ASPECT RATIO INTERFACE ELEMENTS TO MODEL COMPRESSIVE FRACTURE IN CONCRETE

Marcela Gimenes[1], Andrei F. V. dos Santos[1], Eduardo A. Rodrigues[1] and Osvaldo L. Manzoli[1]*

[1]*State University of Sao Paulo*

ABSTRACT

The accurate numerical prediction of concrete's failure under compression remains a complex task. Manzoli et al. [1] developed a Mesh Fragmentation Technique in which high aspect ratio interface elements are placed between the regular mesh elements, delineating the potential crack paths. More recently, Gimenes et al. [2] proposed an extension of this technique introducing a two-layer condensed interface element, this duplication is essential for describing compressive failure as a combination of debonding (mode-I) and sliding (mode-II) cracking on the interfaces, which are respectively ruled by tensile and shear-frictional constitutive damage models.

This study showcases the advances on the use of condensed high aspect ratio interface elements to model compressive fracture in concrete. The technique shows suitability for a mesoscale framework, successfully simulating the mesoscale uniaxial compression tests on conventional and recycled aggregate concrete [2] and allowing to understand the influence of each phase (aggregate, mortar matrix and interfacial transition zone) on the material response. In this case, the model can also easily simulate different friction conditions between the concrete specimen and the steel loading plates.

Moreover, on a macroscale framework, the technique suitability is tested to analyze structural size elements such as reinforced concrete beams and compare the different modes of failure associated with the element geometry (span and effective height). In this case, the numerical and experimental [3] results of a four-point bending test are compared, both qualitatively and quantitatively. For the given reinforcement arrangement, the observed failure modes were concrete crush and shear-compression, both were accurately represented using the proposed approach. Besides, the occurrence of two independent damage variable propitiated the assessment of the predominant damage model activated in each beam configuration.

[1]CIMNE

ABSTRACT

The multiscale pseudo-direct numerical simulation (P-DNS) method is a general and efficient framework for the high-fidelity computational simulation of the physics of complex flows [Id20, Gi21, Ide23, Gi24, Ra24]. This data-driven approach is based on four key concepts: i) numerically solving both scales; ii) computing offline fine solutions in representative volume elements (RVEs); iii) storing homogenized responses in dimensionless databases; iv) online solutions at the coarse level and coupling the fine scale via machine learning-based surrogate models. In this presentation, we introduce the latest applications of the P-DNS framework. We study the turbulent particle-laden flow in electrostatic powder coating sprays, the multiphase flow in porous media for CO2 injection processes in geological reservoirs, and the heat transfer through densely packed granular materials. The reliable results obtained with modest resources confirm the potential of the framework as a general approach to build rapid predictive tools in different scenarios.

AN ADAPTIVE FINITE-ELEMENTS - NEURAL NETWORK METHOD FOR PARAMETRIC PDES

Alexandre Caboussat[1], Maude Girardin[2] and Marco Picasso[2]*

[1]Geneva School of Business Administration, University of Applied Sciences and Arts Western Switzerland
[2]École Polytechnique Fédérale de Lausanne

ABSTRACT

We discuss an adaptive finite-elements neural network method to approximate the solution of a given parametric PDE $F(u(x; \mu)) = 0$, $x \in \Omega$, $\mu \in P$, where Ω and P denote respectively the physical and the parameter spaces. When using neural networks trained with data coming from numerical – in particular finite element – simulations, two main sources of error must be controlled in order to assess the overall accuracy of the method: the error coming from the numerical method that is embedded in the training set, and the error coming from the neural network approximation. More precisely, let ϵ be a given tolerance. Let u_h and u_N denote the finite element and neural network approximations of u respectively and $|||\cdot|||$ be a given norm on $\Omega \times P$. To ensure $|||u - u_N||| \leq \epsilon$, it is sufficient to ask $|||u - u_N||| \leq |||u - u_h||| + |||u_h - u_N||| \leq \epsilon$. The method that we propose to balance the two errors terms uses an adaptive mesh algorithm in order to control the finite element error $|||u - u_h|||$ and adaptively increases the number of training data until the neural network error $|||u_h - u_N|||$ is below the desired tolerance [1, 2]. Numerical experiments will be presented for different model problems, including in particular a Stefan-type problem.

PRECONDITIONING THE INCOMPRESSIBLE STOKES PROBLEM WITH VARIABLE VISCOSITY

Chiara Giraudo[*1], Miroslav Kuchta[2] and Stefano Serra-Capizzano[34]*

[1]*University of Oslo*
[2]*Simula Research Laboratory*
[3]*University of Insubria*
[4]*Uppsala University*

ABSTRACT

Incompressible Stokes problem with spatially variable viscosity arises in numerous applications, including geoscience, material science and multi-phase flow. The linear systems resulting from the model are often large, requiring efficient iterative methods for their solution. However, standard block diagonal preconditioners for the Stokes problem perform poorly in the presence of large spatial variations of the viscosity. We address this challenge by conducting a spectral analysis of the Stokes problem. In particular, when the velocity block in the preconditioner is the stiffness matrix/H1-norm, the spectrum of the preconditioned Stokes problem can be fully characterised by the spectrum of the associated Schur complement, which, in the standard case, is preconditioned with the weighted mass matrix for the pressure. We investigate the influence of viscosity distribution on the eigenvalues and the role of eigenvalue distribution on the preconditioner performance. Building upon the spectral analysis, we design block diagonal preconditioners with tailored pressure block that enhances robustness with respect to the viscosity. We finally discuss efficiency of the preconditioner compared to the standard approach.

A DATA-DRIVEN REDUCED ORDER MODEL FOR THE EFFICIENT SIMULATION OF MESOSCALE ATMOSPHERIC FLOW

Michele Girfoglio[*1], Annalisa Quaini[2] and Gianluigi Rozza[1]*

[1]*SISSA*
[2]*University of Houston*

ABSTRACT

Despite a continuous increase in computational power, simulations of atmospheric flow using classical discretization methods (e.g., finite element methods or finite volume methods) remain computationally expensive. Given the large number of simulations required to quantify uncertainty in weather prediction, alternatives to such discretization methods are needed to reduce the computational time and allow for improved prediction accuracy in short time frames.

In [1] we focused on the application of three data-driven reduced order models to mesoscale atmospheric flows: DMD, HDMD and PODI. In this work we improve the results presented in [1] by using the POD-LSTM method that exploits special neural network architectures in order to predict the future behaviour of the system at hand.

Our approach is validated in terms of computational time and accuracy in the simulation of two well-known benchmarks for mesoscale flow: the rising thermal bubble and the density current.

FRACTURE ANALYSIS OF HUMAN VERTEBRA WITH A PHASE FIELD COMPUTATIONAL APPROACH

Alessio Gizzi[*1], Deison Preve[2], Daniele Bianchi[1] and Pietro Lenarda[3]*

[1]University Campus Bio-Medico of Rome
[2]University of Udine
[3]IMT School for Advanced Studies Lucca

ABSTRACT

This study introduces the application of a phase-field model to simulate and analyze fracture patterns, deformation mechanisms, damage, and mechanical responses in a human vertebra following pedicle screw insertion under compressive loading conditions. The proposed phase-field framework effectively captures scenarios where diverse damage patterns, such as crack initiation sites and propagation paths, arise after spinal fusion procedures, considering various simulated physiological movements of the vertebral body. Spatially varying elastic properties and phase-field parameters have been computationally derived from bone density estimations. A convergence analysis was conducted for the vertebra-screws model, employing various mesh refinements, demonstrating consistent agreement with existing literature on this topic. Consequently, by assuming different pedicle screw insertion angles and considering various vertebral motion loading regimes, a comprehensive set of numerical results characterizing damage within the vertebral model has been obtained. Overall, the phase-field findings corroborate and expand upon the current literature, providing valuable insights for the medical community, potentially aiding in enhancing clinical interventions and reducing post-surgical bone failure and screw loosening. Furthermore, the computational approach investigates the effects of fracture and mechanical behaviour of the vertebral-screws system within various metastatic lesions, opening avenues for addressing life-threatening scenarios.

MULTI-FIDELITY GRAPH U-NET FOR PHYSICS SIMULATIONS

Rini Gladstone[*1] and Hadi Meidani*[1]

[1]*University of Illinois Urbana-Champaign*

ABSTRACT

Physics-based deep learning frameworks have shown to be effective in accurately modeling the dynamics of complex physical systems with generalization capability across problem inputs. While unsupervised networks like PINNs rely only on the underlying governing equations and boundary conditions, they are limited in their generalization capabilities. However, data-driven networks like Graph neural networks (GNNs), DeepONets, Neural Operators have proved to be very effective in generalizing the model across unseen domains, resolutions and boundary conditions. But, one of the most critical issues in these data-based models is the computational cost of generating training datasets. Complex phenomena can only be captured accurately using large enough deep networks that require large training datasets. Furthermore, the numerical error of the samples in the training data is propagated in the model errors, which necessitates the need for accurate data, i.e. FEM solutions on high-resolution meshes. Multi-fidelity methods offer a potential solution to reduce the training data requirements and incorporate physics into the neural networks. To this end, we propose a novel GNN architecture called Multi-fidelity Graph U-Net, which incorporates meshes of different granularity at different levels of a graph U-Net architecture and uses outputs from these levels for training the model. We show that this approach performs significantly better in accuracy and data requirement and only requires training of a single network compared to other benchmark multi-fidelity approaches like transfer learning models. Moreover, we observe that this approach requires shallower networks compared to existing GNN models for physics simulations, thus accelerating the training time and reducing the system requirements. We show the results of our approach using two benchmark dataset - mechanical MNIST multi-fidelity data and cantilever beam with varying size and resolutions.

ALGEBRAIC MULTIGRID SOLVER FOR NONLOCAL EQUATIONS

Christian Glusa[*1]

[1]*Sandia National Laboratories*

ABSTRACT

The naive discretization of nonlocal operators leads to matrices with significant density, as compared to classical PDE equations. This makes the efficient solution of nonlocal models a challenging task. In this presentation, we will discuss on-going research into hierarchical assembly and algebraic multigrid solution techniques that are suitable for nonlocal models.

A STUDY ON RETROFIT PRIORITY OF PIPES IN SEWER NETWORK BASED ON DISASTER RESILIENCE

Tetsuro Goda[*1] and Masaaki Nakano*[1]

[1]*Nippon Koei*

ABSTRACT

In recent years, disasters have become more severe and frequent due to the effects of climate change. There is also a high probability that huge earthquakes such as the Nankai trough earthquake and Tokyo inland earthquake occur within the next few decades. Social infrastructures need to be resilient to such large-scale disasters. In other words, they are required to keep their major functions and to recover quickly after being damaged. In this study, the resilience of a system is quantitatively evaluated using the resilience triangle proposed by MCEER considering the 4Rs, namely, robustness, redundancy, resourcefulness, and rapidity1). We also propose a method to determine the optimal retrofit priority based on resilience evaluation.

A virtual sewer network subjected to large-scale earthquake was selected for the analysis target. The sewer network can be expressed as a directed graph depending on a flow direction, while the nodes and edges represent manholes and sewer pipes respectively. The function of the system is defined as the cumulative flow at the most downstream manhole. The function is decreased when several pipes in the network are damaged and blocked due to a disaster. The resilience of the system can be evaluated from a time series of recovery process of the function obtained through step-by-step emergency restoration to clear the blockages.

It is assumed that seismic retrofitting is conducted on the network in multiple times until all vulnerable pipes are retrofitted. The retrofitted pipes are no longer blocked after a disaster. The resilience of the network after each retrofit phase is given by implementing the restoration simulation. The sum of these resilience values represents effectiveness of the retrofit scenario and can be regarded as the objective function. The optimal retrofit sequence, which minimizes the objective function, was explored using a genetic algorithm as the number of retrofit scenarios is considerably huge.

This study presents a way to quantitatively evaluate the resilience of a sewer network and introduces a method of retrofitting prioritization. It was confirmed that recovery process after a disaster can be precisely understood by handling the system as a network and the result can be useful for evidence-based decision making.

DOMAIN DECOMPOSITION FOR LARGE NEURAL NETWORKS DESCRIBING BATTERY MECHANICAL RESPONSE

Timm Gödde[1] and Bojana Rosic*[1]

[1]*University of Twente*

ABSTRACT

One main challenge related to automotive vehicles is to ensure mechanical safety of battery packs made of thousands of Li-Ion battery cells. During crashes, the cells are subjected to large deformations, which can cause chemical instability. Therefore, one of the main challenges in designing battery cells is to predict their mechanical behavior, while including possible variations in their design, material properties and boundary conditions [1,2]. Simultaneously, we opted to include a probabilistic description of the parameters defining the mechanical behavior, which makes the problem become stochastic. To make the physical model “light-weight”, we design a novel surrogate model that combines domain decomposition methods with deep learning. The idea is to partition the domain into linear and nonlinear regions, and tackle these separately. For this purpose, an alternative minimization method is used, that inherits the objective functions from a classical (or physics-inspired) machine learning setting. The main challenges are the inherit nonlinearity of the problem and the number of parameters describing the networks. For this purpose we will present a novel training approach that takes linearization of the constraints and a reduction of the number of parameters, through a prospective sensitivity analysis, into account. The numerical convergence of the method will be showcased on analytical examples, as well as on the simplified mechanical model of a battery cell.

EXPLICIT MULTI-MATERIAL TOPOLOGY OPTIMIZATION UNDER FINITE DEFORMATION

Byeonghyeon Goh[1], Zongliang Du[2] and Hayoung Chung[1]*

[1]*Ulsan National Institute of Science and Technology*
[2]*Dalian University of Technology*

ABSTRACT

Advances in additive manufacturing technology have significantly enhanced the capacity to produce structures of diverse shapes with complex configurations. Accordingly, interest in the design of optimized structures increased, leading to active research on topology optimization, an optimization methodology with a high degree of freedom. Topology optimization excels in obtaining optimized structural designs compared to trial-and-error methods. Its effectiveness is particularly notable in designing optimized structures considering multi-materials or -physics, which are challenging to approach intuitively. Multi-material topology optimization offers a broader solution space compared to topology optimization considering only a single material. This wider scope allows access to objective functions that cannot be attained with single-material structures. Therein, multi-material topology optimization has been actively researched across various fields including actuators and biomechanics. However, due to the simplicity of analysis, many existing studies adopted a linear elastic constitutive model; there are limitations to design that encompass finite deformation and hyperelasticity which are typical in real-world applications. Although there are some studies considering structural nonlinearity, there is still a lack of research that quantitatively evaluates the performance improvement of optimized structures by harnessing the synergy among multiple materials with distinctive material nonlinearity.

In addition, to consider the multiple materials and the high-fidelity model considering structural nonlinearity simultaneously, a method that can stably implement finite deformation analysis of intermediate designs while lowering the computational burden is needed. One of the efforts to do so is explicit topology optimization. Recent work by Du et al. [1] considering finite deformation showed that the optimal design could be obtained under a small number of design variables and computational costs through explicit topology optimization.

Therefore, in this study, we present an explicit topology optimization approach for multi-material composite structures, considering both geometric and material nonlinearity. By leveraging synergy among multiple materials with distinctive material nonlinearity, the research presents the quantitative evaluation of the performance improvement of optimized structures under large deformation. Also, the methodology incorporating material nonlinearity into multi-material explicit topology optimization is presented, and the validity of the methodology is demonstrated through numerical examples.

MODELING SEA ICE IN A WARMING CLIMATE

Kenneth Golden[*1]

[1]*The University of Utah*

ABSTRACT

The precipitous declines of Earth’s sea ice covers are impacting its polar marine environments and their ecosystems, with ripple effects felt far beyond the polar regions. As a material sea ice exhibits composite structure on length scales ranging over many orders of magnitude. From microscale brine inclusions and mesoscale melt ponds, to rich ice pack dynamics on oceanic scales, and from microbes to polar bears, we'll consider recent advances in modeling sea ice and the ecosystems it hosts. With the session focus on new methodologies, we’ll discuss mathematical and computational approaches that we’ve been developing recently to study complex multiscale systems in the cryosphere. These approaches include homogenization for coupling disparate scales in PDE models, fractal analysis, percolation and random matrix theory, topological data analysis, and uncertainty quantification. This work is helping to advance how sea ice is represented in climate models, and to improve projections of the fate of Earth’s sea ice packs and the ecosystems they support.

RELIABILITY ANALYSIS OF AIRCRAFT WING STRUCTURES BASED ON MONTE CARLO SIMULATION AND FINITE ELEMENT METHOD

Geovane Gomes[*1] and Reyolando Brasil*[2]

[1]*Federal University of ABC*
[2]*University of São Paulo*

ABSTRACT

As the aerospace industry continues to improve its performance and efficiency, ensuring the structural integrity of aircraft components such as wings is fundamental. Classical deterministic techniques for structural assessment may prove inadequate, given that uncertainties in the system can suppress the actual performance of the aircraft, deviating it from the optimal design [1]. On the other hand, the reliability analysis considers these uncertainties, offering a more robust assessment of the structure's safety, by providing the probability of violating a limit state. In this study, we investigate the reliability of aircraft wing structures. We model wings with different profiles, treating material properties and applied loads as random variables to determine the probability of structural failure and the influence of input parameters on aircraft wing strength. The chosen method of analysis is the Monte Carlo simulation (MCS), which is the safest for evaluating the probability of failure, subjected to the number of simulations and the quality of the pseudo-random number generator [2]. The limit state function is evaluated using finite element method (FEM), carried out in the MATLAB® environment.

Keywords: structural reliability, aerospace structures, Monte Carlo simulation, finite element method.

ABSTRACT

The advantages of carbon-reinforced concrete (CRC) over traditional concrete elements reinforced with steel, such as high strength, low weight, and corrosion resistance, make it a promising material for thin, efficient, and more sustainable designs. As the demand for less CO2-intensive materials such as concrete grows, a shift from simple massive elements to thin-walled elements with complex geometries is becoming increasingly necessary. However, to seek optimal design variants, efficient nonlinear numerical calculations that provide reasonable predictions of the structural behavior, including the stress-redistribution process and the failure mechanisms are essential. This paper presents FEM simulations of origami-based folded CRC shells that were experimentally investigated in a previous study. Two FEM modeling approaches were employed in the shell numerical analysis, one using a smeared and the other a discrete representation of the carbon reinforcement. Both approaches employed a damage-plastic nonlinear material model for the concrete. The load-deflection response obtained from the discrete approach closely matched the experimentally obtained curves. Despite an overestimation of the load capacity, the computationally less expensive smeared FEM model was able to qualitatively reproduce the structural response and the correct failure mechanism. Alternatively, a multiscale approach was discussed. In this approach, the structural scale is modelled using shell elements, while the reinforcement geometry is represented by NURBS (Non-Uniform Rational B-Spline) surfaces. The quality of the results obtained from the smeared model is sufficient to determine preferred design variants in typical design situations. However, the development of more accurate modeling approaches that are also computationally efficient, such as multiscale methods for shells, is needed to facilitate the sustainable design and application of thin CRC elements in future research contributions.

DELTA-P1 MODEL IMPLEMENTATION FOR NUMERICAL SIMULATION OF PHOTOTHERMAL CANCER THERAPY IN THREE-DIMENSIONAL HETEROGENEOUS TISSUES

Roberto Carlos Gomez Araque[*1], Carlos Andres Bustamante[1], Raul Adolfo Valencia[1] and Whady Felipe Florez[1]*

[1]*Universidad Pontificia Bolivariana*

ABSTRACT

Photothermal therapy (PTT) stands as a promising avenue for cancer treatment. Pplasmonic gold nanoparticles (GNP) absorb near-infrared light, inducing localized heating for tumor cell apoptosis. Predicting spatial temperature in preclinical models is crucial due to cell death sensitivity to temperature changes. Heat transfer models, particularly those relying on the radiative transport equation (RTE), are essential for this purpose, but their accuracy hinges on suitable approximations for light transport in heterogeneous media with NPs. The Pennes bioheat equation, which describes heat transfer in biological tissues, is known to be highly sensitive to the chosen approximation for the RTE when modeling PTT. Hence, a crucial need arises for a tailored approximation in NP-containing media, especially in irregular tumor geometries. Existing models for RTE has limitations; Beer-Lambert ignores light scattering, P1 is only valid under tissues with low absorption and high scattering coefficients [1], and discrete ordinates and MC simulations can be computationally demanding, particularly in real-time scenarios. This study focuses on the delta-P1 model, a modification of the diffusion approximation proposed by Prahl for biomedical applications [2]. Unlike P1, the delta-P1 model treats forward and scattered light independently, preserving precision across a broader range of optical properties, including media with NPs. Moreover, the model is formulated in three dimensions, allowing straightforward implementation in irregular geometries. The delta-P1 model equations are solved by the Finite Element Method (FEM) within the open-source framework FEniCSx. Numerical results for fluence rate in a heterogeneous geometry with nanoshells is compared to MC simulations and the P1 approximation. Temperature distributions are obtained by numerically solving the Penne’s equation. The delta-P1 model shows a significant improvement over P1 in heat transfer simulations, especially in irregular tumor geometries . Delta-P1 model application to irregular geometries has not been reported . Therefore, this study validates and applies the model for simulating light transport in PTT in general geometries. It shows enhanced accuracy in heat transfer simulations, particularly in scenarios with heterogeneous tissues and GNPs. This underscores its potential as a valuable tool for optimizing PTT preclinical models .

TOPOLOGY OPTIMIZATION OF SOLID OXIDE FUEL CELL (SOFC) CHANNELS USING A HYBRID MODELING STRATEGY

Juliano Goncalves[*1], Luis Sa[1], Thiago Lopes[1], Julio Meneghini[1] and Emilio Silva[1]*

[1]University of São Paulo

ABSTRACT

There is a growing demand for energy sources that are mainly dependent on fossil fuels nowadays, which are limited resources and have severe environmental impacts. Consequently, energy diversification and the employment of alternative energy sources are becoming even more critical. In this context, the fuel cell is a device that generates energy from electrochemical reactions, which makes it a cleaner and more sustainable alternative to conventional energy conversion technologies [1]. In this work, we apply a methodology based on the topology optimization method to design both the air and fuel channels of a solid oxide fuel cell (SOFC), aiming to improve its electrochemical efficiency. For that, we propose a hybrid modeling strategy that combines a 3D Finite Element (FE) model for the cell electrodes (cathode and anode) and electrolyte with a simplified 2D model to represent the flow behavior and diffusion in the cell channels. The Brinkmann Equations are used to model the momentum balance in the porous electrodes, coupled with the Stefan-Maxwell model to regard the multi-component species transport. Moreover, the Butler-Volmer equation describes the electrochemical reaction at each electrode, which plays a crucial role in modeling the SOFC performance since it drives all other occurring processes [2]. This hybrid modeling approach allows us to have a good representation of the physics involved in the electrolyte and porous electrodes, which is required to analyze the cell performance more precisely. At the same time, the simplified channel model significantly reduces the computational costs, which is also essential when solving a topology optimization problem. The Globally Convergent Method of Moving Asymptotes (GCMMA) is used to update the design variables during the optimization process, and a few design solutions for the cell channels obtained by the proposed methodology are presented.

RESEARCH ON CONVERGENCE AND OPTIMAL PARAMETERS OF INERTIAL RELAXED LBM FOR FLUID AND SOLID SIMULATIONS

Guangcai Gong[*1] and Ziche Gong*[1]

[1]*Hunan University*

ABSTRACT

The handling of boundary conditions in fluid-structure interaction (FSI) is a difficult task. The lattice Boltzmann method (LBM) has been proven to be efficient in processing boundary conditions in fluid simulations, its application is generalized for solid simulations in recent years. However, LBM usually suffers from slow convergence, which limits its applicable scenarios.

To adress this issue, an accelerated LBM suitable for both fluid and solid simulations based on the inertia relaxed Bhatnagar-Gross-Krook operator (BGK-IR) is proposed. Combining the Chapman-Enskog theory and our previous work, the Navier-Stokes equations and the equation of elastic lamina deformation are restored from the BGK-IR, and the Boltzmann equation based on the BGK-IR has a second-order error with respect to the time step and the inertia term.

During numerical tests, the D2Q9 and the D3Q15 lattice velocity models are selected. The elastic lamina, the 2-D square cavity flow and the 3-D cubic cavity flow are selected as simulation objects. Series of numerical are conducted, and the results are compared with the benchmark solution in detail. The results proves that comparing with the original BGK-LBM, BGK-IR-LBM possessed acceptable accuracy and superior convergence rate. Based on optimal parameters, the time consumption in fluid simulation and solid simulation has been reduced by 60.72% and 35.25% respectively.

Our work discusses the application of the BGK-IR operator in fluid and solid simulations for the first time. The superior convergence of BGK-IR-LBM, as well as its applicability for both fluid and solid simulations, are demonstrated. Despite that BGK-IR-LBM incurs ill accuracy as the value of the inertial term becomes large, given its rapid convergence rate, a hybrid algorithm could be developed to restart the calculation process from the relaxed solution and compensate for the lack of calculation accuracy. This is our future work.

NEW SECONDARY DEFLECTIONS FOR THE FLOW OF PRANDTL-MEYER

Julian Gonzalo Gongora Rincon[*1] and Ricardo Tomas Ferreyra*[1]

[1]*Universidad Nacional de Cordoba*

ABSTRACT

A new formulation by components for the deflection of the Prandtl-Meyer flow is applied. For this purpose, the radial and transverse components of the deflection of the flow are recognized through a geometric analysis to complement the classical specialized literature. Typically, through the last decades the deflection was obtained by numerical methods by integrating from an initial state (incident flow) and arriving at the presetting final state (deflected flow). So, the integration in general covers the expansion region. The goal of this paper is to provide access to the infinite intermediate geometry in analytical form and to reach exact, selective and by components procedures and formulations. The contribution to the field of Computational Fluid Dynamics CFD is to facilitate the deeper analysis of the Prandtl-Meyer flow from nonlinear secondary tangential components of the deflected flow.

RESEARCH OF THE SIMULATION ACCURACY OF THE RING RADIAL ROLLING PROCESS

Andrzej Gontarz[1] and Piotr Surdacki*[1]

[1]*Lublin University of Technology*

ABSTRACT

The paper presents the results of research the accuracy of the simulation of the hot rolling process of steel rings. This process involves reducing the cross-section of the pre-formed charge, resulting in rings with relatively large diameters in relation to the cross-sectional dimensions. In numerical simulations of the process, there are problems with obtaining good agreement between the experimental and theoretical dimensions of the product. For this reason, it was considered advisable to perform simulation quality tests using selected commercial programs. The research consisted of carrying out experimental tests of ring rolling with selected process parameters, and then simulating these tests using three commercial computational programs based on the finite element method. Each program uses a special module for ring rolling and a general module. In the first stage, the friction factor was determined taking into account the similarity of theoretical and experimental results regarding the occurrence of the slip phenomenon. In the second stage of the research, the dimensional accuracy of the simulation was determined based on the difference in the internal and external diameters of the rolled rings obtained as a result of the simulation and in the actual rolling process. Based on the results obtained, the advantages and disadvantages of the computer programs used were indicated.

THERMODYNAMICS-INFORMED GRAPH NEURAL NETWORKS FOR DIGITAL HUMAN TWINS

Lucas Tesán[1], David González[1], Francisco Chinesta[2] and Elías Cueto[1]*

[1]Universidad de Zaragoza
[2]ENSAM Institute of Technology

ABSTRACT

Key Words: Human Digital Twins, Geometric Deep Learning, learned simulators, Thermodynamics
Numerical simulation has established itself as a fundamental resource in the modelling of the behaviour of physical systems, allowing large-scale calculations to be carried out. However, the emergence of more sophisticated biological models and the need to enhance the performance of these calculations, with a view to more ambitious goals, motivates us to explore alternatives to the traditionally established methods, such as the finite element method (FEM).

Geometric deep learning models [1], based on the thermodynamics of the problem and their ability to identify the dynamics of unknown systems [2], even in the presence of highly nonlinear behaviour, are a promising perspective to address this increasing complexity. Following the line of these learning models, our work aims to validate their applicability to biological systems and to explore the new possibilities that artificial intelligence can offer to this field.

NUMERICAL SIMULATION OF THE PHASE-CHANGE EVOLUTION DURING THE STRAND EXTRUSION IN FUSED DEPOSITION MODELING

Felipe González[*1], Stefanie Elgeti[21] and Marek Behr[1]*

[1]*RWTH Aachen University*
[2]*TU Wien*

ABSTRACT

A numerical study of the phase-change evolution during the extrusion and deposition of a single strand in a fused deposition modeling (FDM) process is carried out. The FDM process is a popular fabrication process mainly used in manufacturing functional parts and rapid prototyping. The numerical framework is based on the stabilized finite-element method and the Arbitrary Lagrangian Eulerian (ALE) formulation. A boundary-conforming approach is used to track the filament motion, allowing an accurate description of the strand shape since the free surface matches exactly the strand boundary [1]. The mesh motion is enhanced by using the surface-reconstruction virtual-region method (SR-VR) [2], which is designed for problems with large mesh translation and topology changes, such as FDM. Furthermore, the SR-VR method allows the extrusion of both mesh and material from the printed nozzle, leading to continuously enlarging the domain over time. The Cross-WLF viscosity model is used to represent the shear thinning and the temperature-dependent behavior of the polymer material.

Our boundary-conforming framework is coupled with a source-based interface-capturing method to follow the phase transition during the process. In particular, the same method is used to track the melting evolution inside the nozzle and the solidification front after the deposition. Thus, the developed framework enables the study of key parts of the process, such as melting, extrusion, deposition, cooling, and solidification, in a single simulation. Results of temperature distribution, phase-change evolution, and strand shape at different process parameters will be presented and discussed.

CHARACTERIZATION OF PIG VERTEBRAE UNDER AXIAL COMPRESSION: INTEGRATING RADIOMIC TECHNIQUES AND FINITE ELEMENT ANALYSIS FOR ACCURATE DIAGNOSIS OF SKELETAL SYSTEM DISORDERS

Cristian A. Hernández-Salazar[1], Diego F. Villegas-Bermúdez[1] and Octavio Andrés González-Estrada[1]*

[1]Industrial University of Santander

ABSTRACT

Research on pig bones, given their anatomical similarities to human tissues, has significantly advanced diagnostic tools for the diagnosis of skeletal system disorders. Employing radiomic techniques, medical image segmentation and finite element analysis, we can comprehensively assess bone damage, density loss and mechanical functionality, providing a remarkable advance in personalized medicine. Experimental tests were performed on L3-L6 porcine vertebrae under compression axial loading conditions to analyze their mechanical properties and determine the force response versus displacement and maximum loads in the elastic range. Using computerized axial tomography, we generated three-dimensional models using segmentation techniques and applied anisotropic material models for finite element analysis. The methodology demonstrated strong correlation with experimental data, showing differences of less than 0.8% in elastic modulus and 1.53% in displacement. This approach provides strong support for accurate medical results, using the models as diagnostic references. It also allows to better understand the interactions of implants with the surrounding bone tissue and to guide the design of medical devices for optimal osseointegration and patient healing.

A FINITE ELEMENT BASED UNRESOLVED CFD-DEM METHOD FOR HIGHLY DENSE PARTICLE FLOWS

Joaquín González-Usúa[*1], *Guillermo Casas*[1], *Ignasi De-Pouplana*[12] *and Eugenio Oñate*[1]

[1]*CIMNE*
[2]*UPC*

ABSTRACT

In this work, we develop a fully coupled fluid-particle interaction algorithm for particle-laden flows. The flow is solved using the Volume Averaged Navier-Stokes equations (VANS), discretized employing Finite Element Method (FEM), and stabilized via the Variational Multiscale (VMS) framework. The Discrete Element Method (DEM) is utilized to track individual particles. The transfer of the information from particle to the continuum consists of a polynomial kernel-based projection that lets us generalize the CFD-DEM to solve problems that require fluid element sizes of the same order as that of the particles.

We show some particularities in our algorithm. First, the transfer of the information from particle to the continuum consists of a polynomial kernel-based projection that lets us generalize the CFD-DEM to solve problems that require fluid element sizes of the same order as that of the particles. Second, to improve the stability of the fluid phase solution, we split the drag force into two parts. We treat the part dependent on the particle’s velocity explicitly and the part dependent on the fluid velocity implicitly as a reaction term.

We present some verification examples demonstrating the conservative properties of the coupling and the algorithm's ability to handle dense and highly dynamic multiphase systems such as fluidized beds.

COMPUTATION OF LEAKY MODES OF MICROSTRUCTURED OPTICAL FIBERS

Jay Gopalakrishnan[*1]*

[1]*Portland State University*

ABSTRACT

Many modern microstructured fibers guide light by anti-resonant reflection effects. Such guidance mechanisms are often inherently lossy. The loss can be estimated from leaky modes that satisfy an eigenvalue problem derived from Maxwell equations on the fiber's transverse geometry. Using a discrete mixed eigenproblem with Nedelec finite elements, we solve for the eigenvalues and estimate confinement losses. After describing this methodology, the talk will demonstrate that the certain modeling choices have an outsized influence on computed confinement losses. For example, one can obtain disparate mode confinement loss profiles for the same optical fiber design by changing the outer material properties far away from the guiding core. These sensitivities are then tracked to certain fine scale features in modes. We then design an adaptive scheme for leaky modes. The scheme is able to automatically capture the fine scale features. Results obtained by applying the algorithm to various microstructured optical fibers show its utility.

VARIATIONAL MULTISCALE METHOD FOR VOID EVOLUTION AND TRANSPORT IN PROCESS MODELING OF POLYMER MATERIALS

Shoaib Goraya[1] and Arif Masud*[1]

[1]*University of Illinois Urbana-Champaign*

ABSTRACT

The manufacturing of fibrous composites involves cure cycles under high temperature conditions that initiate cross-linking polymerization in the resin to produce a structurally hard composite. Chemical reactions during curing also produce gaseous constituents result in formation of voids in the cured material. We present an integrated computational method for process modeling in polymer materials, considering the discrete microstructure evolution of the material in the early phase when the resin is still in a viscous liquid form, allowing voids to evolve and migrate together with curing of the material. The mathematical framework comprises of a hierarchically coupled system of partial differential equations, which include (i) the unified compressible-incompressible formulation using Navier-Stokes equations for the velocity and pressure in the two fluids, (ii) the advection-diffusion-reaction equation for the evolution of the concentration of contaminants responsible for void growth, (iii) the level-set equation for the evolution of resin-void interface, and (iv) the Laplace-Young equation for incorporating surface tension jump condition across the interface. The sharp discontinuity in viscosity and density across the interface of the liquid and gaseous phases triggers instabilities in the numerical solution due to the (i) discontinuous flux gradients, (ii) pressure overshoot/ undershoot affecting the coupled velocity field, and (iii) local oscillations arising from the singularity of the signed-distance field function and its gradient in the level-set equation. Additionally, the discontinuous diffusion coefficient and strong discontinuity in the concentration field at the interface causes instability in the solution of the advection-diffusion-reaction equation.

We present a stabilized finite element method, facilitated by the variational multiscale (VMS) method, to address these instabilities without smoothing the material jump or the surface tension effects over the interface. The new method is endowed with discontinuity capturing feature that naturally emerges when fine-scale models are embedded with the surface tension jump terms at the discrete interfaces. In the regions with sharp gradients, these variationally projected fine-scale models augment the stability of the coarse-scale formulation to accurately capture sharply varying solution fields without the need for expensive adaptive remeshings. For advection-diffusion-reaction equation, interface condition is enforced via Lagrange multiplier for which analytical solution is derived by embedding discontinuity capturing fine scale models in coarse scale formulation. The resulting formulation allows for one-way coupling between the concentration equation and the momentum equations. Numerical test cases demonstrating void evolution, migration, shape change, growth, and coalescence during the curing process are presented and validated through carefully designed experiments.

DESIGN OF A STRUCTURAL BATTERY COMPOSITE WITH A BI-CONTINUOUS 2-PHASE MATRIX USING A VIRTUAL TEMPERATURE CONSTRAINED TOPOLOGY OPTIMIZATION

Jonathan Gorman[*1], Reza Pejman[1] and Ahmad Najafi[1]*

[1]*Drexel University*

ABSTRACT

Structural Battery Composites (SBC) are an innovative class of materials exhibiting multifunctionality by concurrently resisting stresses and providing energy storage capabilities. SBC's can be used to reduce weight through their integration into structural design elements – for instance in electric vehicles. Previous studies have found optimized designs of SBCs; however, the solutions obtained in these works do not possess bi-continuous material distributions [1]. In these cases, regions of Structural Battery Electrolyte (SBE) do not exhibit full continuity between the electrodes, leading to difficulty in passing current between the terminals.

To establish SBC designs with bi-continuous material distributions, this study adds a virtual temperature constraint to the design framework. Previous works have implemented virtual temperature constraints to restrict enclosed voids or islands of solid material in structural designs [2]. In this technique, each phase of the SBC design will be assigned an artificial thermal conductivity: high conductivity for the SBE and low conductivity for the structural phase. Moreover, the SBE phase will function as a fictitious heat source. At the battery electrode locations, zero temperature Dirichlet Boundary Conditions are applied to allow dissipation of the artificially generated heat. By imposing a constraint on the p-norm of the virtual temperature distribution, an efficient current path within the battery can be delivered.

A multi-objective formulation is used in this design framework via the normalized-normal-constraint method that minimizes the stiffness and maximizes the ionic conductivity of the SBC designs. To improve computational performance, this methodology uses the portable extendable toolkit for scientific computing and message passing interface. Furthermore, the sensitivity analysis is fully analytic and implemented using the adjoint method. The versatility of this new framework is demonstrated through several numerical examples.

ADVANCED SAMPLING ALGORITHMS FOR ACCELERATING MULTI-FIDELITY INFORMATION FUSION

Alex Gorodetsky[*1], John Jakeman[2] and Thomas Dixon[1]*

[1]*University of Michigan*
[2]*Sandia National Laboratories*

ABSTRACT

Assessing the effects of input, parameter, and model uncertainties of high-fidelity simulation models is extremely computationally challenging. Sampling methods based on Monte Carlo become infeasible and surrogate methods may lose fidelity. Multifidelity methods have emerged as a complementary technique that enables one to rely on much fewer evaluations of computationally expensive models with little sacrifice in the accuracy of statistical estimates. These methods work on the basis that ensembles of low-fidelity models and experimental data can be leveraged to accelerate the estimate of the statistics in an unbiased manner. In this talk we describe our latest advances in sampling-based approaches for information fusion. These approaches will explore optimal linear estimators, demonstrating the power of approximate control variates to represent a vast majority of other approaches in the literature. In addition, we will discuss the challenges and opportunities of deploying these tools to outer loop settings such as inverse problems, optimization, and data-driven learning. Specifically, we will describe how the approximate control variate [1] can be generalized to encompass any linear information fusion technique, including the multi-level best linear unbiased estimator [2]. We will also discuss how these techniques can be parameterized and extended to predict multiple outputs so that they can be embedded in extensive outer-loop schemes.

STRUCTURE-ENFORCING AAA ALGORITHM FOR MECHANICAL SYSTEMS

Ion Victor Gosea[*1], Serkan Gugercin[2] and Steffen W. R. Werner[2]*

[1]*Max Planck Institute for Dynamics of Complex Technical Systems, Magdeburg*
[2]*Virginia Tech*

ABSTRACT

Learning physics-based reduced-order models from data has been a particularly prominent endeavor in both applied mathematics and mechanics in recent years. The AAA (Adaptive Antoulas-Anderson) algorithm by Nakatsukasa, Sete, and Trefethen has become an established data-driven method for rational approximation, harmoniously blending interpolation and least squares (LS) fitting on a data set composed of frequency-response measurements. The fitted models are linear first-order systems characterized by a barycentric representation of their transfer functions. The main contribution presented here is the extension and adaptation of the AAA algorithm for fitting linear systems with second-order dynamics, perfectly suited for applications to mechanical systems. The main innovations are structured barycentric forms for transfer functions of second-order systems, together with the incorporation of optimization techniques that can cope with the extra parameters encountered (and with the nonlinearity of the least-squares problems to be solved). More precisely, the proposed approaches are iterative in the sense that the dimension of the fitted models increases at each step until a certain accuracy on the available data is achieved. This is accomplished by imposing a set of interpolation conditions with interpolation points chosen in a greedy fashion so that the approximation quality may improve at each step of the iteration. Fixing this interpolation property, the systems' transfer functions are then rewritten in different barycentric forms using different parameterizations. Thereafter, an optimization problem is solved at each step in order to determine viable values for the remaining free parameters. Here, different tools are explored, ranging from standard LS approaches to nonlinear LS methods. Numerical examples include the application of the newly developed methods to established mechanical benchmark models, such as a butterfly gyroscope, an artificial fishtail, a hysteretic plate, and also a bone model.

SIMULATING SOFT CORAL VORTEX-INDUCED VIBRATIONS BY COUPLING A WAKE OSCILLATOR MODEL TO A CO-ROTATIONAL BEAM FINITE ELEMENT FORMULATION

Alexandre Villié[12], Mauricio Vanzulli Pena[3], Jorge Pérez Zerpa[3], Jérôme Vétel[1], Stéphane Étienne[1] and Frederick Gosselin[1]*

[1]Polytechnique Montréal
[2]TU Berlin
[3]Universidad de la República

ABSTRACT

Soft corals sway with the low-frequency swell of surface waves and vibrate at a high frequency due to vortex-induced vibrations. It is hypothesized that these high-frequency vibrations allow the soft-coral colony to intercept more food particles and thus improve its feeding. In this conference talk, we present a simulation workflow to couple a co-rotational beam finite element formulation with a wake-oscillator model and an empirical drag formulation. This workflow allows simulating the low frequency, large amplitude sway of the branched structure and its high frequency response to vortex-induced vibrations. To validate these simulations, we perform water tunnel experiments on 3D-printed idealized coral colony structures. Simulations and experiments are performed for ramified structures with different numbers of branches, and for incrementing reduced velocity. Whereas a cantilevered beam exhibits well-defined and spaced-out lock-in ranges where the frequencies of vibration and of vortex shedding coalesce, a ramified structure with more and more branches exhibits a more and more continuous lock-in over increasing reduced velocity. A ramified structure with many branches possesses natural frequencies close to one another. There is thus always a natural frequency close to the frequency of vortex shedding. Moreover, the natural frequencies of branched structures are unevenly spaced. Single frequency, high amplitude response is observed when vortex shedding occurs in a region of low frequency density, and multimodal, low amplitude response is observed when it occurs in a dense frequency region.
Flexibility allows the coral colony to lower the drag it faces under fluid flow. The vibrational response of the colony allows it to “sweep more water” and encounter more particles. Whereas a beam without branches can maximize this gain in the lock-in region of the second mode, a branched structure smooths out the capture gain over a larger reduced velocity range.
More details of the work can be found in Villié et al. (2024). The code developed in this work is integrated in the open-source co-rotational finite element software ONSAS of Vanzulli and Pérez Zerpa (2023).

AN OPERATOR LEARNING APPROACH FOR BRITLE FRACTURE ANALYSIS

Somdatta Goswami[*1]*

[1]*Johns Hopkins University*

ABSTRACT

In brittle fracture mechanics, parameters like failure trajectories, potential failure zones, and damage indices play crucial roles. While high-fidelity numerical solvers exist to predict these parameters accurately, they are computationally demanding and require fine crack resolution. Additionally, even small adjustments in domain parameters or material properties necessitate separate simulations. To alleviate this computational burden, there is a need for rapid and adaptable surrogate models. However, the discontinuous nature and intricacy of fracture mechanics pose significant challenges to developing such models. In our research, we introduce a physics-informed variational deep operator network (PI-DeepONet) for brittle fracture analysis. PI-DeepONet is trained to link the initial defect configuration with key variables of interest, such as damage and displacements. Once trained, the network can quickly provide the overall solution for any initial crack configuration and loading conditions in the domain. By incorporating physical principles into the model and enhancing data during training, the surrogate model can accurately handle both interpolation and extrapolation tasks. Given the sensitivity of fracture modeling to variations, our proposed PI-DeepONet, employing a hybrid training approach, demonstrates strong accuracy in predicting relevant quantities. This approach can be readily extended to various dynamic systems with complex behaviors.

MACHINE LEARNING-BASED ANOMALY DETECTOR FOR EXTERNAL FLOW

Riku Goto[1], Takeru Ishize[1], Remo Miura[1] and Koji Fukagata[1]*

[1]*Keio University*

ABSTRACT

Anomaly detection techniques for fluid flows have a crucial importance in fluids engineering. Recently, various machine learning-based anomaly detection methods for fluid systems have been proposed [1]. Machine learning is a data-driven method, which does not require a detailed mathematical model of the target system. Additionally, it is known to provide better performance in detecting the detail of anomalies such as the size and location compared to conventional methods [2]. For example, a machine learning-based burst detection method has been developed for pipelines [3]. However, there are still remaining issues in the application of data-driven anomaly detection methods to external flows. Most of the studies propose image-based methods but do not assume situations where the images needed for anomaly detection cannot be collected.
Motivated above, the aim of this study is to expand the applicability of anomaly detection methods based on machine learning. Hence, we propose an anomaly detection model to identify deformations of an object based on physical quantities in the flow around the object. Specifically, we build a machine-learning model that predicts object shape from the physical quantities. To demonstrate the performance of the proposed model, we consider a flow around a circular cylinder at the Reynolds number of Re_D=100 and flows around anomalous shapes. We prepare a total of 21 anomalous shapes based on seven different anomalous positions and three different scales, 4, 12, and 20% of the radius. We investigate the dependence on three input information patterns: 1) flow field behind the object, 2) sensor measurement behind the object, and 3) lift and drag coefficients. The results show that three machine-learning models are able to accurately detect anomalous shapes of 12 and 20% of the cylinder radius. On the other hand, we observe that the detection accuracy decreases for anomalies with a 4% radius, depending on the type of input information and the location of anomalies.

ESTIMATION OF 3D DISTRIBUTIONS OF MECHANICAL PARAMETERS FOR BRIDGE BY THE VEHICLE–BRIDGE INTERACTION SYSTEM IDENTIFICATION METHOD

Masaki Sakai[1], Yuka Goto[1], Eugene Madahemuca[1], Ryota Shin[1] and Kyosuke Yamamoto[1]*

[1]University of Tsukuba

ABSTRACT

The Vehicle-Bridge Interaction System Identification (VBISI) method, which estimates mechanical parameters of both the vehicle and the bridge (mass, damping and stiffness), bridge vibration and road unevenness from vehicle-mounted sensor information (vehicle position and vertical acceleration vibration) has been proposed and validated by numerical simulation [1]. Nevertheless, its accuracy in real vehicle-real bridge systems is low and the refinement of the dynamic model is a challenge. The method is an optimisation problem where the mechanical parameters are searched for in order to minimise the residual difference between the estimated road unevenness of the front and rear wheels. Numerical simulations of the VBI are carried out for each candidate value of the mechanical parameters to estimate the road surface irregularity. Calculating the loss function for the VBISI method requires performing a VBI simulation based on the estimated parameters, so the computational cost of the parameter exploration process increases rapidly when detailed bridge 3D models are introduced into the simulation. Therefore, a 3D modelling scheme for bridges that can be calculated with high accuracy while reducing the computational load is needed. This study employs Higher-order Hermite family Conforming (HHC) finite elements and incorporates generalised three-variable plate theory to realise a bridge model that retains accuracy while constraining computational expenses. It is confirmed that the VBISI method is capable of estimating the three-dimensional distribution of bridge parameters using this model.

SPACE-TIME ANALYSIS FOR THE CONTAINER PROBLEM

Manfred Göttlicher[*1]

[1]*University of Applied Sciences Erfurt*

ABSTRACT

The container problem describes the behavior of elastic porous media in a rectangular container, which is completely saturated by an ideal incompressible liquid. Displacement and velocity at the bottom are zero. Motion is possible only in the vertical direction. The top load starts with zero at the beginning and increases to its maximum at the end of duration T. By time the liquid extrudes on the surface of the container while the stress moves to the shrinking elastic solid due to its compression [1]. Space and time gradients are zero in the beginning, the time gradient is zero at the end of duration T also.

The analysis bases on a space-time potential that contains a linear elastic term, a darcy flow term, and a boundary load term [2], [3]. The variation of the potential results in a space-time principle leading to overall equilibrium. The boundary load on the top covers the elastic top load and the pressure difference between top and bottom. Realistically its time gradient is zero in the beginning and zero at the end of duration T.
Quadratic approximation of the displacement in space results in linear elastic stress distribution and cubic liquid pressure distribution. It fulfills compatibility of displacement, strain, and velocity. The cubic approximation of the displacement in time starts with a time gradient of zero and ends after the duration T with a time gradient of zero. Displacements and velocities are zero in the beginning.
The state at the end of duration T results from the minimum of virtual worktime which is the integral of virtual work over space and time. For T towards infinity solutions are available for low order approximation according to the rule of Bernoulli L' Hospital.
The potential decreases for higher order approximation which indicates convergence.

ACTIVE MEMBRANE RESPONSE OF THE BAT WING

Nakhiah Goulbourne[*1]

[1]*University of Michigan*

ABSTRACT

Birds, bats, and insects have evolved unique wing structures to achieve a wide range of flight capabilities. The compliant skin of the wing distinguishes bats from all other flying animals, and contributes to the remarkable, highly maneuverable flight performance and high energetic efficiency. The structural and functional complexity of the bat wing skin is one of the least understood although important elements of the bat flight anatomy. The wing skin has two unusual features: a discrete array of very soft elastin fibers, and a discrete array of skeletal muscle fibers. The latter is intriguing because skeletal muscle is typically attached to bone, so the arrangement of intramembranous muscle in a soft skin raises questions about its role in flight. In this presentation, a multiscale chemo-mechanical constitutive model for bat wing skin is developed. The chemo-mechanical model links crossbridge cycling to a structure-based continuum model that describes the active viscoelastic behavior of the soft anisotropic skin tissue. A computational approach is employed to investigate the effect of membrane muscle activation on wing deformation and aerodynamic performance. Specifically, results are presented that quantify for the first time: i) the influence of in-plane kinematic motion on the fluid-structure interactions of the wing, ii) the effect of wing muscle activation on the 3D shape conformations of the wing and the resulting aerodynamic performance, and iii) the role of trailing edge muscle activation on wing aeromechanics and aerodynamic performance.

TOWARDS SIMULATIONS OF INDUSTRIAL GRANULAR MATERIAL PROCESSING USING GPU COMPUTING

*Nicolin Govender**[1]

[1]*University of Johannesburg*

ABSTRACT

Particle shape plays a crucial role in the resulting macroscopic behavior of granular material yet the majority of DEM simulations use simple spheres with non-physical constructs such as rolling friction without fully understanding the implications thereof. While there have been shape studies using super quadric's and ellipsoids over the years, they still have the same single point contact resolution as spheres. The majority of industrially relevant granular materials are however non-curve linear and have shapes that are best captured by polyhedral shapes. Apart from mechanical behavior, thermal conduction as well as cohesion between these particles occurs over a finite-contact area that is more faithfully captured by polyhedra. In this talk the role of particle shape will be explored for a number of industrial cases such as mills, screw feeders and silos along with prescriptions for when shape and size simplifications can be used. The underlying theme of the talk will be on the use of GPU computing in the past decade to advance the physics fidelity of DEM simulations along with reduced run-times. Finally an outlook to the future of using high fidelity DEM to generate data for statistical models and physics informed neural networks that can provide answers in the age of digital twins will be presented.

REDUCED ORDER GEOMECHANICS MODELS

Robert Gracie[*1] and Saeed Hatefiardakani*[1]

[1]*University of Waterloo*

ABSTRACT

Simulation of geomechanics problems is often extremely time consuming as they must span multiple spatial and temporal length scales, often include nonlinearities, and coupled processing. As a result, it is challenging to apply such models in real time scenarios and to calibration or optimization processes which require many model executions. Reduce Order Models (ROM) are fast and accurate (ideally) models trained from computationally complex Full Order Models (FOM), in this case large finite element method simulations of coupled processes. This presentation will discuss the pros and cons for the two dominant types of ROMs, intrusive and non-intrusive. ROM construction and training of parameterized ROM, in which injection rate and material parameters are variable inputs will be discussed. The construction of intrusive ROM for porous media flow, poro-elasticity and poro-elasto-plasticity will be discussed, specifically the challenges associated with non-linear problems. The selection of hyper-parameters, such as the number of modes and the number of sampling points, will be discussed. Lastly, performance of ROM vs FOM presented, where it will be shown that relative performance of the ROM over the FOM increases with the complexity (cost) of the FOM – speed-up of more than 1000 times are possible when the FOM exceeds 100,000 degrees of freedom.

AN EQUILIBRATED FLUX A POSTERIORI ERROR ESTIMATOR FOR ADAPTIVE REFINEMENT IN DEFEATURING PROBLEMS

*Denise Grappein**[1], Annalisa Buffa[2] and Rafael Vazquez[3]*

[1]*Politecnico di Torino*
[2]*EPFL*
[3]*Universidade de Santiago de Compostela*

ABSTRACT

An adaptive refinement strategy, based on an equilibrated flux a posteriori error estimator, is proposed in the context of defeaturing problems. Defeaturing consists in the simplification of a geometry by removing features that are considered not relevant for the approximation of the solution of a given PDE. The proposed adaptive strategy is twofold, accounting both for standard mesh refinement and geometrical refinement, which consists in choosing, at each step, which features need to be included into the geometry in order to significantly increase the accuracy of the solution. With respect to other estimators that were previously proposed in the context of defeaturing, the use of an equilibrated flux reconstruction has two main advantages [1]: first of all, it allows to sharply bound the numerical component of the error on the totally defeatured domain, and secondly, it allows to avoid the evaluation of the normal trace of the numerical flux on the boundary of features. This makes the estimator and the adaptive strategy particularly well-suited for finite element discretizations, in which the numerical flux is typically discontinuous across element edges. The inclusion of the features during the adaptive process is tackled by a cutfem strategy, in order to never remesh the computational domain as the features are added. The estimator then also accounts for the error committed by weakly imposing the boundary conditions on the boundary of the added features.

MODES OF PT-SYMMETRIC FIBERS WITH GAIN AND LOSS

Tamara Gratcheva[*1], Jay Gopalakrishnan[1] and Yogesh Joglekar[2]*

[1]Portland State University
[2]Indiana University

ABSTRACT

We model a dielectric optical fiber whose transverse cross section has a lossy core and a gain-medium core, both placed symmetrically about a transverse coordinate axis. The balanced gain and loss mediums are placed to achieve parity time-reversal symmetry (PT symmetry). Non-Hermitian physics of PT symmetric models have gained substantial interest in recent years and there have been many studies into breaking thresholds and exceptional points of analytically solvable models. Our non-Hermitian PT symmetric model generates spectra which cannot be solved analytically. For computing the modes of the fiber and efficiently tracking its changes with respect to some parameters, we utilize the FEAST algorithm. We find a rich variety of exceptional points, re-entrant PT symmetric phases, and a non-monotonic dependence of the PT symmetry breaking threshold on the system parameters. In addition, we investigate spectral variations with respect to angular and distance perturbations in the placement of cores.

PHYSICS-AWARE DEEP AUTOENCODERS FOR MODEL ORDER REDUCTION

Stephen Baek[1], Shahab Azarfar[1], H.S. Udaykumar[2] and Zoe Gray[1]*

[1]University of Virginia
[2]The University of Iowa

ABSTRACT

To capture the dynamics of systems whose intrinsic solution space does not fall into a linear subspace with a small dimension, nonlinear model order reduction techniques are essential. Compression of the full-order model into a computationally more tractable reduced-order model presents challenges to traditional ROM techniques. Recently, deep autoencoders have gained popularity for their ability to learn a lower-dimensional latent representation of the original full-order manifold where the nonlinear dynamics evolves. However, "off-the-shelf" autoencoders are often purely data-driven and simply learn input-output mappings between statistical distributions. Hence, the majority of these autoencoders ignore the underlying physics priors by failing to preserve the geometry and topology of the nonlinear dynamics manifold, which carry fundamental information about the global behavior of the associated dynamical system.

In this work, we explore several autoencoder-based model reduction strategies to bridge the gap between state-of-the-art deep learning research and the domain-specific needs for reduced-order modeling. We achieve this by quantitatively comparing two categories of physics priors: i) learning bias priors to preserve geometric properties of the dynamics manifold; and ii) inductive bias priors to preserve topological properties of the manifold. In particular, we investigate the performance improvement in autoencoder-based ROMs when they are regularized with an isometry distortion measure, introduced in Lee et al. [1], which captures the induced change in the Riemannian metric, i.e., the intrinsic notion of local length and angles, over the nonlinear dynamics manifold. The conformally-constrained encoder and decoder of this class of models prevent arbitrary change in the amplitude and direction of the infinitesimal dynamics of the physical system when encapsulated into the latent space. In addition, we investigate two inductive bias methods, namely PARC [2] and LaSDI [3], which preserve the topology of the manifold by constraining the flow of the underlying dynamical system. Through these experiments, we compare different design and training schemes for autoencoder-based ROMs and underline the remaining challenges.

TOWARDS TRUSTWORTHINESS THROUGH THE LENS OF GEOMETRIC INTERPRETATION

Zach Grey[*1]

[1]*National Institute of Standards and Technology*

ABSTRACT

High-dimensional parameter spaces present a dilemma for the current state-of-the-art AI models: we have limited analytical foundations for understanding and quantifying the reliability of these methods despite an apparent usefulness of the models in applications. Common intuitions break down in high dimensions (no such thing a nearest neighbor!) and numerical methods are complicated by implicit biases related to multiple model-fidelity along with a lapse in trustworthiness of extrapolation and interpolation. This work emphasizes geometric strategies for inferring intrinsic dimensionality and systematic parameter dimension reduction to resolve this impasse. We will explore arguments for improved understanding and trustworthiness of AI/ML technologies through well-posed notions of between-ness (distance) and reduced dimensionality---facilitated by principled interpretations and explanations of an applied geometry.

DATA-BASED ESTIMATES OF EXTREMES OF RANDOM FUNCTIONS

*Mircea Grigoriu**[1]

[1]*Cornell University*

ABSTRACT

The safe design of, e.g., flood protection systems, aircrafts and high-rise buildings, requires accurate estimates of extremes of river flows, aerodynamic forces and other random functions. The characterization of extremes of random functions is challenging since they require detailed information on these functions which is rarely available in applications. To overcome these difficulties, we construct finite dimensional (FD) models, i.e., deterministic functions of time and a finite set of d random variables, fit them to the available information and show that they can be used as surrogates under some conditions.

Let $X(t)$ be a stochastic process defined on a time interval $[0,\tau]$, e.g., τ can be the duration of a wind storm acting on a building and suppose that the information on this process consists of n sample paths $x_i(t)$, $i=1,\ldots,n$, of this process. Our objective is to estimate the distribution of the extreme X_τ of this process in $[0,\tau]$. Generally, the data set is insufficient to estimate the distribution of X_τ. The following three-step algorithm is used for solution. First, an FD model $X_d(t)=\sum_{k=1}^d Z_k\,\varphi_k(t)$ is constructed for $X(t)$, where $\{\varphi_k\}$ are basis functions and $\{Z_k\}$ are random coefficients. For example, $\{\varphi_k\}$ and $\{Z_k\}$ can be eigenfunctions of the correlation function of $X(t)$ and projections of the realization of $X(t)$ on these functions. Second, an extension of the polynomial chaos (PC) representation, referred to as PCT, is used to construct the joint distribution of $\{Z_k\}$. This distribution and the expression of $X_d(t)$ are used to generate an infinite supply of FD sample paths. Third, conditions are established under which the distribution of the extreme $X_{d,\tau}$ of $X_d(t)$ in $[0,\tau]$ converges to that of X_τ so that FD paths can be used to estimate the latter distribution. Wind pressure time series recorded at the boundary layer wind tunnel facility at the University of Florida are used to illustrate the implementation and assess the performance of the algorithm.

LEARNING METRIPLECTIC SYSTEMS FROM FULL AND PARTIAL STATE INFORMATION

*Anthony Gruber**[1]

[1]*Sandia National Laboratories*

ABSTRACT

A method is presented for learning metriplectic systems from data which is energy-conserving and entropy stable by construction. In addition to respecting metriplecticity, this method comes with approximation results demonstrating its ability to learn general metriplectic dynamics as well as an error estimate indicating its generalization to unseen timescales. Examples are provided which illustrate the performance of this approach in the presence of both full state information as well as when entropic variables are unknown.

COMPARING PRECONDITIONING STRATEGIES FOR THE IMPLICIT FORMULATION OF THE IMMERSED BOUNDARY METHOD

*Cole Gruninger**[1] and Boyce Griffith*[1]

[1]*University of North Carolina at Chapel Hill*

ABSTRACT

The Immersed Boundary (IB) method represents a straightforward and adaptable computational strategy for simulating fluid-structure interaction. Despite its flexibility, the IB method encounters significant timestep size limitations when applied to modeling stiff structures. Fully implicit formulations of the IB method remove the severe timestep size restriction posed by the explicit formulation; however, the linear system derived from the implicit formulation of the IB method proves challenging to solve iteratively without the support of an effective preconditioner. In this context, we introduce and analyze several novel preconditioning strategies designed to enhance the efficiency of implicit formulations of the IB method. We apply our preconditioning strategies to a number of model and application based problems and demonstrate a marked increase in computational speed, offering a compelling alternative to traditional explicit timestepping schemes.

ORDINARY STATE-BASED PERIDYNAMIC HYGRO-MECHANICAL COUPLED MODEL FOR MOISTURE DIFFUSION AND CURLING ANALYSIS IN SOIL DESICCATION

Xin Gu[*1], Panyong Liu[1], Yang Lu[1], Xiaozhou Xia[1], Lei Wang[1], Erdogan Madenci[2] and Qing Zhang[1]*

[1]*Hohai University*
[2]*University of Arizona*

ABSTRACT

Soil curling is a natural phenomenon in thin soil fragments induced by desiccation cracks, and it further increases the potential threats of soil cracking. When analyzing soil curling especially together with soil desiccation cracking, the existing numerical investigations usually encounter challenges arising from various factors, e.g., inadequate knowledge of soil curling mechanism, complex soil characteristics with diverse parameters, moving boundary conditions during deformation, and crack initiation and growth. Therefore, the present study attempts to reveal the soil curling mechanism through a fully coupled hygro-mechanical ordinary state-based peridynamic (OSB PD) model and corresponding solutions. Specifically, the PD form of the moisture diffusion equations for saturated and unsaturated states are derived by employing the Hamiltonian principle with nonconservative Lagrangian action and peridynamic differential operator (PDDO). Also, the PD bond force is derived by considering the energy equivalent principle for a fully coupled hygro-mechanical model. For the numerical implementation, both staggered and monolithic schemes are developed for the coupled hygro-mechanical problem. The method of controlling the maximum number of bond breakage for non-convergence is explored in the monolithic scheme as well.

A model of soil strip desiccation deformation and curling is constructed while considering realistic moving boundaries of moisture and displacement with relevant parameters, and soil characteristics evolution from saturated to unsaturated states. This model successfully captures the entire curling process, including concave-up and concave-down curling. Also, the influence factors of liquid limit, extra evaporation surface, and thickness on the curling performance are explored. Summarily, the coupled hygro-mechanical peridynamic model provides a potential strategy in soil desiccation cracking investigation for real-scale simulation and fine mechanism exploration.

TOWARD THE REALISATION OF AN ACTIVE FAULT DIGITAL TWIN TO MONITOR SLOW EARTHQUAKES

Adriano Gualandi[*1], Davide Faranda[2] and Gianmarco Mengaldo[3]*

[1]*University of Cambridge*
[2]*Laboratoire de Science du Climat et de l'Environnement*
[3]*National University of Singapore*

ABSTRACT

The discovery of slow earthquakes has revolutionised our understanding of fault friction and of the seismic cycle. Slow slip events (SSEs) play an important role in the seismic budget calculation, releasing equivalent magnitudes even larger than M7. SSEs can be seen as regular earthquakes in slow motion. They do not radiate seismic waves because they are too slow, but they can trigger large (M>7) destructive earthquakes. Therefore, we need to accurately model them if we want to better assess the seismic hazard of seismogenetic structures. We will present the results of a near real-time procedure to retrieve the spatio-temporal evolution of slow earthquakes. To achieve this goal, we use daily sampled Global Navigation Satellite System (GNSS) position time series retrieved in the Cascadia subduction area. This region is ideal because of the high number of major slow earthquake recurrences, and the high density of geodetic stations. The automatic procedure to extract the tectonic contribution from the geodetic observations is based on a variational Bayesian Independent Component Analysis (vbICA) method, an unsupervised learning approach rooted in multivariate statistics that allows us to disentangle the tectonic signal from other sources of deformation (e.g., due to hydrological load). We use the version of the algorithm adapted to handle missing data, a common issue with geophysical observations [2]. The selection of the Independent Components (ICs) is automatised based on the power spectrum of their temporal evolution as well as the coherence of the corresponding spatial distribution. The slip distribution on the fault, regularly updated with the incoming of new data, will be used to determine the temporal evolution of relevant dynamical quantities like the system’s dimension [3], and it constitutes the first step to attempt the forecast of slow earthquakes in near real-time.

STRUCTURE-PRESERVING INTEGRATION FOR NONLINEAR VISCOELASTODYNAMICS

Jiashen Guan[*1] and Ju Liu*[1]

[1]*Southern University of Science and Technology*

ABSTRACT

Numerous polymeric and biological materials may undergo large deformation with intrinsic viscous dissipative mechanisms. Achieving accurate simulations of their mechanical behaviors requires stable and accurate time integration schemes. Traditional time integration schemes are prone to lose stability when applied to nonlinear systems, resulting in a pathological growth of the total energy. Extensive research has indicated that structure-preserving integrators enjoy superior robustness and accuracy in long-term simulation of nonlinear problems, and this leads to a growing interest in the design of such type of integrators.

In this presentation, we will introduce a structure-preserving integrator designed for finite viscoelasticity models[1] constructed within a concrete thermomechanical framework. It can be viewed as a theory built based on the kinematic assumption introduced by Green & Naghdi and generalized by Miehe[2]. Additionally, we also introduce a two-parameter family of nonlinear strain measures, which accurately describe material behaviors over a wide range of deformation states. The numerical schemes are developed using the following critical techniques[3]. Firstly, a velocity-pressure mixed formulation is utilized, which allows the introduction of a new Hamiltonian for fully incompressible materials. We mention that this type of Hamiltonian is different from existing ones in the literature. Secondly, a smooth generalization of the Taylor-Hood element based on NURBS is adopted to construct the semi-discrete formulation, which is inf-sup stable and robust for large-strain analysis. Thirdly, we propose strain-driven constitutive integration formulas for the viscous flow rule, which facilitates the design of the final scheme. Fourthly, the discrete gradient method is applied to devise the time marching scheme for the overall system, with the directionality property extended for inelastic problems. We will present numerical examples to justify the claimed properties of the proposed methods.

EXTENDED DVM ALGORITHM AND TOPOLOGY OPTIMIZATION OF RAREFIED GAS THROUGH A DISCRETE ADJOINT SYSTEM

Kaiwen Guan[*1] and Takayuki Yamada[1]*

[1]*University of Tokyo*

ABSTRACT

In this study we present a topology optimization method for rarefied gas flows. The discrete velocity method (DVM) is used to solve the Shakhov kinetic equations, which is a substitution of the Boltzmann equation for modelling rarefied gas flows. The widely-used density method is applied to characterize material distribution in the computational domain, where we develop an extension to the Shakhov equation by modifying the convection term. The extension is continuous with respect to the pseudo design density, and accurately captures the flow conditions in a domain where solid and fluid are mixed. The model topology optimization problem is presented in discretized form, where the discrete numerical variables in DVM are treated as state variables, and the steady state condition of the flow is represented by the zero of a flow residual function. Sensitivity analysis is conducted by considering local linearization of the flow residual, where simple derivations lead us to a discrete adjoint equation. The discrete adjoint equation can be treated as a linear system of equations, where the flux Jacobian of the primal problem is transposed. We argue that the adjoint system can be solved using iterative methods such as the lower-upper symmetric Gauss-Seidel (LU-SGS) method, in a similar way as the primal problem is solved. Gradient-based methods can be used to find the optimal design of flow structures according to the sensitivity obtained from the adjoint system. Numerical examples are provided to demonstrate the validity of the extension of Shakhov equation, the obtained adjoint sensitivity, as well as the topology optimization results.
This study presents a more efficient approach to topology optimization of rarefied flow. Compared to existing approaches [1,2], the present study simplifies the cumbersome derivation of continuous adjoint system, and speeds up convergence due to the use of implicit time-marching schemes. The adjoint system is developed at the steady state of the deterministic numerical approach, hence there is no need to record intermediate results, which lifts the burden in computer memory. We expect this method to be widely used for design problems in rarefied gas dynamics.

A MULTI-BODY DYNAMIC MODEL WITH COUPLED RIGIDITY, FLEXIBILITY AND LUBRICATING FOR THE EVALUATION OF THE VIBRATION PERFORMANCE FOR THE PISTON ENGINE

Nanxiang Guan[*1], Yongpeng Gu[1], Zhifeng Xie[1] and Min Zhou[1]*

[1]*Tsinghua University*

ABSTRACT

The piston engine is one of the main power machinery in the world. It outputs power by means of the reciprocating motion of the piston. The development of piston engines tends toward high speed and high power density. However, high-order reciprocating inertial force will become an important excitation source of vibration and noise with increasing the piston speed. The key technology for vibration reduction is how to design a compact structure and maximize balancing the multi-order reciprocating inertial force in the limited space. Hence, based on studying the theory of reciprocating motion and balancing technology of piston engine, we propose an accurate calculation method of high-order inertial load, and establishes a multi-body dynamic model with coupled rigidity, flexibility and lubricating for the evaluation of the vibration performance of a piston engine.

According to the results of modal experiment, the flexible body model with the body, crankshaft and support frame is established based on modeling the connecting rod and piston with rigid bodies; meanwhile, the model for oil film lubricated bearing is established by using Reynolds equations. The rigid-flexible coupling model of the whole engine and the discrete Reynolds equation for hydrodynamic lubrication are fully coupled for solutions. The results of vibration acceleration from the simulation and the test are well conformed. It is proved that the engine model and calculation method is reliable. And a numerical verification method for the vibration performance evaluation of the modified engine balance mechanism and the development of new engines is provided.

WAVE PROPAGATION SIMULATION FOR COUPLE STRESS ELASTODYNAMICS USING MIXED FINITE ELEMENT METHODS

José Ortiz-Ocampo[1] and Nicolás Guarín-Zapata[1]*

[1]Universidad EAFIT

ABSTRACT

In recent years, there has been a growing interest in architected materials and the exploration of microstructural interactions and their influence on the macroscopic properties of continuum media [1]. These interactions go beyond classical continuum mechanics models, prompting researchers to propose non-classical models with additional parameters to capture these effects. One such model is couple stress theory, which incorporates microstructural effects through a generalization of Cauchy's postulate, introducing additional mechanical interactions involving couples per unit surface or couple-stresses [2]. However, these models result in higher-order partial differential equations, requiring higher continuity formulations of the Finite Element Methods [3]. To overcome this problem, this work presents a mixed finite element formulation for wave propagation in the time domain. It allows the direct simulation of oscillatory phenomena where the dispersive behavior of waves is presented and the computation of bulk properties for heterogeneous materials.

APPLICATION OF RADIAL BASIS FUNCTIONS IN AN IMMERSED BOUNDARY METHOD FOR PARALLEL CFD SIMULATION

Olivier Guévremont[*1], Lucka Barbeau[1], Vaiana Moreau[1], Federico Galli[2], Nick Virgilio[1] and Bruno Blais[1]*

[1]*Polytechnique Montréal*
[2]*Université de Sherbrooke*

ABSTRACT

Using Computational Fluid Dynamics (CFD) to predict flow and reactions in complex porous media is becoming increasingly feasible, but computing costs still limit the cases that can be tackled. Large (real) domain sizes, high Reynolds numbers, and wide ranges of pore scales affect both the memory and computing efforts required to make accurate and useful predictions. An approach to conduct real-scale simulations in porous media is the use of adaptive mesh refinement (AMR), which allows for the capture of rich and complex gradients in pressure and velocity fields that often occur in porous media. In this context, AMR is challenging because it requires constant remeshing while maintaining the topology of the porous media. Furthermore, this challenge is exacerbated when hexahedral meshes are used.

This work focuses on the implementation, verification, and validation of a method based on Radial Basis Functions (RBF) networks to represent any geometry, enabling the application of Immersed Boundary (IB) conditions within complex porous media. IB methods alleviate the challenges of building conformal grids and enable the use of Cartesian grids, whose simplicity and efficient data structures allow for dynamic AMR during solver execution.

The RBF-based representation of porous media for IB imposition is performed in the Finite Element (FE) solver Lethe, which is based on deal.II. The solver takes advantage of Cartesian hierarchical grids to solve massively parallel simulations on distributed architectures. Building on the same idea, RBF networks use compactly supported basis functions that are distributed among parallel processes while preserving ease of evaluation. The verification of arbitrary feature-capturing capabilities is done using the Method of Manufactured Solutions (MMS), with analytical solutions tailored to verify the flow around the given shapes. The solver is validated by comparing the pressure drop within centimeter-scale porous monoliths (100 to 300 microns pore size) digitized by X-ray microtomography, for Reynolds numbers up to 1000.

The presentation emphasizes on RBF network training and optimization in a parallel framework. The algorithms for the initialization and distribution of the RBF nodes among the processes are covered, as well as the MMS formulation and validation setup. The presentation demonstrates that RBF networks are a light, versatile, and powerful method to represent porous media in pore-resolved simulations, especially when IB methods are involved.

CONTROLLING DAMAGE - OPTIMIZATION BASED ON ANALYTICAL GRADIENTS AND APPLICATION IN FORMING

Fabian Guhr[1] and Franz-Joseph Barthold*[1]

[1]*TU Dortmund*

ABSTRACT

Decrease of material usage under the same operative load calls for application of tight tolerances to manufactured parts within the industrial setting. This in return requires a more detailed description of the material models used to simulate a manufacturing process. While plasticity is incorporated in most simulations and many optimization environments, the aspect of damage evolution and accumulation is another important effect to consider. Within the field of optimization, consideration of ductile damage is a scarcely researched topic. However, inclusion of damage modelling enables optimization of processes, such that damage can be reduced and therefore failure of a part under operative load can be prevented.

Introduction of damage mechanics within simulations comes with additional challenges, such as the inherent mesh-dependency of standard local damage models. Gradient-enhanced, non-local damage models have the advantage of mesh-independency, but introduce an additional global damage variable to the problem and require long computation times. Derivation of the gradients for gradient-based optimization also requires handling of internal history variables and its numerical implementation [1]. However, when derived and implemented, these analytically derived gradients are very efficient. For industrial applications, like forming, however, the inclusion of contact mechanics adds another difficulty to optimization. Derivation of analytical gradients for a discontinuous problem is very complex. To circumvent this problem, an optimization framework around a commercial FEM solver is derived. The finite element simulation, with the troubling contact mechanics, is handled within the commercial software, and an optimization environment is structured around this software. This allows damage optimization of forming processes [2].
This talk presents an overview of damage optimization in two fields of research. In the first field, a non-local, ductile damage model is enhanced with sensitivity analysis by a variational approach. The analytically derived gradients are applied within gradient-based optimization and enables creation of damage tolerant structures. The second field of research aims to directly optimize forming processes. This is achieved by creating a framework around the simulation software Abaqus and enables direct optimization for forming processes like extrusion and deep-drawing. Solutions of the optimization problems are optimal process parameters, which correlate with reduced damage accumulation.

[3]Zhejiang University

ABSTRACT

Sodium montmorillonite (Na-MMT) is the main active mineral in clays. It is very sensitive to changes in temperature and degree of hydration. Meanwhile, montmorillonite is characterized by wide distribution, low permeability and high adsorption capacity. It is a potential nano-adsorbent, a nanofiller for polymer nanocomposites, and a basic material for engineered barriers for nuclear waste disposal. However, studies at the microscopic level are insufficient to fully investigate the coupling effects of temperature and water content on the structural properties of Na-MMT. In this study, a molecular dynamics (MD) approach was used to simulate the structure and microscopic mechanical properties of Na-MMT. The aim of this study is to investigate the effects of different temperatures (200 K to 600 K) and water contents (10%, 20% and 30%) on the mechanical properties of Na-MMT. Parameters such as van der Waals force, energy, elastic modulus, shear modulus, bulk modulus and Poisson's ratio were compared. The simulation results reveal several important findings: (1) The behavior and motion of water molecules are significantly affected by the temperature increase, which leads to interlayer expansion and thus reduces the mechanical properties. (2) Na-MMT exhibits anisotropy, with higher mechanical properties in the Y-direction than in the X- and Z-directions as temperature and temperature increase, and the overall ultimate stress shows a decreasing trend. (3) Damage induced by temperature and hydration level is most likely to occur in the Z-direction. The increase in the number of water molecules between the layers and the diffusion due to temperature resulted in a significant weakening of the interlayer van der Waals forces. The results of this study contribute to a deeper understanding of the microscopic characteristics of Na-MMT and provide ideas for the microstructural changes behind the swelling mechanism of bentonite.

NONLINEAR REDUCED MODELS FOR PARAMETRIC PDES

Diane Guignard[*1]

[1]*University of Ottawa*

ABSTRACT

Reduced order modeling is a powerful tool for approximating the solution to parametric/random partial differential equations. The usual approach is to construct one linear space which accurately approximates the parameter-to-solution map, and then use it to build an efficient forward solver. However, such approach is not suitable for problems with slowly decaying Kolmogorov n-width (e.g., convection-dominated problems) as they would require using a linear space of high dimension. For such problems, nonlinear reduced models present an attractive alternative. In a so-called library approximation, the idea is to replace the single linear space by a collection of affine spaces of small dimension and then use, for any given parameter, the appropriate space in the library. In this presentation, we introduce new algorithms for generating such libraries and illustrate their performances on several numerical examples.

CONCURRENT MULTISCALE SIMULATIONS OF NONLINEAR RANDOM MATERIALS: A PROBABILISTIC LEARNING PERSPECTIVE

Peiyi Chen[1], Johann Guilleminot[1] and Christian Soize[2]*

[1]Duke University
[2]Université Gustave Eiffel

ABSTRACT

In this work, we focus on the construction of statistical surrogates for concurrent multiscale modeling in structures comprising nonlinear random materials. We specifically address the case of highly stochastic, highly nonlinear (and potentially, non-local) homogenized constitutive models, and use probabilistic learning to approximate the mapping between deformation and stress variables. The approximation problem is formulated using conditional statistics, and probabilistic learning on manifolds is used to draw samples of the nonlinear constitutive model at mesoscale. Two applications, relevant to inverse problem solving and forward propagation, are presented in the context of nonlinear elasticity. It is shown that the proposed framework enables accurate predictions, despite the small data regime and the very high levels of nonlinearity and stochasticity exhibited by the system.

Mesh-free particle methods for multi-physics problems

INFLUENCE OF CAVITY PARTITION ON THE DAMPING PERFORMANCE OF ADDITIVELY MANUFACTURED PARTICLE DAMPERS

Honghu Guo[*1] and Takezawa Akihiro*[1]

[1]*Waseda University*

ABSTRACT

Particle damping is an effective passive method of vibration suppression. The remarkable advantages of particle damper, such as insensitivity to ambient temperature and availability at a wide range of frequencies, make it available for various applications [1]. However, a limitation for applying traditional particle damper is that an additional installation space is needed.

Additive manufacturing (AM), especially laser powder bed fusion (LPBF) technology, has been gradually adopted as an efficient method for fabricating multifunctional structures. By utilizing LPBF, a new integrated particle damper can be produced by deliberately leaving unfused powder inside the structure, named additively manufactured particle damper (AMPD). It has unique merits, such as neither mass nor cost is increased, and no additional space is required [2-3]. However, the damping mechanism and performance of AMPD are still unclear, more investigation is needed.

This research focuses on investigating the damping mechanism and performance of AMPDs with different cavity partitions experimentally and numerically. A series of particle dampers of 316 L stainless steel with different numbers and sizes of unit cells were produced using LPBF. A complex power experimental method was used to test the damping performance of AMPDs at a frequency range of 200-2000 Hz and an acceleration range of 50-200 m/s2 directly. A numerical simulation approach based on the discrete element method (DEM) was developed to investigate the damping mechanism of the AMPDs.

As a result, the numerical results of the proposed simulation model agreed well with experimental data at a frequency of 200 Hz. A consistently larger clearance between the ceiling of the wall and the powder bed was observed in the AMPDs with larger cavity sizes. Furthermore, dividing a larger cavity of AMPD into several smaller cavities emerged as an effective approach to maintaining the damping performance at higher frequencies.

FATIGUE CRACK PROPAGATION BEHAVIOR ANALYSIS OF 15MNTI STEEL BASED ON CYCLIC COHESION MODEL

Jingyi Guo[*1], Jian He[1] and Xiaodan Sun[1]*

[1]*Harbin Engineering University*

ABSTRACT

15MnTi steel is widely used in high load structures such as Bridges, pressure vessels, ships and vehicles due to its excellent mechanical properties. In the course of service, the failure of steel structure is mostly caused by fatigue fracture. In order to investigate the crack growth of 15MnTi steel under fatigue load, the cohesive zone model (CZM) was used to simulate the crack growth. The cohesive zone mode can simulate brittle and plastic fracture behavior by using the function of crack interface opening force and opening displacement to avoid the stress singularity of crack tip. On this basis, a cyclic cohesive zone model was established to study the fatigue crack propagation behavior. This model effectively links damage, tractive force, and cumulative displacement while incorporating the process of fatigue crack growth to accurately simulate material damage evolution under fatigue load. Experimental studies on crack growth in 15MnTi steel at three stress ratios reveal a linear relationship between crack growth rate and stress intensity factor range for different stress ratios. The parameters of Paris formula were calculated using crack growth rate and stress intensity factor range, which provided reference for the selection of model parameters. By utilizing the finite element software Abaqus user element subroutine (UEL) and compiling the cyclic cohesive zone model using Fortran language specifically for 15MnTi steel, simulations were conducted to analyze the evolution of crack tip state under various stress ratios and discuss the corresponding crack growth behavior based on experimental observations. The results demonstrate that the fatigue crack propagation rate varies linearly with both stress ratio range and stress intensity factor range, consistent with experimental findings. The results of the opening and closing evolution of the crack tip are consistent with the law of crack propagation, which indicates that the plastic behavior of the crack tip can be effectively characterized by the cyclic cohesive zone model. Furthermore, parameters obtained from the cyclic cohesive zone model's Paris formula closely match experimental data, thus validating its accuracy and feasibility in simulating fatigue crack propagation behavior.

GEOTAICHI: A TAICHI-POWERED HIGH-PERFORMANCE NUMERICAL PACKAGE FOR MODELING MULTISCALE AND MULTIFIELD PROBLEMS IN GEOTECHNICS

Ning Guo[*1], Yihao Shi[1] and Zhongxuan Yang[1]*

[1]*Zhejiang University*

ABSTRACT

This study introduces GeoTaichi, a high-performance numerical package designed for modeling multiscale and multifield problems in geotechnics based on the Taichi parallel programing language. It aims to provide a user-friendly, extensible, and accessible framework that can harness modern computer resources, including multicore CPUs and GPUs. While GeoTaichi is implemented in pure Python, it exhibits scalability and efficiency in solving large-scale problems.

The study primarily focuses on three modules currently available in GeoTaichi: the discrete element method (DEM), material point method (MPM), and the coupled method (MPDEM). The paper outlines the code structures and highlights the most significant features of GeoTaichi. Several benchmark tests are conducted to demonstrate the validity and robustness of the package. Furthermore, the performance of GeoTaichi is compared with similar codes in the field. The DEM simulation results reveal that GeoTaichi exhibits good scaling characteristics when the particle number exceeds 0.3 million on GPU. It is also shown that the DEM module in GeoTaichi offers approximately 70% speedup compared to similar tools utilizing GPU, while reducing memory usage by 350%. Moreover, the coupling scheme MPDEM in GeoTaichi proves to be significantly more efficient than other in-house codes with similar functionalities.

RESEARCH ON HYBRID STRESS FINITE ELEMENT METHOD IN MULTIPHASE COMPOSITES AND CAE SOFTWARE DEVELOPMENT

Ran Guo[1], Rui Zhang[1], Wenhai Gai[1] and Yangming Su[1]*

[1]*Kunming University of Science and Technology*

ABSTRACT

Aiming at the CAE technology in industry, our team, leading by the presenter, has been focusing on hybrid stress finite element method(VCFEM), and developing the core of CAE technology, the new element methods, for more than 20 years under the continuous funding of several National Foundations, and has achieved some results in material damage modeling simulation. The team has made a number of achievements in material damage simulation: a series of new VCFEM elements containing complex microstructures (e.g., inclusions, voids, and cracks, etc.), considering damage evolution, and simulating the whole process of crack initiation and expansion; a micro-meso-macro multiscale method, which realizes cross-scale simulation of damage evolution; a series of high-efficiency and high-precision solid-solid coupling methods; and a series of high-efficiency and high-precision solid-strength coupling methods. A set of CAE software for material damage analysis has been developed, with more than 500,000 lines of code in Fortran, C++ and Python, which realises the damage evolution analysis of real multi-phase materials with millions of microstructures (inclusions, voids or cracks).

COMPUTATIONAL PHYSICAL MECHANICS: FROM ADVANCED MATERIALS TO HYDROVOLTAIC SYSTEMS

*Wanlin Guo**[1]

[1]*Nanjing University of Aeronautics and Astronautics*

ABSTRACT

Our understanding of the nature and universal and our ability of creation and production depend on how small we can see (spatial scale), how fast we can capture (temporal scale) and how weak signal we can distinguish (energy scale). When the spatial scale goes down from macroscale to micro-, nano- and pico-meter scale, temporal scale reduces from second to femto- to atto-second, and more importantly, the related energy scale of an externally applied field drops for eighteen orders from joule to atto-joule (1 nN times 1 nm = 6.42 eV), falling into the energy scale of the local fields of matter which consist of electronic structures, charge, molecular orbital and spin states, or well enter the regime of quantum mechanics. Therefore, at nanoscale, matters show distinctly different performances from their bulk materials mainly due to the strong coupling between the local fields of matter and external applied fields, turning common materials such as carbon, even insulators, into functional nanomaterials with exceptional properties we expected for nanoelectronics, spintronics as well as energy conversion devices. Now our experimental ability in spatial, temporal and energy resolutions has experienced revolutionized advance. This revolution opens up a new way for new functional devices and efficient energy conversion technology, but also raises great challenges for computational physical mechanics.

Just as water breeds life, when water meets nanomaterials, the local fields of water molecules, ions, protons and nanomaterials will inevitably be coupled at liquid-solid interfaces, harvesting electricity from water by the novel hydrovoltaic effects we have discovered in the last decade, creating new generation artificial intelligence, leading to intelligent hydrovoltaics for understanding our brain. generating new intelligent characteristics and green energy technology.

In this talk, 1) the rich force-electric-magnetic-optic-thermal coupling functional characteristics and the latest progress of computational physical mechanics will be reviewed; 2) the multi-field coupling effect at the solid-liquid interface of functional materials and water, especially the hydrovoltaic effects, and the recent advances; 3) consider the sustainable development challenge, the basic scientific questions of hydrovoltaic energy, ecology, and intelligence will finally be discussed.

A SYMPLECTIC DEEP AUTOENCODER FOR HAMILTONIAN SYSTEMS

Wei Guo[*1]*

[1]*Texas Tech University*

ABSTRACT

In this talk, we introduce a novel symplectic deep autoencoder for model order reduction (MOR) of simulating parametric Hamiltonian systems with high dimensional state variables. The existing MOR techniques for parametric Hamiltonian systems suffer two limitations. First, the inherent symplectic structure of Hamiltonian systems is not necessarily inherited by the reduced order model. This may lead to instability and blowup of the system energy. Second, due to non-dissipative nature of Hamiltonian systems, the popular global linear subspace solution representation becomes less effective, and it is related to the slow decay of the Kolmogorov n-width of the solution manifold. To overcome the difficulties, we propose a deep autoencoder using HenonNets that can preserve the symplectic structure. HenonNets are constructed by composing a sequence of Henon maps which are parametrized by neural networks. Since a Henon map is symplectic, a HenonNet preserves symplectic structures when used to learn a nonlinear embedding of the solution manifold. Hence, the reduced system is still Hamiltonian, and the system energy and long-term stability is preserved. A collection of numerical tests is presented to verify the effectiveness of the proposed MOR technique.

RELIABILITY ANALYSIS AND DESIGN OF MULTI-LINE DYNAMICALLY INSTALLED ANCHOR

Xinshuai Guo[*1], Jun Liu[1] and Ping Yi[1]*

[1]*Dalian University of Technology*

ABSTRACT

A novel multi-line dynamically installed anchor was previously proposed by the author to allow for the mooring of multiple floating devices, resulting in a significant reduction in the total number and cost of anchors required for floating wind farms. This study focuses on performing reliability analysis and design for the multi-line dynamically installed anchor, taking into account the spatial variability of soil properties and the uncertainty of loads. To begin, a method is proposed and validated to reduce the number of random variables used in the Karhunen-Loève expansion, aiming to improve computational efficiency while maintaining accuracy. Building upon this, the study combines the random finite element method with the Kriging model and Monte Carlo simulation to investigate the random capacities and probabilistic VHMT failure envelopes of the multi-line dynamically installed anchor in spatially variable soil. A procedure for analyzing the design failure envelope of the multi-line anchor in spatially variable soil is proposed. Finally, the reliability design of the multi-line dynamically installed anchor is conducted and compared with the reliability design of multi-line pile anchors when considering the spatial variability of soil as well as the uncertainty of loads. The results demonstrate that the cost for the multi-line dynamically installed anchor is less obvious than that of multi-line pile anchors. Overall, this study provides valuable insights and methodologies for the practical engineering design of multi-line dynamically installed anchors.

TOPOLOGY OPTIMIZATION FOR MULTI-AXIS ADDITIVE MANUFACTURING

Yifan Guo[1], Jikai Liu[2], Yongsheng Ma[3] and Rafiq Ahmad[1]*

[1]*University of Alberta*
[2]*Shandong University*
[3]*Southern University of Science and Technology*

ABSTRACT

Compared to 3-axis additive manufacturing, multi-axis additive manufacturing has the advantage of reducing self-supporting structures. In 3-axis additive manufacturing, the angle between the structure and the direction of gravity, also known as the overhang angle, is unchangeable. This leads to the necessity of using support materials when the overhang angle is below a certain angle (threshold). However, in multi-axis additive manufacturing, this situation can be addressed by rotating the direction of the printing platform to increase the overhang angle beyond this threshold, eliminating the need for support materials. Therefore, multi-axis additive manufacturing brings new opportunities for the design of self-supporting structures.

This work proposes a self-supporting topology optimization design method for multi-axis additive manufacturing. This method concurrently optimizes both the structural shape and fabrication sequences. Optimized parameters include the material distribution of the structure, printing order, and the rotation angles of the printing platform. The proposed method establishes the overhang constraint using a novel convolution approach, which avoids the commonly observed "dripping effect" in self-supporting designs. Regarding the fabrication sequences, a pseudo-time field is introduced to represent the printing order. The manufacturing process can be divided into multiple steps by partitioning the time field. In each step, the printing platform angle remains constant, and the structure printed in this step is self-supporting. Moving to the next step, the printing platform angle can be optimized and changed, while ensuring that the structure printed in this step remains self-supporting relative to the new printing platform angle. This process is repeated until the printing is completed. For simplicity, we assume a constant fabrication speed, i.e., each step has the same material volume. In addition, this work also addresses the avoidance of collisions between the print head and the already printed structure by introducing a collision constraint. In this constraint, users can define the direction and shape of the print head.

The results obtained through the proposed method not only yield optimized self-supporting structures but also provide an interference-free manufacturing process for multi-axis additive manufacturing. Numerical and printing results will be presented to demonstrate the feasibility of this method.

Buckling analysis and design of thin-walled structures based on novel and intelligent computational methods

ISOGEOMETRIC DYNAMIC STABILITY ANALYSIS OF COMPOSITE SHELL STRUCTURES

Yujie Guo[*1]*

[1]*Nanjing University of Aeronautics and Astronautics*

ABSTRACT

The load carrying capacity of thin-walled structures is known to be significantly influenced by stability aspects such as buckling. A reliable prediction of buckling phenomena requires a robust and accurate analysis tool and consideration of a number of inherent structural imperfections which often dominate the overall non-linear elastic response. In this contribution, we will study the dynamic buckling problems of composite thin-walled structures in the framework of isogeometric analysis considering geometric imperfections. Our approach exploits the higher order approximation and continuity properties of NURBS modelled shell structures and considers arbitrary openings and cut-outs, as common in industrial applications. We will present a number of challenging shell buckling problems to reveal and assess the reliability and accuracy of the isogeometric analysis approach for geometric imperfect thin-walled composite structures. Besides, different types of dynamic loads and stacking sequences are evaluated and their influence on the dynamic buckling behaviors of the composite shell structures are studied in detail.

A DEEP LEARNING APPROACH TO MICROSTRUCTURE-RESOLVED MULTISCALE MODELING, OPTIMIZATION AND UNCERTAINTY QUANTIFICATION

Ashwini Gupta[*1] and Lori Graham-Brady*[1]

[1]*Johns Hopkins University*

ABSTRACT

Efficiently modeling material behavior and properties across multiple scales is crucial for designing heterogeneous materials with enhanced properties. However, multiscale modeling by creating a full-scale finite element (FE) discretization of multiscale resolution is often prohibitively expensive. Moreover, employing an FE-squared based multi-level discretization approach introduces errors along element boundaries and is highly dependent on the choice of micro-scale boundary conditions. To address these challenges, we propose a novel deep learning based approach to bridge scales in multiscale mechanics modeling. Our novel U-Net deep learning model, based on a convolutional neural network (CNN), is trained on a small dataset comprising complex microstructures and their corresponding stress tensor fields. By learning the underlying physics from micro-scale simulations, the deep learning model transfers this knowledge to conduct multiscale analysis of macroscopic boundary value problems at micro-scale resolution. Demonstrating a robust ability to generalize, our approach is applied to model various complex materials. We compare the results of our deep learning-based approach with conventional multiscale modeling methods across a range of macro-structure shapes, loadings, and boundary conditions. Additionally, we showcase the versatility of our approach in applications such as uncertainty quantification, multiscale design, and microstructure-resolved multiscale optimization.

A TRIPHASIC MODEL FOR THROMBUS GROWTH AND FORMATION USING REALISTIC GEOMETRIES

Ishan Gupta[1], Martin Schanz[1] and Tim Ricken[2]*

[1]*Graz University of Technology*
[2]*University of Stuttgart*

ABSTRACT

Aortic Dissection (AD) carries a high mortality rate, with approximately 40% of individuals with type B AD living for less than a month. The onset of AD involves a tear in the inner layer (intima) of the aortic wall. This leads to the formation of a secondary blood-filled channel called a false lumen where thrombosis occurs. Given the challenging prognosis of AD, a computational model is presented to understand thrombus formation and growth. Given the complexity of biological systems, we use a macroscopic continuum-mechanical approach based on the Theory of Porous Media.

The model categorizes the aggregate into solid, liquid, and nutrient constituents. The constituents are assumed to be materially incompressible and isothermal, and the whole aggregate is assumed to be fully saturated. Fluid flow in the porous media is described by Darcy's law, and the volume fractions quantify the constituents. Therefore, the regions with thrombus formation are determined using the solid volume fraction. The balance equations consist of coupling terms that represent mass exchange and interactions between phases. These terms are crucial for modelling thrombus formation and growth.

The study introduces equations and numerical examples specific to thrombosis in type B AD. We present the initial studies using 2D geometries. The simulations show that the thrombus grows in the low-velocity regions of the blood. We further study the impact of different parameters on thrombus growth. Thereafter, we extend the triphasic model to 3D geometries to simulate thrombosis and present the model’s usefulness in actual cases. Overall, the proposed model offers a cost-effective approach for numerically simulating thrombosis, providing valuable insights into the understanding and prediction of thrombus development in AD.

[3]*University of Aberdeen*

ABSTRACT

A robust computational method for investigating the thermomechanical response of physically inelastic non-linear systems to dynamic loading was developed. A non-linear dynamic problem of thermo-electromechanics for layered beams was formulated using the Kirchhoff–Love hypotheses. For the case of harmonic loading, a simplified formulation was given based on a single frequency approximation and utilizing the concept of complex moduli to characterize the non-linear cyclic properties of the material. As an example, the forced vibrations and dissipative heating of a roller-supported beam were considered. The developed formalism of thermo-electro-mechanical problem was used for estimating the self-heating caused by the electromechanical losses in piezoactive layers and the mechanical losses in electrically passive metal layer. The heating temperature evolution with time was computed. It was shown that even very small temperature increases due to the dissipation of electromechanical energy over the single vibration cycles may lead to a significant temperature rise for the multi-cycle processes. Following [1-3], the cyclic behaviour of PZT was considered to be a viscoelastic one with relatively small loss moduli. Complex moduli for this material were assumed to be independent of the frequency, temperature, and strain intensity. To avoid dangerous overheating, safe vibration regimes were found. For this purpose, the thermal fatigue life characteristic was introduced. It corresponds to the classical fatigue life, but with the Curie temperature taken as the failure criterion. To prevent overheating, active suppression of the vibration can be used. This was illustrated by numerical examples. The developed method was also successfully used for describing the thermal state under active damping regimes for other thin wall structures with piezoelectric layers for the case of small to moderate inelastic strains in the metal layer.

MODELING THE QUASI-BRITTLE FRACTURE OF STRUCTURAL MATERIALS USING A MIXED STABILIZED TWO-FIELD FINITE ELEMENT FORMULATION

Carlos Felipe Guzmán[*1], Willy Morocho[2], Sebastián Cáceres[2] and Ernesto Castillo[2]*

[1]*University of Santiago of Chile*
[2]*University of Santiago*

ABSTRACT

The fracture process zone (FPZ) is typically characterized as a small region around a crack where non-linear phenomena occur, such as plasticity. In brittle materials, this zone is small and can be safely neglected. However, in quasi-brittle materials, which exhibit a combination of brittle and ductile behavior rather than a clear manifestation of either, the material within the FPZ tends to damage and displays a softening curve after reaching peak load. This behavior is frequently observed in structural materials like concrete and timber, and it can be challenging to model due to its dependence on several factors, including: load type (tension or compression), fiber orientation (particularly relevant for timber), and the presence of a structural size effect.

Traditionally, displacement-based irreducible Finite Element (FE) formulations have been widely used for simulating structural materials like concrete or timber. However, this approach comes with significant drawbacks, such as mesh dependence and convergence problems, when applied to certain phenomena like softening, localization, and fracture. To address these challenges, various techniques have been employed, including extended FE methods, gradient-enhanced models, and phase-field modeling.

In this work, we propose the utilization of a mixed finite element (FE) formulation in which both displacement and strain serve as primary unknowns within the system. To ensure satisfaction of the Ladyzhenskaya–Babuška–Brezzi (LBB) condition, which is associated with saddle point stability in mixed formulations, we employ the Variational Multiscale Method (VMS) to introduce stabilizing terms into the system. Implementation is conducted using FEniCS, an open-source FE software that offers a high-level programming interface written in Python, enabling direct manipulation of the equations' variational form. We validate the implementation by comparing the obtained results with those reported in the literature for a series of simulations involving notched specimens. As failure criteria, we adopt Rankine and Drucker-Prager models, complemented by an exponential softening law that has been modified to capture structural size effects.

The results demonstrate remarkably good performance in terms of both force-displacement curves and stability of the solution field, even when using low-order interpolation elements and irregular meshes. Despite a slight increase in CPU time, the formulation accurately predicts the maximum load, softening curve, and structural size effect in various specimens, exhibiting minimal mesh dependence.

ABSTRACT

The present work discusses the development of High-Altitude Low-Orbit 3D [1,2] (HALO3D), a monolithic software system built to compute aerothermal loads on future hypersonic civilian aircraft. The HALO3D-Navier-Stokes (HALO3D-NS) module uses an edge-based Finite Element (FE) approach for the RANS equations and is capable of accounting for thermo-chemical non-equilibrium, electromagnetic interactions, finite-rate surface chemistry, and weak-ionization. This can be transparently linked to the ablation, rarefied-regime Direct Simulation Monte Carlo (HALO3D-DSMC), and mesh optimization (OptiGrid) modules [3]. At intermediate Knudsen regimes, a hybrid NS-DSMC framework (HALO3D-HYBRID) is used to obtain the flow solution, which is more accurate than a full-NS computation and is faster than a full-DSMC computation. The mesh optimization approach generates optimized meshes that improve solution quality across Reynolds, Mach, and Knudsen regimes. Moreover, a set of mesh optimization cycles for NS takes less time than a single structured mesh computation of similar accuracy. Improved inter-particle collisions and solution quality have also been observed with optimized meshes for both HALO3D-DSMC and HALO3D-HYBRID. OptiGrid functions by equidistributing an error estimate of a set of flow variables throughout the domain, and this is evident in all the flow regimes considered, thus showing that OptiGrid is regime- and solver-independent. The error estimate is constructed from the Hessian of a scalar set of flow variables and electric potential for Magnetohydrodynamic applications. Equidistributing this error estimate dramatically improves the scalars while, interestingly, often reducing mesh size. This presentation showcases benchmark simulations enabled by OptiGrid for complex geometries at different flow conditions, along with plots of the error estimate. The user- and mesh-independent aspects of OptiGrid are also evident across flow regimes through mesh convergence studies that show different initial meshes of any arbitrary quality converging to statistically identical meshes. Such mesh convergence studies go much further than heuristic or sequential refinement approaches and truly eliminate the effects of the mesh on the solution, thus filtering the effects of the flow module. These aspects of OptiGrid illustrate the effectiveness of such an approach in producing “certifiable” flow solutions.

ABSTRACT

We present ParaSDG, a distributed implementation of an adaptive cSDG (causal Spacetime Discontinuous Galerkin) solver. The cSDG method is a powerful numerical scheme for solving hyperbolic systems of PDEs that features local conservation properties, linear computational complexity, unconditional stability without stabilization, supported by powerful adaptive space-time meshing capabilities. In lieu of synchronous time marching, it constructs unstructured spacetime meshes according to a causality constraint that localizes the solution process to small clusters of spacetime elements called patches. The solution on each patch depends only on adjacent, previously-solved spacetime elements and prescribed initial/boundary data. This structure supports an efficient asynchronous patch-by-patch solution procedure.

We focus in this presentation on ParaSDG's distributed architecture which features a fine-grained, patch-wise parallel structure in lieu of traditional domain decomposition and novel stochastic procedures for dynamic balancing of distributed data storage and computational load. ParaSDG presents a lock-free, task-based architecture in which all processes communicate and execute asynchronously. Solver processes handle the bulk of the computation (spacetime patch construction, localized patch solution, and adaptive meshing) as embarassingly parallel work in process-private memory. Server processes manage a space-like front mesh, the only distributed data set in ParaSDG. Patches represent the basic unit of parallel computation, so there are no domain decompositions. Wrangler processes communicate with t he servers via an MPI layer to isolate the solvers from the latency of accessing the distributed data. In particular, each wrangler extracts and feeds fragments of the front mesh to a paired solver and updates the front mesh with new patch solutions. Wranglers and solvers communicate via lock-free queues in interprocess shared memory for efficient asynchronous execution. Numerical examples demonstrate ParaSDG's adaptive meshing capabilities and scaling performance in problems set in two and three spatial dimensions.

ABSTRACT

We present a new spacetime formulation of linear elastodynamics based on Hamilton's Principle of Stationary Action using differential forms and the exterior calculus on manifolds. In previous work, we formulated the same problem using an energy-based, rather than action-based, format to weakly enforce the Equation of Motion and the constitutive relations. This improved formulation supersedes the earlier one. It replaces the purely kinematic independent spacetime fields (displacement, velocity, strain) with mixed kinematic and force-like fields (displacement, linear momentum density, stress). As before, we identify these tensor fields as components of two tensor-valued differential forms in d spatial dimensions: displacement u (a 0-form) and the spacetime momentum flux M (combines linear momentum density and stress into a single spacetime d-form). We formulate the governing equations of motion and constitutive relations in terms of these two forms, their exterior derivatives, and material parameter fields for elastic response and material density. The spacetime exterior derivatives include jump parts to support our intended implementation on spacetime broken Sobolev spaces. After formulating a Lagrangian Functional of (u, du, M and dM) we apply Hamilton's Principle and Stokes Theorem to obtain a weak problem statement that is simpler than the previous one. Expressing all jump terms with respect to Riemann solutions yields unconditionally stable finite element formulations. We describe an implementation in ParaSDG, a distributed discontinuous Galerkin solver with adaptive spacetime meshing capabilities in up to E^3 x R, and present numerical results to demonstrate the new formulation's accuracy, efficiency and convergence properties.

ABSTRACT

This paper presents the development of a land use classification model based on semantic segmentation using aerial photographs. The land use data is an important part of geospatial information and can be used in a wide variety of urban development planning and disaster prevention measures. However, these data have been of limited use to date due to their low update frequency and the difficulty of obtaining high resolution data. In previous studies [1], several single-category segmentation models have been built mainly for roads and buildings, creating a limited data set.

The purpose of this study is to create a high-resolution, multi-category land use data set using aerial photographs and the deep learning method. We focused on the method of data expansion, batch size, and CNN hierarchy to obtain quantitative knowledge of the effect of these parameters on the classification results. For the deep learning model for semantic segmentation, the PSPNet (Pyramid Scene Parsing Network) [2] is employed. In order to examine the validity of multiple classification models developed with different parameters, aerial photographs of the target area were applied to this model. Furthermore, we applied the segmentation results to a two-dimensional tsunami run-up simulation and verified their contribution to improving the performance of the simulation.

SIMULATION AND OPTIMIZATION OF PHOTOVOLTAIC PANEL ARRAY CONFIGURATIONS IN WIND FLOW

Elie Hachem[*1], Theodore Michel[1] and Philippe Meliga[1]*

[1]*Mines Paris - PSL*

ABSTRACT

Among the renewable energy solutions of today, solar - more specifically photovoltaic (PV) - power plants are seen as key actors of the energy transition in Europe, and are taking on new designs and functions, seeking more adaptability and efficiency. However, PV power plants still face the major risk of strong winds often leading to breakage, hindering the efforts of green energy development. The aerodynamic loading of PV panels in wind flow has become an important research topic to quantify breakage risk and limits, but such approaches in the literature have been limited so far to panel spacing and simple tilt configurations. We introduce here a novel approach combining high-fidelity numerical simulations of large scale PV fields subjected to a turbulent atmospheric boundary layer wind flow, and a Deep Reinforcement Learning (DRL) algorithm trained to optimize the individual tilts for the purpose of maintaining safe aerodynamic efforts. An efficient and flexible computational pipeline has been developed, in which the mesh is adapted anisotropically around the fluid-solid interface using a metric map built after simulation-dependent parameters based on the boundary layer theory. The wind flow is computed with an in-house variational multiscale (VMS) stabilized finite element solver. The latter can be applied efficiently to high Reynolds number flows (since the built-in small-scale component of the solution operates as an implicit large eddy simulation) and supports elements of aspect ratio up to the order of 1000:1, which is key to solve the numerically complex strongly anisotropic wind motion generated by the extremely thin build of the panels. Finally, DRL optimization is achieved with the in-house single-step PBO algorithm, that interacts once per episode with the environment to learn the mapping from a given initial state to the optimal action, and uses heuristics from the CMA-ES evolution strategy to exploit the anisotropy of the cost function in the descent direction. The main sub-processes of PV field simulations are seamlessly integrated within a single agent-environment workflow. This includes the geometric computational domain creation from an array of panel tilts, the mesh adaptation algorithm, CFD simulations, and reward computation. We will discuss results obtained for 2d and 3d arrangements of 6 full-scale panels mounted on stands, whose individual tilts are optimized under various reward functions and using different turbulence models. Each optimal configuration is non-intuitive and reward-specific, and will be shown to perform better than the classic tilt configurations found in the literature.

ABSTRACT

Additive manufacturing techniques offer new opportunities to produce high quality structures with enhanced performances. In particular, selective laser sintering was recently used to fabricate lattice structures for high energy absorption applications. The printed parts seem homogeneous at surface. However, upon close examination, micro-porosity appears and has significant influence on the structural behavior. This created porosity is non-uniformly distributed across the structure, making classical multiscale approaches, such as FE2, not adequate to address this problem due their intensive computational burden.

In this study, we present a stochastic multiscale modeling method to address structures with non-uniform distribution of porosity at micro-scale. The method is based on the interaction-based deep material network (IB-DMN). The IB-DMN aims to determine an accurate low-dimensionality representation of the microstructure topology, which will substitute the microscopic FE model during the multiscale analysis. This will considerably alleviate the computational cost. The IB-DMN is a network composed by nodes linked through interaction mechanisms, both of them characterized by attributes. It is able to replace microscopic FE problem when it is able to accurately replicate its effective behavior for any arbitrary loading cases. This is achieved through a pre-processing step during which the network attributes are tuned to align IB-DMN predictions with FE results. Once trained, the IB-DMN is employed as a surrogate in the multiscale analysis.

We extended the method into two main directions. First, the material used during the printing process exhibit a coupled viscoelastic-viscoplastic (VE-VP) behavior. We included viscous effects in addition to history dependency to account for this behavior, which were not previously studied. Secondly, we developed the porosity guided IB-DMN (PgIB-DMN) to effectively address the variable porosity ratios across the structure without training. This new method consists on the construction of limited number of base IB-DMNs with known porosity ratios. Afterwards, the behavior of any new microstructure is computed by combining the responses of the base DMNs.

The IB-DMN was trained using only elastic and elastoplastic data. Its generalization performances were investigated for new VE-VP porous materials under different loading conditions and across various strain rates. The performances were extensively compared to FE simulations and mean filed homogenization. Overall, the reduced model demonstrated remarkable extrapolation capabilities and speedup. The PgIB-DMN allows to accurately predict the behaviors of new microstructures without requiring any additional training. Additionally, it permits to effectively carry out stochastic multiscale analysis accounting for the continuously variable porosity.

A GRAPH NEURAL NETWORK TECHNIQUE FOR SHAPE OPTIMIZATION: APPLICATION TO MULTI-OBJECTIVE FLUID-ACOUSTICS OPTIMIZATION

Farnoosh Hadizadeh[*1] and Rajeev K. Jaiman*[1]

[1]*University of British Columbia*

ABSTRACT

Aero/hydroacoustic noise is a major concern in the design of marine propellers, and wind turbine blades that can be minimized through shape optimization. To this end, we propose a novel data-driven approach based on the Finite-Element Inspired Graph Neural Network (ϕ-GNN) proposed by [1] for shape optimization applications. GNNs demonstrate effectiveness in handling arbitrary unstructured meshes without requiring model modifications. Our study focuses on employing ϕ-GNN for the reduced-order modeling of the Navier-Stokes equations to alleviate the computational costs inherent in shape optimization. Of particular interest is to predict incompressible flow fields for varying shapes in 2D high-Reynolds number flows. The proposed model can efficiently predict the quantities of interest for various shapes based on the provided mesh and physical parameters.

The proposed technique relies on an Encode-Process-Decode structure. Grid vertices in a computational fluid dynamic domain are treated as nodes and used as inputs to the graph neural network. These nodes are initialized with physical parameters, including angle of attack and Reynolds number, to pass messages on a mesh graph. They learn a mapping between spatial positions and the target data generated by the full-order Navier-Stokes computations. We demonstrate the effectiveness of the network by predicting the flow field around a wide range of airfoils to obtain the airfoil broadband self-noise resulting from the interaction of a turbulent boundary layer with a sharp trailing edge. Far-field noise is evaluated using Amiet's theory [2] to calculate the wall pressure spectrum based on the boundary layer parameters. We extract the boundary layer parameters from the network, and the results are compared with the full-order computations. The findings indicate that the online flow field around an airfoil can be predicted in seconds, which is hundreds of times faster compared with the full-order results. Finally, we integrate the network with a multi-objective optimization algorithm to minimize the overall sound pressure level while ensuring favorable integrated quantities of interest.

WIND TURBINE DAMAGE EQUIVALENT LOAD ASSESSMENT USING GAUSSIAN PROCESS REGRESSION COMBINING MEASUREMENT AND SYNTHETIC DATA

Rad Haghi[1], Cassidy Stagg[2] and Curran Crawford[2]*

[1]*Tufts University*
[2]*University of Victoria*

ABSTRACT

Assessing the structural health of operational wind turbines is crucial, given their exposure to harsh environments and the resultant impact on longevity and performance. However, this is hindered by the lack of data in commercial machines and accurate models based on manufacturers' proprietary design data. To overcome these challenges, an innovative approach to evaluate and predict loads in wind turbines using Gaussian Process Regression (GPR) is proposed. The study introduces a method that blends aero-servo-elastic simulations of publicly available wind turbine models and real-world data from Supervisory Control and Data Acquisition (SCADA) systems to create a hybrid database. By incorporating both simulated and real-world data, we aim to overcome the limitations of each data type and enhance the model's predictive accuracy. Then a GPR model is trained on the hybrid data. The GPR model validation involves an extensive analysis of a year's worth of SCADA data from an operational wind turbine. The results demonstrate the GPR model's ability to interpret and predict turbine performance, confirming its potential as a reliable tool in the structural health monitoring and load prediction of wind turbines. The accuracy of the model is further highlighted through its ability to predict turbine loads under various wind speeds, which is critical for ensuring the longevity and efficiency of wind turbines. This research discusses the broader applications of this approach in the field of asset reliability and health management. The methodology can be adapted to address the challenges associated with limited data availability in commercial wind turbines, thereby contributing to the overall advancement of predictive maintenance strategies in renewable energy systems.

LATTICEGRAPHNET: A TWO-SCALE GRAPH NEURAL OPERATOR FOR SIMULATING LATTICES AND STRUCTURES

Ayush Jain[1], Ehsan Haghighat[2] and Sai Nelaturi[2]*

[1]Georgia Institute of Technology
[2]Carbon Inc.

ABSTRACT

This study introduces a two-scale Graph Neural Network (GNN), namely, LatticeGraphNet (LGN), designed as a surrogate model for replacing costly nonlinear finite-element simulations of three-dimensional latticed parts and structures. The LGN architecture is based on MeshGraphNet [1] but with two networks: LGN-i, which learns the reduced dynamics of lattices, and LGN-ii, which learns the mapping from the reduced representation onto the three-dimensional tetrahedral mesh. LGN can predict deformation for arbitrary input lattices.

Our pipeline is trained on a set of high-fidelity nonlinear Neo-Hookean finite-element simulations with large deformation, buckling, and self-contact considerations and evaluated by studying the compressive response of lattices on unseen geometries. Every simulation step deforms the tetrahedral mesh at a rate of 20 mm/s for a total of 0.315s using 15 implicit time steps. However, the complexity of FEA simulations results in a long runtime, on the order of 48 hours to 10 days per model, depending on the mesh size, topological characteristics, and nonlinearities due to buckling and self-contact, therefore the need for speed up using machine learning.

We find that our approach provides reasonable responses until 25\% compressive strain and can predict nonlinear behavior such as buckling. Homogenization of the LGN outputs showed similar force correlations with FEA simulations but contained inaccuracies. LGN significantly reduces inference time while maintaining high accuracy for unseen simulations, hence establishing the use of GNOs as efficient surrogate models for evaluating mechanical responses of lattices and structures. To our knowledge, this is the first study that tackles the three-dimensional response of lattices with nonlinearity and buckling considerations.

NEW SPAR TYPE FLOATING WIND POWER PLANT BEHAVIOR SIMULATION FOR REDUCTION OF MOTION BY SPH METHOD

Seiya Hagihara[*1], Rikuto Ideta[1], Yuhi Uchino[1], Satoyuki Tanaka[2], Shinya Taketomi[1] and Yuichi Tadano[1]*

[1]Saga University
[2]Hiroshima University

ABSTRACT

It is important to stabilize behaviors for the efficiency of the floating wind power plants. And it is necessary to consider safety in the case of a design for the floating wind power plant about the natural disasters such as tsunamis. To predict behaviors of floating wind power plants in the ocean are very important for the safety and the ability of efficiency for power generation by numerical simulations. The particle methods which are the smoothed particle hydrodynamics (SPH) method [1] and the moving particle semi-implicit (MPS) method [2] are recently applied to fluid dynamics analyses for predictions for behaviors of structures under natural disasters such as Tsunami.

The SPH method including the artificial viscosity coefficient and the artificial density diffusion coefficient are proposed by M.Antuono et al.[3] and D.Molteni et al.[4] that is the δ-SPH method. The numerical correction terms are added to the momentum conservation equation and mass conservation equation in the delta-SPH method respectively. The 3-dimensional delta-SPH method analyses are applied to calculate the behaviour of the conventional and the new spar type wind power plant models. The new spar type has the plate for the reduction of motion. The calculated results are compared with each other.

HIGH-ORDER METHODS FOR HYPERBOLIC SYSTEMS WITH LOCAL EVOLUTION

Thomas Hagstrom[*1]

[1]*Southern Methodist University*

ABSTRACT

For challenging problems in wave theory, it is easy to show that high-order/high-resolution methods are far more efficient than their low order counterparts in terms of degrees-of-freedom required to achieve an acceptable accuracy. However, considering for example standard discontinuous Galerkin discretization schemes, the cost of time-stepping grows rapidly with order, due to the artificial stiffness induced by one-sided differentiation at element boundaries. In this work we conisder methods which circumvent this issue by employing staggered meshes. In particular we will consider methods based on Hermite interpolation as well as staggered DG schemes employing more standard polynomial bases. In both cases we will prove that the degrees-of-freedom in each element can be evolved independently with comparable orders of accuracy in both space and time and with time steps limited only by domain-of-dependence constraints. We will also discuss methods for applying boundary conditions for the staggered schemes. Experiments on multicore and GPU-based architectures will be presented.

MODELING LEFT VENTRICULAR ELECTROMECHANICS IN PATIENTS WITH HYPERTROPHIC OBSTRUCTIVE CARDIOMYOPATHY

Hannah Haider[*1], Lei Shi[2], Hiroo Takayama[1] and Vijay Vedula[1]*

[1]*Columbia University*
[2]*Kennesaw State University*

ABSTRACT

Hypertrophic obstructive cardiomyopathy (HOCM) is an inherited cardiac disease where the left ventricle (LV) myocardium thickens abnormally around the basal plane, dynamically obstructing aortic blood flow. Untreated HOCM often results in abnormal LV outflow tract pressure gradient and is associated with an increased risk of heart failure and sudden cardiac death. HOCM patients with symptoms refractory to medical management are treated with a surgically performed septal myectomy or a transcatheter-based alcohol septal ablation. While myectomy is the current gold standard, where a surgeon resects the excess myocardium using an open-heart procedure, alcohol ablation involves injecting alcohol at the hypertrophied septum, leading to a permanent scar and restricted motion alleviating obstruction [1].

Both procedures rely heavily on the operator's experience and lack objectivity in predicting their effectiveness to relieve obstruction without causing complications, including perforated septum, heart block, repeat interventions, and arrhythmia. Image-based computational modeling offers a non-invasive platform to perform virtual treatments and evaluate the outcomes of each procedure before intervening on the patient. However, modeling of myectomy and ablation is a challenging task that should account for multiphysics interactions, including electromechanics and blood flow, if the goal is to predict the relief of obstruction. Moreover, both procedures alter the myocardium's structure and function. This underscores the need for a patient-specific modeling framework to develop personalized treatment plans.

As a precursor to the multiphysics model of HOCM, we present a computational workflow to simulate ventricular electromechanics in HOCM patients using time-dependent computed tomographic (CT) images. Our workflow employs a novel inverse finite element analysis (iFEA) framework to estimate passive myocardial material parameters from dynamic CT data, while using state-of-the-art structurally-based constitutive models, accounting for myofiber disarray, and applying physiological boundary conditions [2]. We introduce a novel coupling algorithm between the 3D model and a lumped parameter network (LPN)-based model of the circulatory system, to perform closed-loop multiscale modeling of myocardial mechanics under physiologically relevant loads [3]. We also introduce a novel tuning framework to personalize the multiscale model to clinical measurements and image-based volumes and displacements, and apply the framework to a healthy subject and 3 HOCM patients. Finally, we will discuss our strategy to couple the personalized electromechanics modeling framework with a 3D blood flow model that is instrumental to performing virtual surgery simulations of myectomy and ablation.

MODELING CONSIDERATIONS IN THE SIMULATION OF SELF-HEALING FIBER REINFORCED POLYMER COMPOSITES

Vikita Kamala[1], Jack Turicek[1], Jason Patrick[1] and Ghadir Haikal[1]*

[1]North Carolina State University

ABSTRACT

The hierarchical architecture of fiber-reinforced composites (FRC) enables the design of lightweight materials with outstanding mechanical properties. This structure, however, makes FRC uniquely susceptible to interlaminar fracture (i.e., delamination). Recent research has shown that delamination damage can be reversed by Introducing a tough thermoplastic healing agent between individual reinforcing layers, thereby endowing FRC materials with a highly attractive self-healing ability [1-3]. Nevertheless, the effect of softer thermoplastic inclusions on other mechanical properties (e.g., shear), have not been fully explored.

In this presentation, we discuss a computational approach for assessing the mechanical response of glass-fiber composites containing a 3D printed poly(ethylene-co-methacrylic acid) (EMAA) thermoplastic healing agent. We employ 3D finite element models to investigate the impact of EMAA inclusions in a 3-point flexure (i.e., short beam shear) test and validate the numerical model with experimental data. The study emphasizes the impact of different assumptions, including material constitutive models and boundary conditions, on model fidelity and provides guidelines on computationally efficient and accurate modeling of FRC materials with interlaminar inclusions. This work contributes a reliable framework for the computational exploration of material design and illuminates research gaps in the simulation of self-healing composite materials [4].

FAILURE ANALYSIS IN FLEXOELECTRIC CONTACT MECHANICS

Arezoo Hajesfandiari[1] and Ali Hadjesfandiari*[2]

[1]*New York University*
[2]*Central Connecticut University*

ABSTRACT

In classical continuum mechanics, maximum principal stresses usually occur directly on the surfaces. However, the equivalent or von Mises stress which is a combination of stress tensor components has its peak value inside the bodies beneath the surfaces. This character is famous in Hertzian contact mechanics, where the maximum von Mises stresses appear beneath the contact surfaces, thus contradicting a common appearance of failures in surface fatigue. In this type of failure, pitting initiates from the surface contacts and rapidly proceeds to failure by spalling. To explain this discrepancy, it has been shown that couple-stresses can cause the critical stress to reach its maximum on the surface [1]. This suggest that flexoelectric effects can have a more significant impact on the mechanical behavior of dielectric bodies especially in contact at micro/nano and macro scales. In particular, the state of deformation and stresses in the vicinity of the contacting area deviates remarkably from what is predicted by Hertzian contact theory [2,3].

In the present work, by using couple stress based flexoelectric theory [2,3], we investigate the distribution of an equivalent von-Mises stress near the contacting area of isotropic flexoelectric bodies. Since analytical solutions for this size-dependent contact problem are not available, we have developed a boundary element formulation to calculate the displacements, rotations, force-stresses, and couple-stresses for two-dimensional isotropic flexoelectric contact problems. The numerical results of this non-linear coupled problem model show interesting characters, which are different from those in classical theory. The significance of flexoelectricity in contact mechanics becomes evident through this study, offering an explanation for numerous unexplained phenomena in the field of tribology.

CALIBRATING CONSTITUTIVE MODELS WITH FULL-FIELD DATA VIA PHYSICS INFORMED NEURAL NETWORKS

Craig Hamel[*1]

[1]*Sandia National Laboratories*

ABSTRACT

The Virtual Fields Method (VFM) and Finite Element Model Updating (FEMU), among other inverse problem methodologies, have shown success in calibrating constitutive model parameterizations for various nonlinear material models. However, VFM faces difficulties when only ingesting full-field surface data for specimens where plane-stress assumptions break down, and FEMU remains challenging when calibrating complex models where computational inefficiencies of the inverse problem are intractable. In this work, we use emerging physics-informed machine learning techniques rather than the aforementioned traditional approaches to calibrate constitutive models in large deformation scenarios using full-field experimental data. Physics-informed neural networks (PINNs) can utilize measured data for model calibration while approximately maintaining the known physical laws of the system. PINNs as a computational tool are meshless, with collocation points that are unconnected, meaning there is no need for interpolation strategies between the full-field measurement grid and the computational grid. In an inverse problem, the unknown material parameters are added to the solution basis like VFM. Rather than shape functions, the solution basis in the case of PINNs are the weights and biases of the neural network. Classical PINNs typically work in terms of the strong form of the governing equations and penalize boundary conditions (BCs) in a weak sense. This approach can make imposing the numerous traction-free boundary conditions in a solid mechanics boundary value problem difficult and furthermore it can have large effects on the solution displacement field by having errors in the displacement BC. Also working in the strong form requires enough smoothness in the activation functions and a fine enough sampling of collocation points to accurately resolve the second derivatives appearing in the governing equations of motion. Our method utilizes a combination of an energy formulation and the principle of virtual work with displacement BCs enforced exactly. In this way we have reduced the smoothness requirements and removed several of the objectives from the loss function involving BCs. Traction free BCs are also satisfied by construction. We formulate a loss function with standard error metrics along with a physics-informed term to minimize the error between observed and predicted data while persevering the balance of momentum approximately. This approach is demonstrated using synthetic data, generated from FEM simulations, representative of full-field experimental data for exemplar problems of materials undergoing large heterogenous deformation to calibrate several hyperelastic constitutive models. We will also present preliminary results utilizing digital image correlation experimental data on simple experimental specimen geometries.

OPTIMIZING THE IDENTIFICATION OF TRANSVERSAL COMPRESSION BEHAVIOR OF A HIGH-STRENGTH SYNTHETIC FIBER USING ADVANCED MACHINE LEARNING ALGORITHMS

Quyet-Tien Le[1], Cuong Ha-Minh[2], Quoc-Hoan Pham[1] and Tuan-Long Chu[3]*

[1]Vietnam Maritime University
[2]Université Paris-Saclay, ENS Paris-Saclay, CNRS, Laboratoire de Mécanique Paris-Saclay
[3]Thuyloi University

ABSTRACT

High-strength synthetic fibers are extensively utilized in ballistic protection. However, accurately determining their mechanical properties through experimentation poses significant challenges due to their small cross-sectional sizes, ranging from 1 to 100 µm. Achieving micro-level accuracy demands substantial equipment and specialized human resources. The presented research aims to optimize the identification of the nonlinear transverse compression behavior of any synthetic fiber. Within this study, over 200,000 data points generated from a finite element model validated through rare experimental data on Kevlar KM2 fibers with a circular cross-section radius of 12 µm, achieving large deformations of up to 18%, were analyzed using advanced AI algorithms. Five algorithms—Elastic Net, Bayesian Ridge, Neural Network, Gradient Boosting, and Random Forest—were employed to identify the optimal AI model based on criteria including minimal training data requirements, ease of accessibility, and the ability to swiftly predict any existing fiber type in reality. The analytical results reveal intriguing findings. The optimized AI models identified in this study do not require data on fiber diameter and Poisson's ratio to generate accurate predictive models. However, the initial elastic modulus and loading history are indispensable for any AI algorithm.

MULTISCALE MODELING OF CRYSTAL PLASTICITY: ABAQUS FE2 MODEL AND ITS SURROGATE FE-RNN MODEL

Fengbo Han[*1], Kapil Krishnan[1], Jide Oyebanji[1] and Zhongwei Guan[1]*

[1]*Technology Innovation Institute*

ABSTRACT

This study presents a novel multiscale approach to modeling large-strain plastic deformation in polycrystalline materials, utilizing both a two-scale finite element (FE2) method and its surrogate model based on a recurrent neural network (RNN). The FE2 model integrates a full-field crystal plasticity FE model at the mesoscale within a macroscopic FE model, employing the ABAQUS/Standard implicit FE solver for both scales. In this approach, the homogenized stress response from the mesoscale crystal plasticity model informs the integration points of the macroscopic model at each increment. The effectiveness of the FE2 model was validated through a one-element tension test on polycrystalline aluminum, focusing on stress-strain response and texture evolution. Additionally, compression and shear tests on high-resolution representative volume elements were conducted to observe microstructural morphology evolution under deformation. Although the FE2 model demonstrated accuracy, it was found to be computationally intensive. To address this challenge, a faster multiscale model was developed using an RNN as a surrogate for the mesoscale crystal plasticity model, integrated within the ABAQUS/Standard implicit FE solver. The RNN model was trained on a comprehensive dataset derived from single crystal deformation simulations, covering a broad spectrum of grain orientations and strain paths, thus ensuring robustness and adaptability. This multiscale FE-RNN model was then utilized to simulate complex material deformations, achieving efficient and accurate predictions of material behavior under various loading conditions. Comparative analysis with the Abaqus FE2 model confirmed the surrogate model's accuracy and efficiency. This research introduces a powerful multiscale tool for the efficient and precise simulation of polycrystalline materials, offering significant potential for engineering applications.

CRACK PHASE-FIELD ENHANCED FINITE COVER METHOD REALIZING DIFFUSIVE-DISCRETE CRACK TRANSITION

Jike Han[*1], Yuichi Shintaku[2], Shuji Moriguchi[1] and Kenjiro Terada[1]*

[1]*Tohoku University*
[2]*University of Tsukuba*

ABSTRACT

Fracture is one of the most crucial failure mechanisms in engineering fields. As well as the theoretical and experimental developments to understand the failure mechanisms, numerical simulation methodologies have been studied along with the development of computer hardware. In this trend, the crack phase-field model has been receiving significant attention due to its ability to predict arbitrary crack initiation, propagation, and bifurcation phenomena. However, the original theory of the crack phase-field model describes discontinuous crack propagation but eventually behaves the same as a continuum damage model due to the regularization of the discrete crack surfaces to be the diffusive ones. Accordingly, the crack phase-field model suffers from mesh distortion issues and divergence of Newton-Raphson computations. Also, the independent movements of multiple portions divided by crack are unable to be traced.

In this study, we present a transition scheme [1,2,3] from diffusive to discrete crack topologies. The crack transition scheme can trace an actual crack path as closely as possible and stably update its explicit crack surfaces even in a large deformation regime, including plastic deformation. In the proposed scheme, the crack initiation, propagation, and bifurcation are determined from an energy minimization problem with respect to the displacement field and the crack phase-field, while the predicted path represented by a diffuse crack topology is replaced by a discrete one by introducing the finite cover approximation. Since the discontinuity of the displacement field is introduced, the entire braking process and the subsequent independent motions of multiple portions can be captured by one single numerical setup. We present several numerical examples of brittle, dynamic, and ductile fractures to show the stable update from diffusive to discrete crack topologies within the finite strain framework.

PREDICTION OF MICRO-SCALE MECHANICAL RESPONSES OF CEMENT PASTE USING SCALE-LINKING MATERIAL PARAMETERS CALIBRATED FROM MACRO-SCALE BEHAVIORS

Yong-Woo Kim[1], Se-Yun Kim[1] and Tong Han[1]*

[1]Yonsei University

ABSTRACT

Determining the mechanical behavior of cement paste at the micro-scale by experiment is difficult due to the uncertainties inherent in cementitious materials. Simulations can be used to complement time-consuming experiments and help accelerate the development of new materials and the performance evaluation of existing materials. The evaluation of micro-scale mechanical responses using simulations is also challenging. However, by synergistically combining experiments and simulations, virtual experiments can be performed on realistic microstructures with accurately identified input material parameters. In this study, a multi-scale framework similar to that used in Ref. [1] is used to simulate micro-scale mechanical responses from material parameters calibrated from macro-scale analysis.

The macro-scale cement paste microstructures are obtained from synchrotron micro-CT measurements and the nanoindentation experiment is performed considering an indentation volume comparable to a voxel volume for macro-scale microstructures. The in-situ macro-scale tensile splitting test with micro-CT is used to calibrate the phase-field fracture model implemented based on Ref. [2]. The calibrated macro-scale model is used to determine the input material parameters at the micro-scale through a scale-linking process using the relationship between the nanoindentation property and the characteristic from micro-CT images, i.e., the linear attenuation coefficient. The multi-scale framework for evaluating micro-scale responses calibrated from macro-scale behaviors is demonstrated by conducting micro-scale virtual experiments such as direct tension and splitting tensile tests, which confirmed the validity of the framework.

COMPARATIVE EVALUATION OF 3D-PRINTED AUXETIC TITANIUM STENTS: A THREE-POINT BENDING TEST AND FINITE ELEMENT SIMULATION STUDY

Rahul Vellaparambil[1], Woo-Suck Han[1], Pierluigi Di Giovanni[2] and Stéphane Avril[1]*

[1]École des Mines de Saint-Étienne
[2]HSL S.R.L

ABSTRACT

Conventional stent designs, plagued by limited flexibility, often fail to accommodate the intricate geometries and tortuous paths of endovascular arteries. Auxetic stents, characterized by a unique negative Poisson's ratio, promise enhanced flexibility, offering a promising solution for endovascular applications1. However, the intricate geometries of auxetic stents present a significant challenge for conventional manufacturing techniques.

This study bridges the gap between simulation and reality, evaluating the bending performance of auxetic stents fabricated using 3D printing technology. Employing the Direct Metal Laser Sintering (DMLS) process, we successfully 3D-printed titanium alloy stent prototypes based on auxetic stent designs1 previously investigated. These prototypes were then subjected to rigorous three-point bending tests as per ASTM standards, providing valuable experimental data.

To complement the experimental findings, we developed a comprehensive finite element (FE) model, capable of accurately predicting the bending behavior of both auxetic and conventional stents. The FE model, validated against the experimental data, demonstrated satisfactory accuracy in capturing the bending flexibility of the fabricated stents. Our findings demonstrate the immense potential of 3D printing technologies in fabricating auxetic stents, offering a paradigm shift in endovascular applications. The ability to control intricate stent geometry using 3D printing enables the tailoring of stent design to match the unique anatomies of individual patients. While this study provides a promising foundation for the clinical translation of auxetic stents, further research is warranted to optimize current stent design limitations with 3D printing technologies and incorporate advanced post-processing techniques. By addressing these challenges, we can enhance the reliability and reproducibility of 3D-printed auxetic stents, paving the way for their widespread adoption in endovascular procedures.

NUMERICAL INVESTIGATION OF THE IMPACT OF NATURAL FRACTURES ON THE PRODUCTIVITY OF PARENT AND CHILD WELLS CONSIDERING FRAC HITS

Yanbo Liang[1], Yuanfang Cheng[2], Zhongying Han[2] and Chuanliang Yan[2]*

[1]China University of Petroleum, East China / University of Calgary
[2]China University of Petroleum, East China

ABSTRACT

Abstract: A multi-scale quadruple-medium productivity model for shale gas reservoirs is developed, taking into account gas multiple micro-flow regimes, adsorption effects, and stress sensitivity. This model is based on the principles of poroelasticity and fluid-solid coupling. Subsequently, the model is solved using COMSOL to analyze how the characteristics of natural fractures-such as length, aperture, density, roughness, and dominant orientation-affect the variation in productivity of parent and child wells under frac hits conditions. The simulation results indicate that the production rate of the parent well with frac hits initially experiences a temporary increase followed by a decline, surpassing scenarios without frac hits. In the early stage of child well production, due to frac hits, its rate is lower than the production rate of the parent well. The length, density, and aperture of natural fractures exhibit a positive correlation with the degree of interference, while the dip and roughness of natural fractures show a negative correlation. The impact of natural fracture characteristics on the degree of interwell interference is ranked as density > length > dip > opening > roughness. Among these factors, the impact of natural fracture roughness on production is minimal. When the roughness coefficient changes by 20%, the change rate of production in the parent and child well is only 0.003%, which can be considered negligible. The research findings can guide the prediction of shale gas productivity and the dynamic adjustment of production parameters.

RBF INTERPOLATION METHOD WITH AN ADAPTIVE SHAPE PARAMETER AND A POSTERIORI ERROR ESTIMATION USING SUPERVISED LEARNING

*Maria Han Veiga**[1]

[1]*The Ohio State University*

ABSTRACT

The integration of machine learning methods within PDE numerical solvers to speed-up computation, to account for more detailed descriptions of systems or to improve the quality of the numerical solution has become a common practice. However, often the machine learning models considered are static in nature, they consist of a offline training phase, and once trained are deployed and remain static. This, in turn, places an extreme importance on the correct design of the training set and training procedure, and leads to models which might not be robust (e.g.: when unseen inputs are far away from the training set). In this work, we present a hybrid computation framework in which the machine learning model continuously learns during run-time. In particular, using a novel procedure akin to a posteriori limiting, we obtain a more robust solver by switching between a data-driven method, and a gold standard procedure (which is used to generate the original training data), which in turn will be used to re-train the neural network.

To demonstrate the performance of this framework, we extend our previous work on selecting optimal parameters for radial basis functions approximations. Namely, the choice of the shape parameter highly effects the behaviour of radial basis function (RBF) approximations, as it needs to be selected to balance between ill-condition of the interpolation matrix and high accuracy. Previously, we demonstrate how to use neural networks to determine the shape parameters in RBFs using an unsupervised learning strategy. In this new work, by using error estimators on the network's prediction, we can switch between the data-driven method, and an optimization procedure that can then be used to re-train the neural network.

INTELLIGENT OPTIMIZATION DESIGN FOR VARIABLE-STIFFNESS STRUCTURES

Peng Hao[*1]*

[1]*Dalian University of Technology*

ABSTRACT

Advanced variable-stiffness thin-walled structures with curvilinearly stiffened paths and curved fiber paths as the main features have attracted significant attention. However, the addition of a large number of control parameters also leads to a rapid increase in the dimension of design variables. This paper proposes an intelligent optimization design method for lightweight variable-stiffness structures based on deep learning technology. The basic idea of this method is to use various convolutional neural networks to identify and extract the complex variable-stiffness structure features, and establish an implicit mapping relationship between the structure layout image and the structure performance. Further, the structural layout image is directly used for modeling the Gaussian process and finding the optimization in combination with the surrogate optimization framework, thus forming a driving force for the optimization process. Compared with traditional methods, both the accuracy of the optimization model and the efficiency of optimization are greatly improved, and the efficient solution of variable-stiffness structure layout design problems with dynamic changes in the number of design variables is realized.

NUMERICAL EVALUATION OF EFFECTIVE ELASTIC PROPERTIES OF COMPOSITES WITH ROTATIONALLY SYMMETRIC PARTICLES BY A SURROGATE MODEL

Pascal Alexander Happ[1] and Romana Piat*[1]

[1]*University of Applied Sciences Darmstadt*

ABSTRACT

The development of new and for a specific application optimized particle reinforced composites usually necessitates a costly development process. Great advancements in this field were achieved by utilizing the growing computational powers into the development process and utilized methods such as FEA and analytic methods such as Mori-Tanaka, Lielens and the Self-Consistent Method [1]. The quality of the predictive models were increased by incorporating ever more detailed approximations of the studied particle shapes, resulting in increased computational expenses. The by the authors presented methods of combining the heuristic optimization method of Particle Swarm Optimization [2] with the combination with the generation of surrogate models of complex particle shapes is set to reduce and even enable the computational evaluation of the contribution of different particle shapes on the effective material properties of particle reinforced composites. Particle surrogate models with greatly reduced complex shapes in contrast to the exact particle shapes are generated by utilizing a sphere in combination with on top stacked layers. The material properties of each layer is then evaluated by employing the Particle Swarm Optimization method, which finds the optimal engineering constants for each layer by comparing the resulting effective material properties of the whole composite utilizing the surrogate particle model with the effective material properties of the composite utilizing the exact particle model. This optimization procedure has been carried out for reference volume elements with only one embedded particle, the resulting surrogate particles with the optimized engineering constants have afterwards been employed for reference volume elements containing multiple particle inclusions. Numerical simulations were firstly carried out for 2D particle shapes, as multiple exact particle inclusions could only be evaluated in the 2D case due to the high computational cost of modeling and evaluating multiple complex shapes in 3D. The here proposed methodology was then adapted for the 3D case, enabling the evaluation of the effective material properties of complex particle shapes.

ADVANCING INTEGRATED SILICON PHOTONICS: TOPOLOGY OPTIMIZATION OF MODE CONVERTERS AND SPLITTERS

Fariha Haque[*1] and Alok Sutradhar*[1]

[1]*The Ohio State University*

ABSTRACT

Integrated photonics design requires solving a massive number of degrees of freedom and ensuring fabrication viability with structural integrity. Inverse design tools like topology optimization, can yield non-continuous electromagnetic structures with extremely small features that are challenging to fabricate. The figure of merit depends on the tradeoff between design dimensionality, device footprint, functional complexity, and computational cost. In this study, we present a density-based topology-optimization framework to minimize the field overlap integral and obtain efficient designs simultaneously, ensuring fabrication. We adopt a new method of updating the binarization hyperparameters and a final smoothing to ensure physically realizable material from intermediate densities. Several numerical examples are presented to demonstrate the efficacy of the proposed method.

MESH OPTIMIZATION AND BASIS COMPRESSION FOR EXTREME-SCALE SOLUTION OF PARTIAL DIFFERENTIAL EQUATIONS

Graham Harper[*1], Denis Ridzal[1] and Tim Wildey[1]*

[1]*Sandia National Laboratories*

ABSTRACT

As computing technology moves toward utilizing accelerators with little onboard memory, traditional finite element methods (FEMs) must be adapted in order to fit extreme-scale simulations on fixed resources. One of the main challenges is evaluating and storing basis values for extreme numbers of basis functions. Methods such as sum factorization handle the polynomial degree scaling of those costs, but depend on geometry and choice of finite element basis. As an alternative, we introduce an approach that compresses the physical FEM basis values using measures of mesh cell similarity. Our approach may be used separately or complementary to sum factorization methods. Our compressibility metrics involve Jacobians of the reference-to-physical cell mappings, allowing for broad applicability to simplicial or tensor-product geometry and many finite element bases. When two different mesh cells are similar in shape, the reference-to-physical Jacobians are similar; therefore, the FEM basis values are also similar, and thus do not need to be re-evaluated. The errors made by this approximation may be characterized by considering the transforms specified by de Rham complex. Compressing these basis values allows for greater throughput in evaluating function values while reducing the memory overhead of the simulation. This compression may be additionally improved by performing R-adaptive mesh optimization offline using trust region augmented Lagrangian sequential quadratic programming algorithm [1], which moves mesh nodes so that the mesh cells have more similar shapes. To validate the theory, we present a variety of results related to the approximation quality, mesh optimization, performance metrics, and how one may use this approach to simulate 1 billion mesh cells on a single node of a typical supercomputer.

WATER WAVE EVOLUTION AND EQUATION DISCOVERY THROUGH NEURAL NETWORKS AND MACHINE LEARNING

Jeffrey Harris[1]*

[1]*Ecole des Ponts ParisTech*

ABSTRACT

Despite research into water wave modeling and wave-structure interaction modeling over the decades, there remain many unknowns for even simply-stated cases under strongly nonlinear steep or breaking waves. For example, much work has recently focused on establishing a (potentially) universal breaking criterion. Meanwhile, machine learning techniques have developed to the point of standardizing equation discovery, either in the form of a neural network, or an interpretable equation. Application of the SINDy algorithm on known solutions to water wave propagation easily allows for the Korteweg-De Vries (KdV) equations to be found, an approximation in the weakly nonlinear, weakly dispersive limit. In this work, this is further developed in the time-domain, based on experimental data of irregular steep and breaking waves. Multiple approaches are compared, with a focus on steep unidirectional water waves. Comparison with classical weakly nonlinear surface reconstruction shows advantages.

AN INTERIOR-POINT MULTIGRID BASED APPROACH FOR LARGE-SCALE CONTACT MECHANICS

Tucker Hartland[*1], Socratis Petrides[1], Jingyi Wang[1], Michael Puso[1], Jerome Solberg[1], Tzanio Kolev[1] and Cosmin Petra[1]*

[1]*Lawrence Livermore National Laboratory*

ABSTRACT

A critical aspect of modeling complex engineering systems is the interaction of physical bodies in contact. A number of frictionless contact problems have the property that the modeled state is the minimizer of an energy objective functional. However, generally such problems are: nonlinear, nonconvex and contain an optimization variable whose dimension is unbounded with respect to mesh refinement. We focus on the scalable solution of such large-scale contact mechanics problems on high-performance computing systems. We employ a Newton-based interior-point filter line-search method, that has emerged as one of the most robust methods for nonlinear nonconvex constrained optimization, to computationally estimate minimizers of such large-scale constrained optimization problems. The outer Newton-based interior-point loop converges rapidly; however, each step requires the solution of a large saddle-point linear system. A major challenge with the inner interior-point Newton-based linear system is that, in addition to the general challenges of solving large-scale linear systems, it can become arbitrarily ill-conditioned as the optimizer estimate approaches the optimal point. There are blocks that are amenable to multigrid which is a problem feature that we exploit. In this talk, we detail an interior-point multigrid-based approach for solving such problems and present scaling results obtained from an implementation of said framework on a few contact mechanics example problems. The results show that the solution of various contact mechanics problems can be achieved in a manner that scales well in the large-scale regime.

MACHINE LEARNING DISCOVERY OF OPTIMAL QUADRATURE RULES FOR ISOGEOMETRIC ANALYSIS

Tomas Teijeiro[1], Jamie M. Taylor[2], Ali Hashemian[2] and David Pardo[3]*

[1]Basque Center for Applied Mathematics
[2]CUNEF University
[3]University of the Basque Country

ABSTRACT

We propose the use of machine learning techniques to find optimal quadrature rules for the construction of stiffness and mass matrices in isogeometric analysis (IGA) [1]. We initially consider 1D spline spaces of arbitrary degree spanned over uniform and nonuniform knot sequences, and then the generated optimal rules are used for integration over higher-dimensional spaces using tensor products. The quadrature rule search is posed as an optimization problem and solved by a machine learning strategy based on adaptive gradient-descent. However, since the optimization space is highly nonconvex, the success of the search strongly depends on the number of quadrature points and the parameter initialization [2]. Thus, we use a dynamic programming strategy [3] that initializes the parameters from the optimal solution over the spline space with a lower number of knots. With this method, we found optimal quadrature rules for spline spaces when using IGA discretizations with up to 50 uniform elements and polynomial degrees up to 8, showing the generality of the approach in this scenario. For nonuniform partitions, the method also finds an optimal rule in a reasonable number of test cases. We also assess the generated optimal rules in two practical case studies, namely, the eigenvalue problem of the Laplace operator and the eigenfrequency analysis of freeform curved beams, where the latter problem shows the applicability of the method to curved geometries. In particular, the proposed method results in savings with respect to traditional Gaussian integration of up to 44% in 1D, 68% in 2D, and 82% in 3D spaces.

SOME UNRESOLVED ISSUES IN TRUSS-LIKE MICROSTRUCTURE MATERIAL DESIGN

*Behrooz Hassani**[1]

[1]*Ferdowsi University of Mashhad*

ABSTRACT

Abstract
This article addresses long-standing misconceptions and misapplications in the field of material design by employing the mathematical theory of asymptotic homogenization (AH) and its substitutes [1]. One prevalent approach, persisting in the literature for approximately three decades, involves using the truss and frame cell of periodicity as the base building block of materials [2]. It is shown that using AH to design truss-like cellular composites is a misconception and unachievable. In this context, the flaws in a couple of notable articles that proceed with this approach are explained.
Additionally, the prevalent alternative approaches for imposing the unit initial strain and the periodicity boundary conditions to the base cell are scrutinized and the common flaws are elucidated. The article also briefly touches upon alternative energy methods. Another debated issue is the inconsistency between the bending action of beam members in frame microstructures and the assumption of cell periodicity. Also, common problems and misapplications related to alternative methods for AH in periodic truss and frame microstructures are addressed along with issues of truss nomenclature and finite element misapplications. Finally, some problems related to the recent artificial intelligence-assisted methods are briefly discussed [3].
Recognition of these problems is important, as they potentially impact energy, resource, and effort consumption.

ELEMENT-TYPE ANALYSIS FOR PLANAR ROTATING SQUARE AUXETICS—A FINITE ELEMENT STUDY

Fereshteh Hassani[*1], Zia Javanbakht[2] and Sardar Malek[1]*

[1]*University of Victoria*
[2]*Griffith University*

ABSTRACT

Planar auxetic structures are commonly simulated using 2D elements in a small deformation regime to reduce computational costs. In this study, we conduct an element-type analysis on rotating square auxetics subjected to in-plane tensile loads within a large deformation regime to assess the validity of the 2D assumption. Four types of elements are selected, including plane stress, plane strain, shell, and 3D brick elements. The finite element (FE) results are then compared with experimental test results to identify the element that accurately represents the behavior of a rotating square auxetic. It was observed that, unlike small deformation regime, due to considerable through-the-thickness stress and strain, the 2D assumption is inadequate and fails to predict the actual behavior of the auxetic structure under large deformation conditions.

A HYPER-REDUCED ORDER MODEL FOR NONLINEAR COUPLED POROUS MEDIA FLOW

Saeed Hatefiardakani[*1] and Robert Gracie*[1]

[1]*University of Waterloo*

ABSTRACT

The real-time simulation of complex geomechanical processes, such as hydraulic well stimulation, is computationally expensive since such systems often involve nonlinear and time dependent coupled thermo-hydro-mechanical equations. Finite Element Method (FEM) or similar methodologies can be utilized for the online (real-time) use or parameter estimation using field data; however, the simulation of large models often takes many hours to days. In this presentation, intrusive Model Order Reduction (MOR) techniques are developed for a system of nonlinear hydro-mechanical coupled equations to reduce computational costs. We will discuss various Reduced Order Models (ROM), including the need for a Proper Orthogonal Decomposition-Galerkin (POD-G) to reduce the number of degrees of freedom (DoFs), the need for Discrete Empirical Interpolation Method (DEIM) to accelerate the computation of nonlinear terms, and the need for local DEIM (LDEIM) [1] to apply a further reduction for nonlinear coupled transient problems. The ROM is carried out in an offline-online decomposition. First, some Full Order Models (FOMs) are carried out through a computationally offline stage to create a ROM basis. Then, through an online stage, full-physics FEM formulation will be improved by utilizing MOR formulations, and the trained MOR is employed to predict the response of the system. This presentation is built on our recent work on nonlinear porous media flow problems with time-discontinuous fluid injection rates [2]. Offline training of ROMs and online performance will be discussed for a two-dimensional analysis of hydraulic well stimulation, where a deformable porous medium is saturated with a single-phase fluid flow. The speed-up time and accuracy of ROMs are compared with coupled FOM. We will show that POD with LDEIM produces ROMs with accuracy comparable to FOM that execute significantly faster than FOM. In addition, an application of the presented ROM to a parameter sensitivity analysis is demonstrated. In this case, ROMs are parameterized from injection rate, permeability, and elastic parameters. It is demonstrated that the parameterized ROM can accurately reproduce deformation and pressure around the borehole.

PARAMETER-ROBUST UNFITTED FINITE ELEMENT METHODS FOR A MAXWELL INTERFACE PROBLEM

Tim Haubold[*1] and Christoph Lehrenfeld*[1]

[1]*University of Göttingen*

ABSTRACT

Geometrically unfitted finite element methods such as CutFEM, Finite Cell, XFEM or unfitted DG methods have been developed and applied successfully in the last decades to a variety of problems ranging from scalar PDEs on stationary domains to systems of PDEs on moving domains and PDEs on level set surfaces. These approaches combined with established tools of finite element methods allowed to apply and analyse unfitted methods in many fields. In this talk, we deal with an elliptic interface problem for the time-harmonic quasi-magnetostatic Maxwells equations.

Here the material function μ, the magnetic permeability, can jump at an interface.
Such problems are considered in low-frequency applications. Standard unfitted Nitsche methods are not robust with respect to the parameter k. For example, a standard Nitsche discretization for the curl-curl-operator introduces terms that do no longer vanish for gradient fields. In this talk, we will use a vectorial finite element discretization based on H(Curl) conforming functions. We will tackle the problem of robustness by introducing a scalar potential into the Nitsche formulation and thus apply a careful tailored ghost penalization term.

DESIGN OF WIND TURBINE DIFFUSERS USING STABILIZED METHODS AND THE VMS TURBULENCE MODEL

Hector Sanchez[1] *and Guillermo Hauke**[1]

[1]*EINA*

ABSTRACT

Harvesting the most of the wind resources presents a challenge in wind turbine devices and an important contribution towards the zero emissions objective. It has been shown that, for a given upstream flow conditions, diffusers augmented wind turbines (DAWT) present an opportunity to increase energy production of wind turbines [1]. The design of these devices will be addressed for a horizontal axis wind turbine using stabilized methods, MRF algorithms for fluid-structure interaction [3] and VMS turbulence models [2]. Some geometries that increase the wind harvested kinetic energy will be shown and the performance of the devices will be compared without and with a turbine rotor.

A REVIEW OF VMS A POSTERIORI ERROR ESTIMATION IN COMPUTATIONAL FLUID DYNAMICS

Guillermo Hauke[*1] and Diego Irisarri*[1]

[1]*EINA*

ABSTRACT

VMS theory [1] was initially developed to evince the origins of stabilized methods. In this talk it is shown that stabilization parameters and stabilization terms contain true error information that can be used to obtain explicit and implicit a posteriori error estimates. The technology consists of splitting the exact solution into resolved or coarse scales (finite element solution) and unresolved or fine scales (numerical error). By feeding this splitting into the variational formulation, an exact weak form can be derived for the fine scales as a function of the resolved scales. The way of solving or approximating this equation yields different algorithms and models for error estimation [2]. Furthermore, using the so-called fine-scale Green's function, an analytical representation of the fine scales is possible. Different approximations of this function give rise to various algorithms and models. VMS theory naturally suggests that the error can be computed by the combination of element interior and inter-element faces residuals with the corresponding error time-scales. This technology can be further used for example to generate adapted meshes, to derive reduced order models and in verification and validation algorithms.

A MECHANICAL ANALYSIS OF CELL MIGRATION USING A STRUCTURAL OPTIMIZATION APPROACH

Soham Ghosh[1] and Eric Havenhill[1]*

[1]Colorado State University

ABSTRACT

The goal of this research is twofold that will provide predictive measures of two features of cell mechanics during their directed migration. The first goal is to exploit the use of modern optimization techniques in order to predict the orientation and size of actin stress fibers within the cytoskeleton. The second goal is to quantify the traction forces at these focal adhesion sites through these stress fibers during cell migration. For both scenarios, the cells are subject to a finite actomyosin supply constraint. The experimental measurements of such structural assembly inside the cell during migration is currently unavailable due to the limitations of modern microscopy, specifically because of our inability to image the cells at very high spatiotemporal resolution limited by photobleaching. A structural optimization framework can provide the predictive measure which is otherwise impossible by experimental means. Using this framework further, the quantification of the traction forces during migration is also quantified, which plays a crucial role in cell-matrix communication via mechanosensing. These results can be compared with the traction forces obtained by experimental methods, such as traction force microscopy. The benefit, however, of such a biophysical model as compared to experimental results, is that the parameters of the model can be adjusted to obtain new data regarding cell motion without having to rely on experimentation. The approach utilized here harness the power of modern structural optimization and optimal control. Structural optimization has proved to be a powerful method of generative design. However, the focus of the field has been on static structures, with exceptions to frequency-based structural optimization. Fully dynamic structural optimization has not extensively been studied since most systems do not possess the capability to generate their structural components over time. Therefore, with the power of structural optimization, nonlinear and optimal control theory, combined with the finite element method, a novel dynamic model of cell migration is achieved. He results might provide new methodologies and insights to the biomechanics and applied optimization research communities.

THE PICARD-NEWTON ITERATION FOR THE BOUSSINESQ EQUATIONS

Leo Rebholz[1] *and Elizabeth Hawkins**[1]

[1]*Clemson University*

ABSTRACT

We propose, analyze and test the Picard-Newton iteration for the Boussinesq equations. The Picard-Newton iteration was (seemingly) recently developed as a two step method defined by a Picard step followed by a Newton step. We show this iterative method is an improvement on Newton that retains the quadratic convergence rate but has a larger basin of convergence. This is further improved by introducing Anderson Acceleration into the Picard step, and little seems to be lost when resolving the Picard step to only low accuracy.

MECHANICAL-ELECTROCHEMICAL BEHAVIORS OF GEL ELECTROLYTE

Linchun He[1]*

[1]*Xi'an Jiaotong University*

ABSTRACT

Wearable electronic devices and skin sensors require specific energy storage systems that combine high energy density and rate capability as well as long cycle life with additional features, such as high flexibility, high safety and environmental friendliness.[1] Flexible batteries based on hydrated polymer quasi-solid-state electrolytes (SSEs) are considered as promising solutions in view of their favorably high ionic conductivity and excellent flexibility. The rate capability and capacity retention of such flexible wearable batteries is controlled by the electrochemical and mechanical properties of the SSEs as well as their interfaces with the electrodes. Therefore, it is crucial to advance the development of new SSEs with wide electrochemical window, high stability and excellent mechanical strength in order to enable competitive wearable batteries.

In this work, a novel Zn2+ hydrogel polymer electrolyte has been synthesized, which achieves a high ionic conductivity of 4.8 × 10-4 S cm-1 at room temperature, and practically no change of conductivity up to 40 °C. Moreover, it features a wide electrochemical window ranging from 0 V to 2.06 V (vs. Zn/Zn2+). The mechanical strength of the electrolyte has been significantly enhanced from 0.6 MPa to 1.7 MPa by incorporating low-cost coconut fibers. Zn batteries employing our electrolyte achieve high capacity (80% of theoretical capacity) and maintain high stability and reversibility (99% capacity retention over 500 cycles at 5 C). The novel flexible battery has also been demonstrated to function with outstanding performance over the relevant temperature range down to low temperatures (4 °C) as well as under bending, meeting the key criteria for flexible power supply in wearable electronic devices.

DYNAMIC DISPLACEMENT RECOGNITION OF FRAME STRUCTURES BASED ON COMPUTER VISION

Muyang He[*1], Jiayi He[1] and Xiaodan Sun[2]*

[1]*Harbin Institute of Technology*
[2]*Harbin Engineering University*

ABSTRACT

The safety of engineering structures has increasingly become a concern, and the rapid assessment of structural safety has become a focal point and challenge in this field. With the development of structural health monitoring technology and the emergence of intelligent tools such as computer vision, research on real-time health monitoring of structures that combines both contact and non-contact methods holds significant theoretical significance and engineering application value. The displacement of a structure under external forces is one of the more intuitive variables for structural safety assessment. Traditional contact methods, such as placing displacement sensors on structures, are often constrained by objective factors. Non-contact methods, like utilizing computer vision algorithms such as optical flow estimation and feature matching, can rapidly and accurately obtain structural displacement. They also offer advantages such as being unaffected by the structure itself and having quick deployment. However, improving the accuracy of displacement monitoring based on computer vision is a key focus in this research field. This paper proposes a data processing method for dynamic displacement in structures based on a combination of non-contact and contact approaches. It fuses dynamic displacement identified through computer vision technology with data recorded by acceleration sensors on the structure to enhance displacement monitoring accuracy.

Firstly, a multi-target template matching algorithm based on OpenCV is used to convert the dynamic trajectories of known feature points on the structure into pixel displacements. The dynamic distances of feature points identified by template matching are used to calculate a scaling factor based on known structure dimensions. Secondly, the displacement converted from acceleration sensor data is fused with pixel displacement upsampled to the same frequency as the sensor through Kalman filtering. This process simulates the real displacement of the structure. Finally, the random subspace method is employed for structural modal parameter identification, validating the feasibility of the approach proposed in this paper. The research results indicate that this method can obtain dynamic structural displacement based on computer vision information. The relative error in monitoring data is reduced from 43.75%, as seen in traditional methods, to an average of 7.46%, demonstrating the effectiveness and reliability of the proposed approach.

A NEURAL NETWORK ENHANCED DIFFERENTIABLE MESHFREE METHOD FOR COMPUTATIONAL MECHANICS

Honghui Du[1] *and QiZhi He**[1]

[1]*University of Minnesota*

ABSTRACT

Physics-informed/physics-constrained machine learning approaches have received increased attention for solving both forward and backward computational mechanics problems across diverse engineering applications. However, their predictive accuracy and training efficiency encounter limitations in realistic engineering scenarios, especially those involving kinematic and material nonlinearities. In this presentation, we introduce a newly proposed differentiable meshfree approach--the neural-integrated meshfree (NIM) method [1]. NIM is derived based on a hybrid neuro-numerical approximation, facilitating the efficient training of neural networks while adhering to the underlying governing equations within a consistent meshfree Galerkin framework. The numerical results of several benchmark examples, including stationary and transient mechanics problems, showcase the enhanced performance of NIM in terms of accuracy, scalability, and convergence properties. In addition, we extend the NIM framework to model inelastic materials, where the effects of different loss function formulations on encoding internal state variables and nonlinear material laws are investigated. To highlight the superior performances of the proposed method against existing approaches in the literature, several inelastic material models are considered in the study.

PHYSICS-INFORMED NEURAL NETWORK IN PARTIAL DIFFERENTIAL EQUATIONS FOR FINITE ELEMENT ANALYSIS OF FLASH SINTERING

Ran He[*1], Mingxuan Xia[1], Peter Polak[1], Baber Saleem[1], Michael Yu[1], Xiaoxia Yu[1] and Jingzhe Pan[1]*

[1]*University of Leicester*

ABSTRACT

Flash sintering is characterised by the application of an electrical field to a material body during sintering. This method achieves remarkable heating rates by directly dissipating heat within the ceramics, significantly reducing both processing time and furnace temperature compared to the conventional sintering. This enhancement leads to increased throughput and productivity, marking a notable improvement in the processing efficiency. However, flash sintering presents specific challenges, particularly in controlling deformation and grain growth. This challenge can occur as a result of the resistive heating caused by the applied electric current. To achieve the desired final shape of the material, accurately predicting the temperature distribution in the sintering part is critical. Currently, the Maxwell's functions and heat equation are used to simulate the fields of electricity and heat in the finite element analyses. However, they may not fully capture the actual fields. To address this challenge, this study aims to introduce a new backpropagation strategy for an artificial neural network (ANN) to replace ohmic heating due to electric current in the heat equation for the finite element analysis, and, thus, to accurately predict the temperature distribution and sintering behaviour of the sintering part.

This innovative approach involves a two-step training process for the ANN. The inputs consist of current, temperature and relative density, with the ohmic heating as the output. Firstly, the ANN is trained to learn the relationship between the ohmic heating and the applied electric current based on the existing developed equations. This trained ANN is implemented in COMSOL to simulate the process of flash sintering. Its results are compared with those simulated by the existing equations, showing a good agreement. Subsequently, the ANN is retrained with experimental data. As the experimental data are only available for the surface temperature of the sintering part, not the ohmic heating, the loss function is defined as the mean squared error of the surface temperature instead of the ohmic heating. Hence, a new backpropagation strategy is developed with its mathematical prove. The retrained ANN is again implemented in COMSOL to simulate the process of flash sintering. The simulated temperature and relative density are in good agreements with the experimental data. This validates the feasibility of the proposed backpropagation strategy to replace a parameter/term in the partial differential equation in the finite element analysis of flash sintering.

S-VERSION FEM-BASED STRATEGY FOR SIMULATING HIGH-SPEED CRACK PROPAGATION BEHAVIOUR IN 3D STRUCTURES

Tianyu He[1], Naoki Morita[2], Naoto Mitsume[2] and Kazuki Shibanuma[1]*

[1]*The Uinversity of Tokyo*
[2]*University of Tsukuba*

ABSTRACT

Developing a numerical method to simulate the brittle crack propagation behaviour accurately and efficiently is crucial for ensuring the safety of large-scale engineering structures. This study proposed a novel strategy based on the s-version finite element method (s-method) for simulating high-speed crack propagation in 3D structures.

In the proposed strategy, the high-speed crack propagation is modelled by a combination of the nodal force release method and local mesh update. The global mesh is generated based on the entire domain geometry without considering crack propagation, which significantly simplified the mesh generation procedure. Meanwhile, the local mesh is generated only in the vicinity of the crack front with fine elements to ensure high accuracy. However, ensuring complete coverage of the target domain necessitates extending the local mesh beyond the surface of the 3D structure. Such an incompatibility between the surface of the target domain and boundaries of the local mesh causes non-negligible errors in the conventional s-method. To address this issue, we propose an approach based on Heaviside enrichment to eliminate these errors.

The proposed strategy was initially verified by evaluating the accuracies of the local stress in stationary and dynamically propagating circular crack in a 3D solid, as well as those of the stress intensity factor. The results demonstrate that the proposed strategy provides unprecedented accuracy and efficiency of local stress evaluation in problems of dynamic crack propagation without requiring any complicated remeshing procedures.

Subsequently, to further validate the effectiveness of the proposed strategy for simulating the high-speed crack propagation in real engineering structures, numerical examples to analyse the experimental results of high-speed crack propagation in double cantilever beam-type plate and joint specimens made of polymethyl methacrylate (PMMA) are presented. The numerical results demonstrated the effectiveness of the proposed strategy for simulating high-speed crack propagation in 3D structures. Consequently, the proposed strategy has the potential to serve as a fundamental numerical framework for simulating dynamic crack propagation in engineering structures.

RESEARCH ON AIRCRAFT TIRE SPRAY PROBLEM ON WET RUNWAY BASED ON IMPROVED SPH ALGORITHM

Tingting He[1], Xianpeng Zhang[1] and Fei Xu[1]*

[1]*Northwestern Polytechnical University*

ABSTRACT

Abstract
The tire-generated water spray may enter the engine when the aircraft takes off or lands on the wet runway, and lead to the compressor stall, surge, or even combustion flame-out. Therefore, to study the problem of aircraft tire spray is of great significance to the safety and the airworthiness certification of the aircraft. Based on the self-developed SPH program, the problem of aircraft tire spray will be researched thoroughly by the combination of experiment and numerical simulation in this paper. When simulating this kind of fluid-elastomer interaction problem with traditional SPH (Smoothed Particle Hydrodynamics) method, there are some drawbacks in both fluid and elastomer calculation. For the elastomer simulation, the TL-SPH (Total Lagrangian-SPH) is used to deal with the deformation of tire under complicated motion and load. For the fluid simulation, the Riemann SPH combined with transport velocity technology is proposed to solve the problem of tension instability in free liquid surface splashing. On this basis, the SPH model of tire spray is established. By carrying out the aircraft tire vertical water entry experiment, the morphological characteristics of the tire spray are captured. The morphological description method is determined. These provide the verification basis for the numerical calculation. Then, the formation mechanism of spray is analyzed by numerical simulation. Finally, based on the large-scale tire spray simulation, the phenomenon of tire hydroplaning is studied, and the causes of hydroplaning phenomenon and its influence on spray form are analyzed.

Keywords: SPH (Smoothed Particle Hydrodynamics), aircraft tire spray, fluid-structure interaction, tensile instability.

A PERIDYNAMICS MODEL FOR THE FRACTURE IN GRAPHENE SHEETS

Xiaoqiao He[*1] and Xuefeng Liu*[2]

[1]*City University of Hong Kong*
[2]*Three Gorges University*

ABSTRACT

This work establishes an ordinary state-based peridynamic coarse-graining (OSPD-CG) model based on the interatomic potential at nanoscale to study the fracture in nano-materials, i.e. the fracture in graphene sheets (GS). The PD model for linear elastic solids is generalized as a nonlinear one to model fracture in physical nonlinear materials, i.e. GS. Based on energy conservation, the PD parameters are derived from full atomistic molecular dynamics (MD) simulations in which interatomic potential is used. The PD model is verified by comparing the Young's modulus calculated from PD and the one from MD. The PD simulation results such as the stress-strain relations and the crack propagation patterns are also compared with those from full atomistic MD simulations to show the validity of the PD model. The fracture mechanisms in GS are revealed as well. For example, the primary crack branches into two secondary cracks after propagating straightforward for a short time at initial stage. Then the secondary cracks keep propagating near the boundaries and their propagating directions are changed due to the influence of the boundaries. And in the propagation process of secondary cracks, some micro-cracks even tertiary cracks generate due to the branching of secondary cracks. Furthermore, this work also shows the advantage of the OSPD-CG model here over MD simulations that the current model can be used to study larger scale systems with higher efficiency.

A TPAA-MSSBFEM FOR SOLVING NONLINEAR TRANSIENT HEAT TRANSFER PROBLEMS OF TWO-DIMENSIONAL HETEROGENEOUS MATERIALS

Xiaoteng Wang[1], Haitian Yang[1] and Yiqian He[*1]*

[1]Dalian University of Technology

ABSTRACT

By combining the Multiscale Scale Boundary Finite Element Method (MsSBFEM) and the Temporally Piecewise Adaptive Algorithm (TPAA), a new numerical model is presented to reduce the solution scale of the two-dimensional heterogeneous nonlinear transient heat transfer problems. Utilizing TPAA, a spatially and temporally related problem is transformed into a series of recursive spatial problems, which are solved by MsSBFEM. The solution scale can be effectively reduced by recourse of a bridge between small-scale and large-scale via quadtree Scaled Boundary Finite Element Method (SBFEM) based numerical base functions. In the spatial domain, utilizing the advantages of image-based quadtree gridding, the construction of numerical base function can be conveniently and efficiently conducted particularly for the heterogeneous media with complex geometries at the small-scale. In the updating of numerical base function in the nonlinear multiscale computation, combine with the reduced integration method, the sparse transition quadtree mesh with the fixed element pattern makes the solution of nonlinear heat transfer problem and updates of numerical base function more efficient. The adaptive updating criterion of the numerical base function is proposed, which further improves the computational efficiency of multiscale analysis. The TPAA can maintain temporal computational accuracy via an adaptive process when the step size varies. Numerical examples are provided to elucidate the effectiveness of proposed approaches, and satisfactory results are achieved at both the large and small scales.

MONOLITHIC MULTIGRID FOR THE MARKER-AND-CELL DISCRETIZATION OF THE STOKES--DARCY EQUATIONS

Chen Greif[1] *and Yunhui He**[2]

[1]*University of British Columbia*
[2]*University of Houston*

ABSTRACT

In this talk, we consider the marker-and-cell scheme for numerically solving the Stokes--Darcy equations. The corresponding discrete system has a double saddle-point structure. Designing a fast solver for such a problem is challenging due to the different scale of the physical parameters. We propose a monolithic multigrid solver with a block-lower-triangular smoother based on the block-LU decomposition of the coefficient matrix, which requires solving a Poisson-type equation with a scalar Laplacian and two Schur complement systems. We demonstrate the robustness of a sparse approximate inverse smoother for the Laplacian, and we handle the Schur complement systems by applying simple relaxation schemes as smoothers. The proposed scheme is economical, and yet it is robust with respect to the mesh size and the physical parameters.

CALIBRATION OF DAMAGE PARAMETERS OF SUPER HIGH-RISE FRAME-CORE STRUCTURAL SUBSYSTEM UNDER TORSIONAL GROUND MOTION

Zhuang Guo[1], Yingchang Ma[1] and Zheng He[1]*

[1]Dalian University of Technology

ABSTRACT

The super high-rise frame-core tube structure consists of multiple subsystems that collectively respond to torsional seismic action. The damage progression and failure of multiple subsystems have a direct impact on the seismic safety of the structure. However, current torsional control methods primarily address the torsional regularity of the entire structure, while overlooking the impact of the torsional component of ground motion and the torsional damage within internal subsystems. The characterization of torsional damage in the subsystem subjected to torsional ground motion provide support for subsequent analysis of translation-torsional coupled damage. To elucidate the dynamic characteristics of the structure under torsional excitation, this paper derived the torsional vibration equation for the structure and the restoring force model for each subsystem. The accuracy of the dynamic model was then verified through a combination with the finite element model. To choose a suitable damage index that accurately describes the torsional damage degree of the subsystem, while taking into account the applicability of stiffness degradation to both the overall structure and each subsystem, the stiffness degradation coefficient was identified as the key index to depict the damage degree of each subsystem after the structure enters the elastoplastic stage. Moreover, acknowledging the limitations of the current method for estimating stiffness degradation coefficients, the NSGA-II genetic algorithm was employed in this study. The initial stiffness and yield strength of each subsystem serve as optimization variables in the design of a comprehensive optimization plan that considers both structural cost and overall torsional damage. Considering the time-consuming nature of elastic-plastic time history analysis, an independent torsional pushover analysis method was developed and validated using time history analysis. By introducing reasonable assumptions, the optimization example was designed to preserve solely the simplified structure of the reinforcement layer. Meanwhile, due to the difficult of considering the plastic development of the outrigger truss in the plane with the rigid floor slab assumption, the assumption of concentrated plastic hinges was applied at the connection between the outrigger and the column end. The hysteresis parameters of each subsystem in the optimization example align with those mentioned above. The validity of the assumed hysteresis parameters was confirmed through torsional pushover analysis of the optimization examples. A reasonable estimation of the stiffness degradation coefficient was obtained by incorporating the Q-hysteresis model.

[3]*University of Southern Denmark*
[4]*Odense University Hospital*
[5]*Erasmus MC*
[6]*Queensland University of Technology*

ABSTRACT

Osteon morphology provides valuable information about the interplay between different processes involved in bone remodelling. The correct quantitative interpretation of these morphological features is challenging due to the complexity of interactions between osteoblast behaviour, and the evolving geometry of cortical pores during pore closing. We present a combined experimental and mathematical modelling study to provide insights into bone formation mechanisms during cortical bone remodelling based on histological cross-sections of quiescent human osteons and hypothesis-testing analyses. We introduce wall thickness asymmetry as a measure of the local asymmetry of bone formation within an osteon and examine the frequency distribution of wall thickness asymmetry in cortical osteons from human iliac crest bone samples from women 16–78 years old. Our measurements show that most osteons possess some degree of asymmetry, and that the average degree of osteon asymmetry in cortical bone evolves with age. We then propose a comprehensive mathematical model of cortical pore filling that includes osteoblast secretory activity, osteoblast elimination, osteoblast embedment as osteocytes, and osteoblast crowding and redistribution along the bone surface. The mathematical model is first calibrated to symmetric osteon data, and then used to test three mechanisms of asymmetric wall formation against osteon data: (i) delays in the onset of infilling around the cement line; (ii) heterogeneous osteoblastogenesis around the bone perimeter; and (iii) heterogeneous osteoblast secretory rate around the bone perimeter. Our results suggest that wall thickness asymmetry due to off-centred Haversian pores within osteons, and that nonuniform lamellar thicknesses within osteons are important morphological features that can indicate the prevalence of specific asymmetry-generating mechanisms. This has significant implications for the study of disruptions of bone formation as it could indicate what biological bone formation processes may become disrupted with age or disease.

MODELING OF PDC CUTTER – ROCK INTERACTIONS USING HOSS

Erin Heilman[*1], Esteban Rougier[1], Bryan Euser[1], Luke Frash[1], Meng Meng[1] and Wenfeng Li[1]*

[1]Los Alamos National Laboratory

ABSTRACT

Polycrystalline diamond compact (PDC) cutters are used in geothermal energy drilling operations as they are especially effective due to their resistance to abrasion and strength. It is important to understand the effect of downhole conditions on the bit to accurately model PDC cutter - rock interactions and drilling efficiency. When attempting to increase drilling or cutting efficiency, the time that the drill bit is not in contact with the rock is detrimental for the operation. Cutting efficiency is determined through the weight on the bit, rotational speeds, and other cutter and rock parameters that can be modeled. To accurately describe this interaction, we use the combined finite discrete element method (FDEM) to model the PDC cutter – rock interaction. FDEM can model both continuum and discontinuum (it’s never been clear to me if this is a real word?) mechanical behavior, cutter-rock interaction results in rock fracture and fragmentation, reproducing material behavior similar to targeted rock at downhole conditions. We use HOSS, an FDEM code, for our numerical studies.. We model the cutter as a rigid body acting on a granite block. One of the outputs of the simulations is the cutting force, which we use to understand cutting efficiency in the model. We study the interaction between the PDC cutter and the rock with and without pressure to get an understanding of rock fracturing processes on the surface and downhole. In this presentation we report on the progress of the numerical analysis for this complex multi-physics problem.

EFFECT OF PARTICLE-SIZE-SCALING ON PARTICLE INTERACTIONS IN DEM-SIMULATIONS OF SAND IN THE CONTEXT OF AIR PLUVIATION

Natascha Heim[*1] and Sascha Henke*[1]

[1]*Helmut Schmidt University*

ABSTRACT

DEM (discrete element method) is a widely used numerical simulation method, which models the behaviour of a bulk substrate based on the individual interactions of many particles. One of its possible applications is the modelling of sand behaviour in different laboratory test, for example cone penetration tests [1] or direct shear tests [2]. Furthermore, DEM is specifically of interest as a modelling method for investigating air pluviation, because it models the individual inter-particle and particle-environment interactions, both friction and collisions, which determine the compaction and homogeneity of the created samples.

However, one disadvantage of DEM is the relatively long computational time [3] especially with decreasing particle sizes. This makes larger particle sizes compared to reality more interesting, especially for large scale or repeating simulations. On the other hand, if the size of the chosen particles is too large, certain interactions, such as interactions with other materials and equipment, may not be simulated in a way that properly represents real behaviour. This would lead to preferring smaller sized particles, which again would lead to longer computational times.

Therefore, the chosen particle size as an important aspect of DEM simulations will be discussed, as well as the effects on different simulation aspects. This includes necessary parameter adjustments, the resulting inter-particle and particle-environment interactions as well as the achieved simulation results and accuracies. Of specific interest is the largest particle size, at which accurate and realistic results concerning real-world particle interactions can be achieved. Further, the effects of graded particle sizes to better represent the sand during the pluviation process will also be discussed.

CAN HIGH-ORDER CONVERGENCE BE OBTAINED FOR PRACTICAL PROBLEMS IN ENGINEERING?

*Brian Helenbrook**[1]

[1]*Clarkson University*

ABSTRACT

With all of the interest in high-order methods, it is still not clear whether these methods have an advantage over their low-order counterparts for practical problems. In this talk, high-order hp-finite element moving mesh formulations for problems with moving boundaries and discontinuous solutions will be discussed. In particular, the attainable order of accuracy will be examined for several practical applications. These applications include ducted wind turbines where the rotor is modeled with an actuator disc, solidification of silicon with a moving free-surface and solidification front, and re-entry vehicles with a bow shock where the bow shock is tracked by the moving mesh. In all of these cases the solutions have non-smooth behaviors which makes obtaining design order of accuracy difficult / impossible. We examine whether high-order accurate schemes are still advantageous for these types of problems for both uniform mesh refinement approaches and adaptive meshing. We then investigate coordinate transforms that allow high-order methods to obtain optimal accuracy even for problems with singularities.

MESH MOTION WITH SCIENTIFIC MACHINE LEARNING

Ottar Hellan[*1]*

[1]*Simula Research Laboratory*

ABSTRACT

Mesh motion operators are used in various applications, such as fluid-structure interaction (FSI) in the arbitrary Lagrangian-Eulerian (ALE) formulation or shape optimization with the method of mappings, to map a reference domain to a deformation of the domain. Typically, extension operators are defined by the solution of PDEs, with Dirichlet boundary conditions representing the deformed geometry, but PDE-based extension operators capable of handling large deformations can be prohibitively computationally expensive. Therefore, we investigate replacing these operators with data driven surrogates. Taking inspiration from the PDE nature of typical extension operators and the graph structure of meshes, we propose operator learning- and graph neural network-based methods, tailored for the specific application of learning mesh motion operators. We discuss aspects of network architecture, training, and implementation, evaluating the models as the ALE mapping in an FSI benchmark problem.

ON SEA ICE DYNAMICS APPLYING MIXED LEAST-SQUARES FEM

Sonja Hellebrand[*1], Carina Schwarz[1] and Jörg Schröder[1]*

[1]*University of Duisburg-Essen*

ABSTRACT

The behavior of sea ice has been studied for many decades. In order to model its viscous-plastic behavior at scales spanning several thousand kilometers, different numerical models have been proposed. Based on the established approach in [1], this contribution presents a simulation model for sea ice dynamics to describe the sea ice circulation and its evolution over one seasonal cycle. In course of that, the sea ice concentration and the sea ice thickness are considered, of which the physical behavior is governed by transient advection equations. Here, the sea ice velocity serves as coupling field.
Recently developed approaches base on a finite element implementation choosing a (mixed) Galerkin variational approach, see e.g. [2 and [3]. But therein, challenges may occur regarding the stability of the numerically complex scheme, especially when dealing with the first-order advection equations. Thus, we propose the application of the mixed least-squares finite element method, which has the advantage to be also applicable to first-order systems, i.e., it provides stable and robust formulations even for non-self-adjoint operators, such as the tracer equations (for sea ice thickness and sea ice concentration).
For solving the instationary sea ice equation the presented least-squares finite element formulation takes into account the balance of momentum and a constitutive law for the viscous-plastic flow. The considered primary fields are the stresses, the velocity. the concentration and the thickness. In relation, four residuals are defined for the derivation of a first-order least-squares formulation based on the balance of momentum, the constitutive relation for the stresses, and two tracer-equations. Different approaches can be made with respect to the approximation functions of the primary fields, i.e., choosing e.g. conforming (H(div) interpolation functions) or non-conforming (Lagrangian interpolation functions) stress approximations, while Lagrangian interpolation functions are chosen for the remaining fields. In order to compare such approaches, the box test case is utilized, cf. [3], which is well described in literature.

[2]Vrije Universiteit Brussel

ABSTRACT

Today, offshore wind farms are deployed in offshore concession zones. Such concessions are a cluster of multiple farms. The modeling of the wake effects of wind farms in such clusters cannot be limited to the single farm perspective. Deep array effects due to dense turbine spacing result in important significant internal wake effects, whereas closeness of the farms to each other causes non-neglectable external wakes. As such, it is necessary to have a physics-based model that can scale to the offshore wind farm cluster as whole. In literature multiple analytical wake deficit models are available to predict the individual power output of the turbines in the wind farm cluster. In recent years many research efforts were done resulting in novel model types such as Cumulative wake / curl, Turbopark, TurboGauss,… These recent modeling approaches aim to account better for these deep array effects and long spatial evolution of the wakes (far wakes). Furthermore, novel blockage modeling approaches were developed to describe the velocity deficit at the wind farm inflow due to the inertia effects of the large number of turbines in the cluster. This study aims to benchmark these different models on the Belgian offshore cluster consisting of >2GW of wind power. One year of SCADA data of 5 wind farms are used to calibrate the hyperparameters of the analytical wake models. Once calibrated the accuracy of the models is benchmarked on multiple years of SCADA data of the same 5 farms. With the performance metrics utilized in this work, it is shown that top-hat models perform relatively better compared to their Gaussian counterparts. This could be due to their overestimation of the wake deficit at the wakes' edge, which might indirectly account for wake meandering and wake steering due to turbine misalignment, compared to its Gaussian variant. Novel models, such as the TurbOPark and TurbOGauss models, furthermore, outperform their traditional counterparts (Jensen and the Gaussian model developed by Bastankhah and Porte Agel (2014) in scenarios where wakes propagate through highly varying turbine spacings, getting worse when turbine spacing increases. Additionally, a large performance increase is observed when the wake expansion rate is taken as a function of local turbulence intensity, as described in Niayifar and Porte Agel (2016). Furthermore, scanning lidar data from a multi-month offshore monitoring campaign at one of the farms is used to further validate and benchmark the models.

AN OVERVIEW OF SYMMETRY-PRESERVING NUMERICAL METHODS FOR VERIFICATION

Sebastian Henderson[*1] and Jim Ferguson*[1]

[1]*Los Alamos National Laboratory*

ABSTRACT

Symmetry-preserving numerical methods (SPNMs) are used for numerical approximations when a symmetry group of a system of differential equations is wished to be preserved. Generally speaking, these numerical methods can greatly reduce computational error compared to numerical methods that do not preserve symmetries[1]. SPNMs are used in a wide variety of applications, ranging from robotics to signal processing[2]. For verification, SPNMs may serve as standards for which other algorithms may be compared when analytic solutions are not known in order to determine an estimate of numerical error. We will give an overview of SPNMs and the specifics of how they may be used for verification purposes.

ABSTRACT

High-entropy alloys (HEAs) have attracted significant interest in recent years due to their exceptional properties over conventional alloys. Recently, HEAs have shown remarkable catalytic performance especially for oxygen reduction reaction (ORR) and carbon dioxide reduction reaction (CO2RR). First principle calculation methods such as density functional theory (DFT) are typically used to explore active and stable electrocatalysts. However, the ability to use explore HEAs for catalytic application using conventional DFT is hindered by the vast configuration space due to the large number of possible arrangements of surface sites. This requires a huge number of DTF calculations, which can be infeasible. Machine learning (ML) approaches have been recently used for catalysis prediction. However, a significant drawback of ML is that large data sets are needed for training and validating the ML models. To tackle this issue, robust approaches to efficiently screen the configurational space of catalytic HEA materials need to be developed and employed. An efficient method to navigate the configuration space of HEA alchemical perturbation density functional theory (APDFT). A key advantage of APDFT is that a single Density functional theory (DFT) calculation of the adsorbate's binding energy (BE) can be used to predict many hypothetical catalysts surface structures' BE at a negligible additional computational cost. This characteristic makes APDFT an appealing technique to explore the configurational space of catalytic HEAs at significantly less computational cost. The accuracy of APDFT was assessed for different adsorbates on AuAgPtPdCu HEA surface. The results have shown that APDFT can capture the BE trends with minimal computational cost, suggesting a fast-screening approach with less number of brute-force DFT calculations required. Coupled with APDFT, ML were developed based on fewer computationally expensive DFT calculations, accelerating the screening of HEAs for catalysis applications. Our proposed framework is based on a Gaussian process regression (GPR) model using the data from APDFT calculations for training and validation sets. We propose to use a GPR model based on graph theory to describe the chemo-spatial environment of the adsorbate on HEA surface for BE prediction, coupled with the data from the data from APDFT calculations for training and validation sets. Here, since the model is trained and coupled with low-cost APDFT calculations, we explore millions of compositional spaces with the GPR at minimal cost. This allows to tune the HEA composition to obtain large number of sites with optimal binding energies which eventually can increase the catalytic activity for HEAs.

INVESTIGATION OF GEOTRIBOLOGICAL BEHAVIOUR IN THE SOIL-PILE INTERFACE CONSIDERING CLAY BASED ON NUMERICAL AND LABORATORY INVESTIGATIONS

Sascha Henke[1] and Philipp Wiesenthal*[1]

[1]*Helmut Schmidt University*

ABSTRACT

The contact behaviour between soil and structures is an important aspect in many geotechnical applications. One example is the contact between pile and soil during pile installation which especially for open-ended pipes can lead to soil plug formation.

Within the present research, contact behaviour between clayey soil and pile is investigated by means of numerical and laboratory experiments focussing on the contact behaviour within tubular piles.

First, the contact behaviour between kaolin clay and steel is experimentally investigated with respect to overburden pressure in the so-called Geo-Tribometer developed at HSU. As the results of the experimental investigations show some unexpected results leading to the assumption that the contact failure surface inside the soil specimen changes with differing overburden pressure. Additional numerical simulations are carried out for better understanding of contact stress development.

Second, further laboratory investigations using soil-filled tubular piles show that adhesion effects significantly influence the contact behaviour between soil plug and internal surface of the tube. For estimation of the adhesion values numerical simulations by means of finite element analyses are carried out showing for example that as expected with increasing soil’s pre-overburden pressure the adhesion effect increases.

The results are finally discussed with respect to transferability from the small scale in numerical and laboratory investigations towards prototype scale.

INVERSE UNCERTAINTY QUANTIFICATION IN PASSIVE AUTOMOBILE SAFETY: BAYESIAN INVERSION FOR OPTIMAL PASSIVE SAFETY AT FULL-VEHICLE SCALE

Maternus Herold[*123], Jonas Siegfried Jehle[1] and Matthias Gerdts[2]*

[1]*BMW Group*

[3]*appliedAI Institute for Europe*

ABSTRACT

We introduce an innovative approach to inverse uncertainty quantification in the domain of passive automobile safety, utilizing Bayesian inversion techniques. Our method computes the required input distributions of key safety variables to achieve a desired distribution in the results space. This proactive methodology shifts from a traditional trial-and-error to a question-oriented approach: “What adjustments are necessary to ensure optimal occupant protection?”, conceptualizing the target as a distribution rather than a fixed outcome. A central feature of our methodology is its ability to recognize alternative solutions, yielding similar results. Secondly, balancing between achieving extreme safety results and maintaining robustness under various conditions is addressed with a robustness metric to assess such solution sets. Additionally, the approach benefits from leveraging the analytical describability of certain parts of the safety engineering process. This reduces the size of the required data set and enhances the practicality of the method.
Distinctively, we demonstrate our method’s effectiveness on a full-vehicle scale industry problem, underscoring its scalability and real-world relevance. This demonstration confirms the feasibility of applying our approach in complex automotive safety scenarios. By integrating Bayesian inversion with a data-driven strategy and introducing a robustness quantification metric, our approach offers an efficient and versatile tool for enhancing the safety engineering and verification process in the automotive industry.

DISTORTION COMPENSATION FOR METAL ADDITIVE MANUFACTURING: VERIFICATION, VALIDATION, AND DEVELOPMENT OF A THERMAL MECHANICAL WORKFLOW

Carl Herriott[1], Michael Stender[1], Kyle Johnson[1], Jonathan Pegues[1], Christie Crandall[1] and Sannmit Shinde[1]*

[1]*Sandia National Laboratories*

ABSTRACT

Additive manufacturing in metals has enabled the design and manufacturing of previously unthinkable geometries holding great promise for a wide range of manufacturing applications. Inherent to the additive manufacturing process in metals are residual stresses and distortions which can lead to as-built components not meeting geometric requirements. Mitigation and/or compensation for the combined effects of distortions and residual stresses is a critical step to enabling additive manufacturing in production-level critical structures.

To address the negative effects of residual stresses and distortions, an efficient thermal mechanical simulation-based distortion compensation workflow has been implemented. In this workflow, distortions and residual stresses are predicted for the purpose of an inverse analysis. This iterative workflow modifies the as-designed CAD geometries based on mapped distortions to successfully print a part to meet geometric requirements using an updated CAD geometry. Additionally, common post-processing steps, such as heat-treatment and baseplate removal, are simulated by the workflow to capture their impact on the distortion of the printed part.

This talk will discuss the details of workflow development and verification, sensitivities of this approach, and validation of model results against experimental data for a variety of builds.

STRONGLY STABLE DUAL-PAIRING UPWIND SUMMATION-BY-PARTS FINITE DIFFERENCE SCHEMES FOR THE VECTOR INVARIANT SHALLOW WATER EQUATIONS

Justin Kin Jun Hew[*1], Kenneth Duru[1], Stephen Roberts[1], Christopher Zoppou[1] and Kieran Ricardo[1]*

[1]*Australian National University*

ABSTRACT

We present an energy/entropy stable and high order accurate finite difference method for solving the nonlinear shallow water equations (SWE) in vector invariant form using the newly developed dual-pairing and dispersion-relation preserving summation-by-parts finite difference operators. We derive new well-posed boundary conditions for the SWE in one space dimension, formulated in terms of fluxes and applicable to linear and nonlinear problems. For nonlinear problems, entropy stability ensures the boundedness of numerical solution but does not guarantee convergence. Adequate amount of numerical dissipation is necessary to control high frequency errors which can generate artefacts in numerical simulations. Using the dual-pairing SBP framework, we derive high order accurate and nonlinear hyper-viscosity operator which dissipates entropy and enstrophy. The hyper-viscosity operator effectively tames oscillations from shocks and discontinuities and eliminates poisonous high frequency grid-scale errors. The numerical method is most suitable for the simulations of sub-critical flows typically observed in atmospheric and geostrophic flow problems. We prove a priori error estimates for the semi-discrete approximations of both linear and nonlinear SWE. We verify convergence, accuracy, and well-balanced property via the method of manufactured solutions and canonical test problems such as the dam break, lake at rest. Numerical simulations in two-dimensions are presented which include the rotating and merging vortex problem and barotropic shear instability, with fully developed turbulence.

A HYBRID MODAL AND GRAPH NEURAL NETWORK ANALYSIS: APPLICATION TO FLOW-INDUCED VIBRATION OF LONG FLEXIBLE CANTILEVERS

Shayan Heydari[1] and Rajeev Jaiman*[1]

[1]*University of British Columbia*

ABSTRACT

This study employs a numerical framework to investigate the sustained oscillations of a flexible cylindrical cantilever beam immersed in fluid flow. The flow equations are formulated within an arbitrary Lagrangian-Eulerian (ALE) framework, accounting for the moving boundaries of the structure. The fluid-structure interface is addressed through a partitioned iterative scheme, ensuring stable coupling of the Navier–Stokes equations with low-mass flexible structures experiencing strong inertial effects from the surrounding incompressible flow. The flexible cantilever is represented as a slender structure using linear modal analysis [1,2]. The current investigation focuses on key aspects of numerical modeling: (i) assessing the effectiveness of the modal analysis in capturing the flexible cantilever's dynamics, (ii) exploring response amplitudes and motion trajectories as a function of flow and structural parameters, and (iii) gaining insights into the vortical structures of the flexible cantilever during sustained oscillations. The results of the numerical simulations reveal that within a specific range of the reduced velocity parameter (U*), the cantilever undergoes sustained oscillations. A characteristic tip motion trajectory resembling a figure-eight shape is observed during the beam’s oscillatory behavior.

In addition to full-order simulations, a novel application of a graph neural network reduced order model (GNN-ROM) is explored to serve as a surrogate model for the flexible cantilever problem. The integration of GNN-ROMs aims to enhance predictive capabilities by leveraging graph-based representations of the fluid-structure system. The utilized model integrates the quasi-monolithic graph neural network outlined in Ref. [3]. Operating within the ALE framework, the model employs a multi-layer perceptron for the evolution of mesh displacements and a hypergraph neural network to forecast fluid states based on the present system state. The structural state is implicitly represented through the dynamic movement of the mesh at the fluid-structure interface. Using the full-order numerical simulation data, the model is being trained and validated for various fluid-structure conditions.

MATERIAL-MODEL CALIBRATION FOR DUCTILE METALS USING RADIOGRAPHS OF HIGH-EXPLOSIVE DRIVEN EXPERIMENTS

Kyle Hickmann[*1], Skylar Callis[1], James Carroll[1] and Bryan Kaiser[1]*

[1]*Los Alamos National Laboratory*

ABSTRACT

We present an application of convolutional neural networks to calibration of material-physics models from radiographs of high-explosive induced shock experiments. Material properties for metals and polymers undergoing explosive loading are often poorly understood and are calibrated under simplified experimental conditions, for example uniaxial shock compression, where good physical models of the process exist. For more complex two- and three-dimensional loading regimes velocimetry gives an incomplete picture of the process and dynamic radiographs are used to understand the material properties. Unfortunately, directly relating features of a radiographic image to a material-model calibration is often intractable and the analysis of radiographs becomes necessarily qualitative. With simulation-informed neural-learning we can develop a more quantitative analysis. In this work we use a high-fidelity, multi-physics simulation developed at Los Alamos National Laboratory, to simulate hundreds of variations of a high-explosive shock experiment. The variations are chosen to span the uncertainty in the material-physics process of interest as well as uncertainty coming from experiment timing and secondary materials involved in the experiment. For each simulation we produce a suite of synthetic radiographs that captures uncertainties of the radiographic observation process. From this synthetic radiograph data we train neural networks to learn the inverse mapping between radiograph and material parameters. It is demonstrated that, using a simple convolutional architecture, trained networks can infer material calibrations from synthetic radiographs with high accuracy. Moreover, by using Bayesian-network approaches we can produce estimates of material calibrations with quantified uncertainty. Physics applications of machine-learning methods must be accompanied by an analysis of how networks are making their inferences to build confidence in these predictions and to predict likely shortcomings in the technique. Leveraging a particular network structure, we are able to examine learned-features our model extracts by looking at individual layer outputs. It is shown that our networks heavily weight physically-defensible features in the image during regression. In this talk we give a detailed description of our data-generation methods and the learning problems we address. We then outline our neural architecture and training approach. Methods for human interpretation of the network's inference process are put forward, including techniques to assess sensitivity of inferences to learned features.

SEMI-IMPLICIT MATERIAL POINT METHOD FOR UNSATURATED SOIL WITH CONSTITUTIVE MODEL DEPENDING SUCTION

Soma Hidano[1], Shuji Moriguchi[1] and Kenjiro Terada[1]*

[1]*Tohoku University*

ABSTRACT

Hazardous landslides caused by heavy rainfall. In this situation, the slopes lose the suction, which is the shear resistance of soil, by transitioning from unsaturated to saturated states. To simulate this process, particle-based methods have become popular, and among them, the material point method (MPM) has accomplished a remarkable progress in the area of computational geomechanics.

The MPM is a particle method, but the algorithm is similar to the finite element method (FEM) and uses an Eulerian mesh to solve a set of governing equations. Thus, comparing with other particle methods, the MPM does not require searching for neighbor particles, and this advantage reduces the computational cost. Nevertheless, most of the previous MPM developments for unsaturated soil suffer from two demerits, when explicit time integration is adopted. One is the pore water pressure oscillation caused by using the large water bulk modulus, and the other is the large computational cost. Alternatively, semi-implicit MPMs equipped with the so-called fractional-step method have been proposed by several scholars [1] to overcome these problems. However, few studies have so far been made to deal with large deformation of slopes made of unsaturated soil.

To address this problem, we have recently developed the semi-implicit MPM for unsaturated soil based on Biot’s mixture theory [2]. However, in the simulation of the model experiment, which is infiltration-induced sand slope failure, there is a slight discrepancy between the analysis and experiment results in the timing and mode of failure. This is due to the local reduction of the cohesion and the internal friction angle with respect to the suction as the water seepage. Thus, to improve the performance of failure simulation, we incorporate the suction effect to the cohesion and the internal friction angle in the constitutive model, which is the Hency's hyperelastic model with the Drucker-Prager model. Several numerical examples are presented to demonstrate the capability and performance of the semi-implicit MPM with presented constitutive model. In particular, to validate it with respect to the suction, the analysis is carried out for simulating a model experiment of infiltration-induced failure.

MULTIPLE TIME SCALES AND VARIABLE BOTTOM TOPOGRAPHY FOR DISCONTINUOUS GALERKIN LAYERED OCEAN MODELING

Robert Higdon[*1]*

[1]*Oregon State University*

ABSTRACT

In the numerical modeling of ocean circulation, it is a widespread practice to employ a barotropic-baroclinic time splitting, for which the fast external motions are modeled by a vertically-integrated (barotropic) system that is similar to the shallow water equations and is solved with a relatively short time step. The remaining motions are modeled by solving the full dynamical equations in each fluid layer with a relatively long time step; the present talk is concerned with layered (isopycnic) models, for which the vertical coordinate is a quantity related to density. A barotropic-baroclinic time splitting raises issues that include the following: (1) There needs to be suitable communication between the two subsystems. (2) The layer equations include motions that vary on the fast time scale, so the algorithm must include a mechanism that enables stability when the long time step is used. If a layer interface intersects variable bottom topography, some additional issues include the following: (3) In this case a physical layer thickness can tend to zero, and a numerical approximation to this thickness must remain nonnegative. (4) If sufficient care is not taken, the extracted velocities can be erratic and cause CFL violations. Various steps must be taken to address the above issues. The present talk will describe one of these steps, in which the issues (1)-(2) are closely related to (3)-(4), for the case where a discontinuous Galerkin method is used for the spatial discretization.

A DEEP-LEARNING BASED SURROGATE MODEL FOR SHELL HOMOGENISATION: APPLICATION TO THE FAILURE ANALYSIS OF LAMINATED COMPOSITES

Aewis KW Hii[*1], Bassam El Said[1] and Stephen R. Hallett[1]*

[1]*University of Bristol*

ABSTRACT

In this work, we present a data-driven multi-scale analysis framework for shear-deformable shell finite elements, with application to the progressive failure analysis of laminated composite structures. The framework formulation is rooted in second-order homogenisation [1], with which we have expanded on [2] to allow for the homogenisation of thick shells. When used in a concurrent FE2 analysis, the model yields an accurate estimation of the transverse shear stresses in thick shell problems. As a result, this allows the multi-scale shell element to accurately model in-plane damage and delamination as degradations in the shell stiffness. However, a concurrent framework consumes excessive computational resources and does not scale up for application to large components. To overcome this, we are using a deep learning based surrogate model in place of the online RVE analysis.

The novel contribution here is the creation of a surrogate for the constitutive responses of shells, with application to the failure analysis of composite structures. Unlike their solid counterparts, additional deformation modes such as bending, twisting and higher-order transverse shear need to be considered in shells. These factors significantly increase the dimensionality of the input and output space. In addition, shell homogenisation incorporates length-scale information such as thickness and local shell curvature, and the RVE size approaches that of the structural component. As a result, the combinations of strains seen by a shell element can vary substantially across different clusters of structural geometry and loading/boundary conditions. Therefore, here, we are also augmenting the surrogate model's input space so that the shell material model can generalise to unseen cases.

In summary, this work features a multi-scale shell analysis framework that can predict progressive 3D damage in composite structures, and it builds on existing techniques from second-order homogenisation and deep learning. The long-term objective is to build a fast and robust framework to model complex materials at the structural length scale, which will aid in design space exploration and part optimisation.

EXPLICIT MESHFREE METHODS FOR PREDICTIVE SOLUTIONS IN EXTREME MECHANICS

Michael Hillman[*1], Joseph Magallanes[1] and Dominic Wilmes[1]*

[1]*Karagozian and Case, Inc.*

ABSTRACT

In this talk, I will give a general overview of meshfree techniques used in high-strain-rate simulations. The critical aspects of variational consistency (passing the patch test) and convergence, spatial stability of the node-based equations (kernel, tension, and rank stability), and representation of material stability and instability will then be discussed. Following [1-4] I will show that unless special care is taken, these properties are not guaranteed. For instance, passing the patch tests is non-trivial for most meshfree methods, and proper representation of material stability is generally not obtained without strain-smoothing techniques. It is then shown that the reproducing kernel particle method with natural strain-smoothing stabilization is among the few methods that possess all these essential properties. Results are presented for challenging applications such as fragment-impact problems.

SPLINE-BASED PARAMETERISATION TECHNIQUES FOR PLANE GRAPHS

Jochen Hinz[*1] and Annalisa Buffa*[1]

[1]*EPFL*

ABSTRACT

Isogeometric Analysis (IGA) has emerged as a promising variant of classical FEM for modeling complex problems arising in real-world physical systems. Unlike FEM, IGA employs the de-facto CAD standard of spline-based parametric descriptions for representing the geometry. The same spline technology is then employed as a basis for analysis. Despite the promise of mitigating the CAD to FEM geometrical conversion overhead, Isogeometric Analysis (IGA) has witnessed the development of innovative numerical schemes that leverage the advanced smoothness inherent in spline basis functions. A common challenge in engineering applications is generating a conforming parameterisation of a domain composed of several faces, where only the descriptions of the faces' boundaries are available. In this setting, the geometry can be represented as a plane graph composed of vertices and edges, wherein each edge represents a spline curve or a dense point set. These edges are organized into groups that form closed loops, each representing the boundary of a face.

The purpose of this talk is presenting spline-based parameterisation techniques for plane graphs, respecting the requirement that each face be parameterised individually to, for instance, impose locally differing material parameters. We adopt the concept of harmonic maps as the underlying parameterisation method which is then applied to the faces one-by-one. Each face's multipatch layout is selected from a large catalogue of multipatch templates. The presented technique produces a multipatch paramterisation with a conforming interface between the faces while offering a large degree of automation. It may then be utilized for numerical simulation based on IGA, or converted back into an arbitrarily-dense classical mesh by collocating the face's surface splines.

ASSUMPTION BULGING FREQUENCY OF THE REAL SCALE TANK BY MICRO-TREMOR MEASUREMENT AND THE EIGENVALUE ANALYSIS

Shu Hirai[*1], Taisuke Ono[2], Hirokazu Hirano[1] and Naotsugu Sato[1]*

[1]Chuo University
[2]NYK Co.Ltd

ABSTRACT

In Japan, there have been numerous reports of damage caused by the expansion of water storage tanks during earthquakes which are seismic intensity of 6 or higher, including the 2011 Great East Japan Earthquake and the 2016 Kumamoto Earthquake1). Bulging2) refers to the coupled vibration between tank wall and content fluid. This phenomenon is induced by seismic ground motion. In Japan, seismic design against bulging is introduced quite recently in 2022, which will activate various kind of engineers' interests on it.

Therefore, existing water storage tanks should be promptly examined to determine whether or not bulging will occur and, the method for judgement is required. For this purpose, it is important to understand the natural frequencies of the side walls of the tanks.

In this study, micro-tremor measurement and the eigenvalue analysis to calculate the natural frequency are conducted to estimate the natural frequency. According to the hypothesis of this paper, the real scale stainless panel tanks have natural frequency below 10 Hz, at which bulging damage occurs. According to Ochiai's research3), the frequency of earthquake in nature is roughly 10 Hz or lower, and even when it is higher, the energy of the earthquake is small. In the measurement, the micro-tremor measurement device is installed on the ceiling of the tank and vibrations are measured after lightly tapping on the side walls, followed by spectral analysis and comparison with the results of natural frequency analysis.

As a result, the calculated natural frequency of bulging is consistent with that of the real scale tank, indicating the possibility of bulging occurring in the tank. We found that the micro-tremor measurement method is particularly effective for stainless steel panel tanks, which are considered to have natural frequencies below 10 Hz or less.

FLUID FILM LUBRICATION SIMULATION OF PRESSURE-DEPENDENT NON-NEWTONIAN FLUID USING THE MOVING PARTICLE HYDRODYNAMICS METHOD

Shu Hiramoto[*1], Kazuya Shibata[1], Kyuya Matsumoto[1], Hideyo Negishi[2] and Masahiro Kondo[3]*

[1]*The University of Tokyo*
[2]*Japan Aerospace Exploration Agency*
[3]*National Institute of Advanced Industrial Science and Technology*

ABSTRACT

When a fluid is subjected to extremely high pressure, its viscosity can increase dramatically because the distance between molecules decreases and the intermolecular force increases. Such pressure-dependent non-Newtonian fluid phenomena occur in fluid film lubrication [1] and are difficult to simulate using traditional particle methods. This is because in fluid film lubrication, the lubricant flows in an extremely narrow gap and the fluid pressure fluctuates due to the significant change in viscosity.

In this study, we developed a new model for non-Newtonian fluids whose viscosity changes significantly with pressure. The present model is based on the moving particle hydrodynamics (MPH) method [2] and Roelands' viscosity-pressure equation [3]. The MPH method is characterized by its discrete dynamic stability, which is ensured by the theory of analytical mechanics. Isothermal fluid film lubrication in line contact was simulated in two dimensions with the present model, and the simulated pressure distribution was compared with the numerical solution of the conventional Reynolds equation.

ENABLING LOCAL LATTICE STRUCTURE ANALYSIS IN FINITE TEMPERATURE MOLECULAR DYNAMICS SIMULATIONS

Atsuo Hirano[*1] and Akiyuki Takahashi*[1]

[1]*Tokyo University of Science*

ABSTRACT

Molecular Dynamics (MD) has been widely used to calculate material properties and simulate deformations and fractures of materials with atomic scale. To reproduce experimental results, it is inevitable to perform MD simulations at high temperatures and analyze the local lattice structures. However, it is difficult to analyze the local lattice structures in MD simulations at high temperatures because of the atomic thermal fluctuations. Up till now, various methods are used to solve the problem. To minimize the atomic thermal fluctuation, the simulations were performed at only lower temperatures [1]. However, with the method, it is impossible to reproduce the phenomena peculiar to the high temperatures. Others used the structure relaxation methods at every simulation time step [2][3] although the methods need extensive computational costs. Therefore, it is desired to have a computationally efficient numerical method to enable the accurate local lattice structure analysis in MD simulations even at high temperatures.

This paper presents a new method to reduce atomic thermal fluctuation with a simple algorithm to enable us to identify local lattice structures accurately even at high temperatures. In the method, we introduce new degrees of freedom called "Markers" which are connected to atoms. Since the thermal fluctuation of Markers is reduced, the local lattice structure analysis can be performed accurately with the reduced thermal fluctuations using Markers. The computational cost of Markers is very low, and only one parameter is added for our method.

We verified the performance of this method. The error rate of the structure identification using common neighbor analysis (CNA) can be almost 0% under 1200 K in Fe with our method whereas it becomes about 5% without it. Moreover, the average distance between atoms and Markers can be under 0.1 Å. Therefore, our method can have a good performance of both the thermal fluctuation reduction and the trackability to atoms. Subsequently, our method was applied to the phase transformations in Fe at high temperatures. We observed clearly the phase transformation from face centered cubic (FCC) structure to body centered cubic (BCC) structure. It is expected that our method can be applied to various simulations at high temperatures.

INTEGRATING HUMAN UNCERTAINTY AND CREATIVITY INTO THE EXTENDED DIGITAL TWIN: KNOWLEDGE IS ALL YOU NEED

*Tohru Hirano**[1]

[1]*Daikin Industries, Ltd.*

ABSTRACT

To further develop Society5.0, which advocates human-centered CPSs (Cyber-Physical Systems), and to realize a new paradigm of Japanese manufacturing and social eco-system, we first classify the factors of uncertainty and complexity in the CPS process into uncertainty related to things and uncertainty related to events. Uncertainty related to things can be defined from a quality engineering perspective as factors such as uncertainty related to data and measurements from products (devices) in usage conditions, and variations in boundary conditions and material properties related to models on the Digital Twins. On the other hand, uncertainty related to events is defined to include more complex and unstable ones due to the dynamic changes caused by the complex and uncertain human/social systems.

Then, we define Extended Digital Twins as Digital Twins including the uncertainty and complexity inherent in humans and society. Several mathematical models for human characteristics including emotion, bounded rationality, and creativity are considered. The acquisition and generation of related knowledge from various perspectives are also investigated. The extraction processes of experiential and tacit knowledge of humans in product planning, design, and development, and even in the areas of production, logistics, supply chain, sales, and service operations, are pursued by generative AI. In particular, human emotions are evaluated based on the free-energy principle, and human creativity is considered based on normalized entropy.

IMPACT FRACTURE ANALYSIS METHOD AND ITS APPLICATIONS TO EDGE CHIPPING OF GLASS

Sayako Hirobe[1], Yousuke Sato[2], Yoichi Takato[2] and Kenji Oguni[1]*

[1]*Japan Agency for Marine-Earth Science and Technology*
[2]*AGC Inc.*

ABSTRACT

The impact fracture problem entails dynamic loading accompanieded by stress wave propagation and energy dissipation during collision. Due to these conditions, simulating fracture under dynamic loading is significantly more challenging than under quasi-static loading. In this research, we enhance Particle Discretization Scheme Finite Element Method (PDS-FEM), developed by the authors, to simulate fracture and collision of two objects simultaneously. Subsequently, we apply the proposed method to the simulation of edge chipping of glass.

Edge chipping is caused by concentrated loading applied near a sharp edge of brittle materials. This type of fracture results in the removal of a conchoidal chip from materials and is commonly observed during the manufacturing process. We conducted numerical analyses on the edge chipping of soda-lime glass, subjecting it to the impact of a rigid steel sphere while varying the size of the sphere, impact velocity, and impact distance from the glass edge. Our numerical analysis successfully reproduces 3D complex crack patterns, including Hertzian cone cracks and conchoidal chip scars. To the best of our knowledge, this is the first detailed simulation of the 3D crack morphology in edge chipping. We anticipate that our numerical analysis method is widely applicable to impact fracture studies.

IMPLEMENTING UNCERTAINTY QUANTIFICATION CALIBRATION WHEN PREDICTING FALL PARAMETERS OF IMPACT-INDUCED SKULL FRACTURES IN INFANTS

Jacob Hirst[*1], Brian Phung[1], Bjorn Johnsson[1], Brittany Coats[1] and Ashley Spear[1]*

[1]The University of Utah

ABSTRACT

In 2021, 7.1 million children were victims of child abuse [1], with infants < 1 year of age at the greatest risk of injury and death from abusive head trauma. Infants cannot communicate instances of abuse; thus, verifying reported histories of head trauma (accident versus abuse) is a critical and challenging task for child advocates in the early detection of child abuse. Physics-based models of infant skull fracture can provide valuable insight into patterns that could distinguish between accidental and abusive trauma. Previously, we developed a numerical framework to predict fracture patterns in infant skulls [2]. Using the framework, fall scenarios can be simulated to predict skull fracture to corroborate or refute witness statements in cases of suspected abuse, but the computational expense of these simulations is high and requires considerable specialized effort. To overcome this challenge, several machine learning (ML) models were trained on a finite number of fall simulations to predict fall parameter probabilities given specific skull fracture features extracted from the simulations. The ML models included a random forest (RF) regressor, a Gaussian process regressor (GPR), an artificial neural network (ANN), polynomial regression, ridge regression, lasso regression, and linear regression models. To account for model inaccuracies, bagging ensemble UQ strategies were used with ensembles of the ANN, GPR, and RF and compared to the inherent UQ abilities of the RF and GPR. We then employed a UQ calibration technique that uses linear and exponential scaling on the uncertainty [3]. The calibration method is used on each of the original strategies of UQ, and the uncalibrated uncertainties are compared with the calibrated uncertainties. Quality of uncertainty was measured with plots of residuals vs predicted uncertainty, where the slope of these plots would ideally be 1, and the intercept 0. The calibration method resulted in improved average slopes on test sets across a 5-fold cross-validation. These results suggest that calibration techniques refine the accuracy of UQ for these strategies which, in turn, refine the ML tools mentioned. This results in a more reliable prediction of fall parameters associated with skull fracture patterns, potentially adding a valuable tool for medicolegal teams to use when differentiating an accident from abuse.

LOCAL TIME-STEPPING DECOUPLED ALGORITHMS FOR FLOW AND TRANSPORT PROBLEMS IN FRACTURED POROUS MEDIA

Yanzhao Cao[1], Thi-Thao-Phuong Hoang[1] and Phuoc-Toan Huynh[1]*

[1]Auburn University

ABSTRACT

The numerical simulation of flow and transport in a porous medium with fractures is challenging due to the presence of multiple spatial and temporal scales and strong heterogeneity of the domain of calculation. A fracture may have much higher or much lower permeability than that in the surrounding medium, thus the time scales in the fractures and in the rock matrix may vary significantly. In addition, the width of the fracture is much smaller than any reasonable parameter of spatial discretization. To tackle those challenges, we first consider a dimensionally reduced fracture model, where the fracture is treated as a hypersurface embedded in the porous medium. Then we develop domain decomposition (DD) methods that allow the use of different time step sizes in the subdomains and in the fracture. For each DD method, a space-time interface problem is formulated, based on either the physical or optimized transmission conditions imposed on the fracture-interface. Such an interface problem is solved iteratively and globally in time. The proposed methods are fully implicit and are designed to converge fast while preserving the accuracy in time with nonconforming time grids. Convergence analysis as well as numerical results will be presented for the flow problem of a single phase, compressible fluid, and the linear advection-diffusion equation with high Péclet numbers.

ABSTRACT

The goal of this study is to use Isogeometric Analyses (IGA) [1] for the computation of coupled fluid-structure vibrations with prestressing effects. This topic is relevant in the context of aerospace applications for the design of pressurized liquid launcher propellant tanks. The major objective is to estimate numerically, with IGA, the prestressed hydroelastic vibrations, defined as the coupled vibrations of an elastic structure around a geometrical nonlinear equilibrium in contact with an incompressible free-surface liquid.

The use of the IGA framework, which conserves the geometry from computer aided design models, provide robust frequency estimations in linear structural vibrations [1]. Recent studies have been carried out with IGA for linear hydroelastic vibrations of partially filled structures without prestressed effects showing good agreements between numerical and experimental studies [2]. In the present study, comparisons between Finite Element Method (FEM) and IGA are expected, particularly for 3D geometries using a Projection Based Reduced Order Model (PROM) framework [3]. The methodology is the following. At first, a reference solution using FEM without PROM will be provided to compute the hydroelastic modes for a 3D fluid-structure problem. Comparison using IGA will be proposed with and without PROM procedures.

Errors and convergence rate will be presented to demonstrate the effectiveness of this methodology in the context of prestressed hydroelastic vibrations with PROM using IGA or FEM.

Key Words: Hydroelasticity, Isogeometric Analysis, Projection Based Reduced Order Model

NESTED PHFGMC MICROMECHANICAL MODELS FOR THE NONLINEAR AND DAMAGE OF AUTOMATED FIBER PLACEMENT COMPOSITES

Hadas Hochster[1], Ido Meshi[1], Gal Raanan[1] and Rami Haj-Ali[1]*

[1]*Tel-Aviv University*

ABSTRACT

Automated Fiber Placement (AFP) is an advanced composite manufacturing technology widely used in the aerospace and automotive industries. The AFP technology offers advantages such as improved production efficiency, reduced material waste, and the ability to create complex geometries that may be challenging with traditional manufacturing methods. However, one critical challenge yet to be thoroughly investigated in AFP-composites is predicting elastic properties and damage that may arise from a wide range of inconsistent material properties compared to composites manufactured using traditional technologies. An important aspect is the effect of inherent gaps between material tows and fiber misplacement during the AFP process. To that end, the Parametric High-Fidelity Method Generalized of Cells (PHFGMC) micromechanical mode is employed to construct hierarchical nested models of AFP-composites at the micro and meso levels. The PHFGMC has been established as an advanced micromechanical approach well-suited for analyzing the nonlinear behavior of diverse periodic composite materials. The PHFGMC is a refined dedicated micromechanical model capable of accurately predicting the local-global responses of heterogeneous multiphase composites. In the PHFGMC method, periodicity conditions are imposed between the boundaries of a repeating unit cell (RUC). The RUC can be divided into general quadratic or hexahedral subcells representing the different phases. Average traction and displacement continuities are enforced between the subcells to achieve equilibrium requirements between the adjacent subcells. In addition, a new formulation based on average virtual work was recently introduced for the PHFGMC. This approach is suitable for micromechanical calculations and has comparable computational efficiency to the finite element method [1, 2].
The proposed research investigates nested micromechanical AFP carbon/epoxy material systems models. Therefore, the PHFGMC-RUC is constructed using micrographs to capture the AFP microstructure. Further, results are compared to experimental data to demonstrate the ability of the new PHFGMC-AFP to predict a wide range of mechanical properties.

AUTOMATED AB INITIO-ACCURATE ATOMISTIC SIMULATIONS OF DISLOCATIONS

Max Hodapp[1]*

[1]*Materials Center Leoben Forschung GmbH*

ABSTRACT

A well-known drawback of state-of-the-art machine-learning interatomic potentials is their poor ability to extrapolate beyond the training domain. For small-scale problems with tens to hundreds of atoms this can be solved by using active learning which is able to select atomic configurations on which a potential attempts extrapolation and add them to the ab initio-computed training set. In this sense an active learning algorithm can be viewed as an on-the-fly interpolation of an ab initio model. For large-scale problems, possibly involving tens of thousands of atoms, this is not feasible because one cannot afford even a single density functional theory (DFT) computation with such a large number of atoms.

In this talk, I will present an active learning algorithm for simulating dislocations that identifies local subregions of the simulation region where the potential extrapolates [1,2]. Then the algorithm constructs periodic configurations out of these local, non-periodic subregions, sufficiently small to be computable with plane-wave DFT codes, in order to obtain accurate ab initio energies. The algorithm is tested on two relevant types of dislocations, screw dislocations in bcc tungsten, and dissociated dislocations in fcc aluminum, and I will show that our algorithm reaches near-ab initio accuracy for material properties such as core structure, Peierls barrier, and Peierls stress.

COMPUTATIONAL ANALYSIS OF TURBULENT FLOW STRUCTURES IN THE LEFT VENTRICLE OF THE HEART USING PATIENT-SPECIFIC DATA

Johan Hoffman[*1] and Joel Kronborg*[1]

[1]*KTH Royal Institute of Technology*

ABSTRACT

Blood flow in the left ventricle is characterized by the change in ventricle volume over the heart cycle, the structure of the inner ventricular wall, blood characteristics, and the associated inflow and outflow regulated by the mitral and aortic valves, respectively. In systole the ventricle contracts which leads to an increase in blood pressure, which in a healthy heart closes the mitral valve to the left atrium and opens the aortic valve for the blood to flow into the aorta. Analogously, in diastole, the heart relaxation phase, the ventricle expands, blood pressure drops, the aortic valve is closed and the mitral valve opens to let blood flow into the ventricle from the left atrium. The inflow in diastole has two phases, the E-wave followed by the A-wave, each representing jet flow which breaks down into turbulent flow in the ventricle. Heart valve disease may lead to restricted valve openings, or leaking valves, that changes the blood flow in the ventricle. Similarly, clinical interventions may lead to changes in the ventricular blood flow.

Blood cells and endocardial cells respond to mechanical stresses in the blood flow, and changes in the mechanical stresses may be a risk factor e.g. for thrombosis. In this work we use patient-specific data to build a computational model of the blood flow in the left ventricle of the heart, in which we analyse the mechanical stresses in the blood flow, with a focus on the turbulent flow structures in diastole. The computational model is based on solving the Navier-Stokes equations with a finite element method on a deforming mesh, and the mechanical stresses are analyzed using the triple decomposition of the velocity gradient of the flow.

In previous work we have established a clinical pathway for patient-specific simulations through which we analyzed turbulent flow structures in a finite element model where the mitral valve was modelled as a time varying inflow boundary condition [1]. We here extend this framework to a more realistic simulation using a fluid-structure interaction model of the mitral valve based a unified continuum approach [2].

COMPUTATIONAL MODELING OF FIBER-REINFORCED COMPOSITE LAMINATES UNDER HIGH-CYCLE FATIGUE LOADING

Pieter Hofman[*1], Frans P. van der Meer[1] and Lambertus J. Sluys[1]*

[1]*Delft University of Technology*

ABSTRACT

Fatigue is an important failure process and is often governing for the design of fiber reinforced polymer composites. In recent years, significant progress has been made in accurately simulating high-cycle fatigue crack propagation in composite specimens with initial cracks. However, numerical methods for simulating the complete progressive failure process in laminates are far less matured. In multidirectional laminates, delamination, transverse matrix cracking and ultimately fiber breakage can occur in distinct plies. Virtually testing these complex laminates requires progressive failure modeling frameworks capable of capturing all relevant failure processes and their interaction. Moreover, these frameworks must not only consider propagation of transverse matrix cracks and delamination, but also the initiation of cracks in pristine material.

In this contribution, we present an accurate, efficient and robust progressive failure framework for simulating the interaction between several failure processes under high-cycle fatigue loading. A mixed-mode fatigue cohesive zone model [1], covering both initiation and propagation of fatigue cracks, is embedded in a mesoscale framework [2] for describing the traction-separation relation of inter- and intra-laminar fatigue cracks. The cohesive zone model is based on S-N curves and requires only a few material parameters related to fatigue damage, without using Paris data as input for describing propagation of fatigue cracks. Furthermore, XFEM is used to allow for discrete intra-laminar cracks at arbitrary locations. Discontinuities, representing transverse matrix cracks, are inserted in the elements as soon as a proper fatigue crack insertion criterion is reached. With this approach, a transition from distributed cracking to localized failure can be simulated. Moreover, the effect of thermal residual stresses due to the curing process is taken into account in an adaptive cycle jumping scheme where explicit sinusoidal load cycles are applied before a jump in cycles takes place. With this scheme, the local stress ratio, which varies in the laminate due to non-uniform residual stresses, can be determined in each material point and subsequently used in the (local) constitutive model for the calculation of fatigue damage.

It is shown through numerical examples of open-hole laminates with complex failure mechanisms that the modeling framework is capable of accurately capturing initiation, propagation and interaction of intra- and inter-laminar failure processes. Furthermore, the model shows a good match in fatigue life and damage evolution when compared against experimentally tested quasi-isotropic open-hole laminates.

ACTIVE LEARNING METHODS FOR TRAINING FREE ENERGY MODELS

Jamie Holber[*1], Mostafa Faghih Shojaei*[1] and Krishna Garikipati*[2]

[1]*University of Michigan*
[2]*University of Southern California*

ABSTRACT

We have developed active learning methods to improve data sampling and training for problems in materials physics. Included among these are inverse problem wherein the goal is to determine material properties or mechanisms based on computational and/or experimental data. In the context of initial and boundary value problems, there are often locations in the domain which require dense sampling due to the complexity of the region. However, there are often constraints with our ability to sample data densely over the whole domain. Active learning methods enable us to query data where it will be most useful to ensure a well trained model. We have shown the effectiveness of applying active learning methods to a scale bridging process which uses first principles and statistical mechanics data to determine a free energy surrogate model [GH Teichert, S Das, M Faghih Shojaei, J Holber, T Mueller, L Hung, V Gavini, and K Garikipati. Bridging scales with machine learning: From first principles statistical mechanics to continuum phase field computations to study order disorder transitions in lixcoo2. arXiv preprint arXiv:2302.08991, 2023]. The active learning methods enable us to intelligently sample in a high-dimensional space, allowing us model details related to ordering in our phase field simulations, that are not generally available. We have continued to develop additional active learning methods for adaptative sampling and model parameters and training. The adaptive sampling methods include sampling in regions of interest: wells, non-convexities, etc and sampling in regions of high error, data sensitivity, and data variability. These methods enable the creation of free energy models which provide additional insight into materials using fewer data points.

PHYSICS-INFORMED CRYSTAL PLASTICITY RNN FOR TEMPERATURE-DEPENDENT ANISOTROPIC PLASTICITY IN HCP MATERIALS

Yannick Hollenweger[*1], Dennis Kochmann[1] and Burigede Liu[2]*

[1]*ETH Zürich*
[2]*University of Cambridge*

ABSTRACT

Neural network surrogate models for constitutive models in computational mechanics have been developed and employed for a while. Especially in the field of plasticity, these models are often developed on the basis of existing GRU or LSTM cells that have a proven capability to learn path-dependent phenomena. Major drawbacks of these architectures, however, include the relatively long training times and a time-resolution dependent prediction that extrapolates poorly. Further, most existing work for macro- or mesoscopic surrogate models in plasticity is content to predict relatively simple material behaviors. Hence, in this work, the focus lies on circumventing these drawbacks. We formulate a time-resolution independent neural architecture on the basis of the recurrent neural operator and apply it to learn the temperature-dependent plastic response of magnesium, known for its pronounced plastic anisotropy and thermal dependence. The recurrent neural operator predicts the material behavior withgreat accuracy and is shown to generalize well for various loading cases and temperatures, as well as time-resolutions. Furthermore, it clearly outperforms existing GRU and LSTM models in terms of training and predictive performance. Finally, we perform multiscale simulations with the RNO and achieve at least three orders of magnitude speed-up compared with existing physical models.

QUANTIFYING MODEL-FORM UNCERTAINTY IN CONSTITUTIVE MODELING: A PHYSICS-INFORMED INFORMATION FIELD THEORY APPROACH

Wesley Holt[*1] and Ilias Bilionis*[1]

[1]*Purdue University*

ABSTRACT

Uncertainty quantification (UQ) is often critical for physical inverse problems (inferring a physical model from data). This is especially true when data are sparse or noisy. When solving inverse problems, it is common practice to fix a form for the physical model (e.g., which terms show up in the differential equation) and only then find the probability of the model parameters. However, this approach underestimates uncertainty because it assumes reality can be fully captured by the chosen model form. Physics-informed Information Field Theory (PIFT) is a new, fully-Bayesian framework which quantifies uncertainties coming from the lack of knowledge of the model form (as well as from lack of knowledge of model parameters and from measurement error). PIFT differs from many other model-form UQ methods in that one does not need a library of potential models. Instead, one constructs a prior probability distribution over the function space of all possible physical models. This distribution assigns higher probability to models which obey the hypothesized physics (e.g., a particular constitutive model), with a parameter controlling the degree of trust in the hypothesized physics. We demonstrate the PIFT framework with examples in constitutive modeling and show how it can also deal with ill-posed problems.

AUTOMATED MODEL DISCOVERY USING INELASTIC CONSTITUTIVE ARTIFICIAL NEURAL NETWORKS (ICANNS)

Hagen Holthusen[*1], Lukas Lamm[1], Tim Brepols[1], Stefanie Reese[1] and Ellen Kuhl[2]*

[1]*RWTH Aachen University*
[2]*Stanford University*

ABSTRACT

For solids, centuries of research in the field of physics and mechanics have guided us towards the uncertainty-free conversational laws in continuum mechanics. Following these principles of thermodynamics, material models have been derived that obey these laws. Unfortunately, certain models are only able to explain a specific material behavior. In practice, we usually pre-select a particular model and try to find the best material parameters corresponding to that model to fit our data; instead, it is our strong belief that we should find the best model explaining our data. This is where machine learning algorithms help us achieve this paradigm shift. Since these algorithms lack from knowledge of thermodynamics, it is not surprising that they learn the data used for training very well, but their ability to predict material behavior outside the training regime is disastrous and, most of the time, unphysical. This is already the case for elastic materials and is even worse for inelastic material behavior. To overcome this issue, a family of Constitutive Artificial Neural Networks [1] has been developed that combines thermodynamic knowledge with modern machine learning techniques. These networks are designed for elastic material behaviour and satisfy thermodynamics a priori. As most materials exhibit inelastic deformations, a critical missing link is to expand the general concept to inelastic materials. One way to do so is to introduce a pseudo potential depending on stress-like quantities associated with the inelastic rate [2]. Here we extend CANNs to inelastic material behavior (iCANN) [3]. Therefore, our network discovers both the Helmholtz free energy and the pseudo potential, which explain the experimental data the best. As the design is not limited to a specific inelastic phenomenon, thermodynamics are satisfied a priori regardless of the inelastic behavior. Our vision for iCANNs is that they help us to reveal the various inelastic phenomena hidden in the data, such as plasticity, viscosity, phase transformation, degradation, growth and remodeling. For illustrative purposes, we specialize the general architecture of our iCANN to visco-elasticity and demonstrate that it is capable of discovering a model for polymers and skeletal muscle data.

A COUPLED TWO-MUSCLE-ONE-TENDON MODEL OF THE AGONIST-ANTAGONIST MYONEURAL INTERFACE

Carme Homs Pons[*1] and Miriam Schulte*[1]

[1]*University of Stuttgart*

ABSTRACT

Conventional amputations destroy the mechanical link between the agonist-antagonist muscle pair. A novel surgical approach, the agonist-antagonist myoneural interface (AMI), aims to mitigate the amputation's damage by surgically re-connecting the naturally paired muscles with a tendon, so that the mechanical and sensory connection is maintained.

Skeletal muscles are made of an active hierarchical tissue, with each muscle containing thousands of muscle fibers and millions of sarcomeres, the smallest contracting unit. We model skeletal muscles with OpenDiHu, an HPC framework for neuromuscular simulations that couples a 3D finite element mechanics muscle to a model for the action-potential propagation through 1D muscle fibers and a model for the electro-chemical phenomena in the sarcomeres. OpenDiHu is capable of mapping between meshes and time subcycling, so that all models are embedded in a single OpenDiHu muscle solver.

We use this muscle solver to develop a two-muscle-one-tendon AMI model using preCICE. The agonist and the antagonist muscles are modeled by identical OpenDiHu solvers, while the tendon participant is modeled by a simpler, 3D finite element OpenDiHu solver.

We model the mechanical coupling of the muscles through the tendon using the fully-implicit multi-coupling scheme in preCICE. In each coupling iteration, values of displacement, velocity and traction are exchanged across adjacent surfaces. Results show that when one muscle contracts, the tendon is displaced and the other muscle elongates as expected.

We aim to involve neural coupling as well, so that we can model the monosynaptic and disynaptic reflexes, i.e., the exchange of proprioceptive information. Thereby, we expand our muscle solver with models of sensory organs, e.g., muscle spindles and the motor neurons that activate muscle fibers. Our plan is to connect the agonist-antagonist muscles directly using two additional serial-explicit schemes to account for the reflex feedback loops and combine them with the multi-coupling scheme for mechanical coupling. As a result, challenging circular loops for communication arise.
We are making steps towards the integration of neural coupling in our two-muscle-one-tendon model, and all the different required OpenDiHu models already exist independently. We are also working to use real muscle geometries obtained from patient imaging. In the long run, we intend that our two-muscle-one-tendon AMI model is used as a tool for surgeons to decide on critical anatomical parameters, such as the prestretch of the muscles, prior to the AMI procedure.

DEVELOPMENT OF AN INFINITESIMAL DEFORMATION ANALYSIS METHOD FOR TRUSS STRUCTURES BASED ON A QUANTUM APPROXIMATION OPTIMIZATION ALGORITHM

Rio Honda[*1], Katsuhiro Endo[2] and Mayu Muramatsu[1]*

[1]*Keio University*
[2]*AIST*

ABSTRACT

In this study, we develop a deformation analysis method for truss structures using the Quantum Approximate Optimization Algorithm (QAOA) [1]. Structural analysis is crucial in the field of engineering to evaluate the durability of structures and to derive optimal structures. However, as the size of the structures under analysis increases, the computational requirements often become immense. To solve this issue, high speed computation technologies such as quantum computing are becoming increasingly important.
There have been attempts to use quantum computers for structural analysis. One such attempt involves the use of quantum annealing, a method specialized in solving combinatorial optimization, for structural optimization of trusses [2]. However, quantum annealing is limited to handling binary variables of 0 or 1, which poses a problem when dealing with real numbers as it requires the combination of multiple qubits. This often exceeds the handling capacity of current quantum Ising machines, even for small analysis targets.
To overcome this limitation, our study adopts an alternative quantum computing approach, the quantum gate model. In a quantum gate model, the principle of superposition allows a qubit to take on a superposition of multiple states. This characteristic enables the handling of extensive information with a smaller number of qubits, presenting a significant advantage.
QAOA is a quantum gate model algorithm that can solve combinatorial optimization problems, similar to quantum annealing. This algorithm could be particularly useful for application in Noisy Intermediate-Scale Quantum (NISQ) devices. The state can be determined with fewer measurements by properly acting the shift operator [3]. In our research, QAOA is used to perform deformation analysis on truss structures, and the goal is to efficiently perform quantum computations and to demonstrate its effectiveness.

ELASTOPLASTIC COMPUTING SAINT-VENANT FLEXURE-TORSION AND WARPING TORSION IN THREE DIMENSIONS

Hong-Ki Hong[*1] and Hsien-He Huang*[1]

[1]*National Taiwan University*

ABSTRACT

A prismatic rod of arbitray cross section shape --- singly or multi-connected solid sections, open or closed thin-walled sections, even multi-cell sections --- is studied. For this rod the Saint-Venant flexure-torsion theory is unified with the theory of warping moment and warping torsion, allowing the stress function and warping function to vary along the axial direction and establishing formulae between warping moment and axial stresses. A case study of H shape illustrates the variation of warping moment (i.e. the so-called bimoment), axial stresses, warping torsion, and warping displacements.

The centroid for axial force and the shear center for transverse forces are investigated both for thin-walled sections and for solid sections. The computation excuted for the rod made of elastic material is further extended to flow elastoplastic material modeled by an evolving cubic distortional yield hypersurface with a normality plastic flow and combined isotropic-kinematic rule of hardening-softening.

EXPLORING THE USE OF METAMATERIALS TO MITIGATE VORTEX INDUCED VIBRATIONS OF WIND TURBINE BLADES

Sergio Gonzalez Horcas[*1], David Roca[12], Enrique Ortega[12] and Juan Cante[12]*

[1]Universitat Politècnica de Catalunya (UPC)
[2]International Center for Numerical Methods in Engineering (CIMNE)

ABSTRACT

The historical upscaling of horizontal axis wind turbines has presented significant engineering challenges, including a heightened susceptibility to aeroelastic instabilities such as Vortex Induced Vibrations (VIV) [Horcas et al. (2022)]. This work explores, for the first time, the use of Locally Resonant Acoustic Metamaterials (LRAM) [Roca et al. (2019)] for the mitigation of such phenomenon on rotors. LRAM are composed of a regular array of lightweight repeating unit cells, each containing one or more resonators that can vibrate in response to external forces. The present work casts the targeted aeroelastic instability as a two-dimensional problem, consisting of a blade section connected to an elastic mounting. The flow is modeled using a computational fluid dynamics finite volume code. The structural properties of the mounting are obtained through modal analysis of a reference blade, and the effect of the local resonators is subsequently included. A partitioned fluid-structure interaction strategy is then employed to solve both physics in the time domain. The presentation analyzes the impact of the proposed metamaterial on the aeroelastic mechanism and sheds light on the potential of such an approach for vibration mitigation. However, additional work is anticipated to further assess the benefits of the technology, including the consideration of three-dimensional effects and the explicit modeling of the local resonators.

MICRO-CONTACT MECHANICS WITH SOFT PARTICLE IN TRIBOLOGY

Jeng-Haur Horng[*1], Jin-Long Lin[1] and Yang-Yuan Chen[1]*

[1]National Formosa University

ABSTRACT

This study focuses on establishing the establishment of the tribological analysis method for the machine parts when soft particles enter the machine part interface, their influence on tribological characteristics and their detection methods, and constructs a theoretical framework for soft particle interaction at the three-body contact interface, including its influence and detection methods. The detection technology can be used as a reference for future smart manufacturing. There are three main research results completed in this year: (1) Derived the three-body contact formula for soft particles, which establishes the relationship between external force, real contact area, and separation. This formula serves as a fundamental theoretical framework for interpreting experimental results and guiding future development of nano-lubricants. (2) Established a wedge-shaped relationship between real contact area (At/An) and load (F/AnE) at the three-body contact interface. The upper limit represents surface-to-surface contact, while the lower limit represents surface-to-particle contact. The height of this wedge is primarily influenced by surface roughness, with smaller roughness leading to a higher wedge value. (3) Employed a four-ball tribotester to analyze changes in tribological performance after introducing particles into the machine part interface. Results revealed a rapid increase in wear with increasing particle weight percentage. For an interface containing 1.48 wt% particles, the pitting area was 6.6 times larger compared to the particle-free interface. (4) Preliminary vibration measurements suggest a close and positive correlation between wear/pitting growth and MF4 values.

TIME-DEPENDENT FUNDAMENTAL SOLUTION FOR NUMERICAL MODELING OF FOURIER AND NON-FOURIER BIOHEAT TRANSFER

Ivan Dominik Horvat[*1] and Jurij Iljaž*[1]

[1]*University of Maribor*

ABSTRACT

Numerical modeling of bioheat transfer has proven to be a powerful tool for predicting the thermal behavior of biological tissue in various medical fields. Currently, the Pennes model [1] is most commonly used for modeling bioheat, mainly because it is comparatively straightforward to implement and assumes an infinite speed of the heat wave. However, recent research shows that heat propagates at a finite speed in materials that have a cellular or inhomogeneous structure [2], resulting in a pronounced time lag between the temperature gradient and the heat flux. For this reason, non-Fourier models, such as the MCV model [3] based on the research of Maxwell, Cattaneo and Vernotte, have been developed.

In this presentation, a novel in-house algorithm based on the subdomain boundary element method for the numerical solving of bioheat transfer in biological tissue is presented, taking into account the Fourier and non-Fourier models of heat transfer, with the novelty being the implementation of the time-dependent (parabolic) formulation, which increases the accuracy of the solution compared to the elliptic formulation. The algorithm was verified using analytical examples and validated with experimental results from the literature. From the results, we can conclude that the developed algorithm successfully solves both Fourier and non-Fourier heat transfer problems.

ADAPTIVE SPACE-TIME MESH REFINEMENT FOR INCOMPRESSIBLE FLOWS

*Tamas Horvath**[1]

[1]*Oakland University*

ABSTRACT

This talk presents an adaptive mesh refinement technique for space-time finite element methods. The mesh adaptation can refine and coarsen the spatial mesh, therefore limiting the number of elements in a time-dependent simulation. Throughout the simulation, the spatial mesh, consisting of triangles, undergoes a red-green-blue refinement/coarsening step at every time level, and the space-time mesh, consisting of tetrahedra, is created by connecting the original and the updated meshes. The tetrahedral meshes guarantee that for incompressible flows, the solutions obtained by the space-time embedded/hybridized discontinuous Galerkin method are pointwise mass conserving and pressure robust. Numerical simulations will be presented to demonstrate the effectiveness and efficiency of the proposed method.

RESPONSE OF STREAMWISE VORTICES TO BLOWING AND SUCTION CONTROL IN TURBULENT CHANNEL FLOW

Shohta Hosouchi[*1], Tomohiro Nimura[1], Akira Murata[1] and Kaoru Iwamoto[1]*

[1]*Tokyo University of Agriculture and Technology*

ABSTRACT

Turbulent frictional drag constitutes a significant component of fluid drag in wall turbulence, and the opposition control [1] is a reasonable turbulence control strategy for reducing friction drag. This control method aims to counteract vortices near the wall that induct turbulent friction drag, through blowing and suction from the wall. Specifically, the velocity (v) in the wall-normal direction on a horizontal plane slightly away from the wall is detected, and an opposite velocity (-v) is imposed from the wall. However, the opposition control does not individually address numerous vortices in turbulence. The control also detects fluid motions other than streamwise vortices on the sensing plane, and the blowing and suction is applied to them. By forcusing on the dynamics of vortices, we anticipate even more efficient turbulence control.

The present study concentrates on the developing and decaying process of vortices. Vortices were identified by the second invariant II of the velocity gradient tensor, and their development/decay was assessed using the substantial derivative DII/Dt. Based on these values, streamwise vortices were statistically sampled in a direct numerical simulation of a fully developed turbulent channel flow over a sufficient time period. These sampled vortices were imposed with blowing and suction from the wall, inspired by the opposition control, and their responses were investigated.

The opposition control was applied on the sampled vortices, and their temporal evolution was tracked. The results revealed that the opposition control damped the vortices. However, there was no significant difference in the time required for the vortices to disappear entirely with or without control. Subsequently, the sampled vortices were subjected to either blowing ($v > 0$) or suction ($v < 0$) control. The findings indicated that blowing flow decayed the sampled vortices, whereas suction flow did not affect them. A control strategy based on these findings would be applied to the turbulent channel flow. We will discuss the details of the effect of blowing and suction on vortex dynamics and evaluate drag reduction rates.

ABSTRACT

The glymphatic system is a brain-wide system of perivascular networks that facilitate exchange of cerebrospinal fluid (CSF) and interstitial fluid (ISF) to remove waste products from the brain. A greater understanding of the mechanisms for glymphatic transport may provide insight into how amyloid beta (Aβ) and tau agglomerates, key biomarkers for Alzheimer's disease and other neurodegenerative diseases, accumulate and drive disease progression. In this study, we develop an image-guided computational model to describe glymphatic transport and Aβ deposition throughout the brain. Aβ transport and deposition are modeled using an advection-diffusion equation coupled with an irreversible amyloid accumulation (damage) model. We use immersed isogeometric analysis, stabilized using the streamline upwind Petrov-Galerkin (SUPG) method, where the transport model is constructed using parameters inferred from brain imaging data resulting in a subject-specific model that accounts for anatomical geometry and heterogeneous material properties. Both short-term (30-min) and long-term (12-month) 3D simulations of soluble amyloid transport within a mouse brain model were constructed from diffusion weighted magnetic resonance imaging (DW-MRI) data. In addition to matching short-term patterns of tracer deposition, we found that transport parameters such as CSF flow velocity play a large role in amyloid plaque deposition. The computational tools developed in this work will facilitate investigation of various hypotheses related to glymphatic transport and fundamentally advance our understanding of its role in neurodegeneration, which is crucial for the development of preventive and therapeutic interventions.

ABSTRACT

Development of a Hybrid Model for battery electrode production with a physics-inspired data-driven approach
Somayeh Hosseinhashemi, Christoph Thon, and Carsten Schilde
Institute for Particle Technology (iPAT), Technische Universität Braunschweig

Process development in the industry is primarily based on trial and error and often involves expensive and time-consuming experiments. Typically, simulation analyses are used to build a process model. However, the simulations cannot always consider the manufacturing process's limitations in their modeling. Therefore, the process parameters determined by such a model remain almost theoretical. Alternatively, artificial intelligence methods can be beneficial. The expression of the relationship between physical quantities is widely used in many fields. However, these relationships are quite complex for many systems, making it difficult for conventional methods to determine the correct model. This work uses a hybrid modeling technique, incorporating physics-based knowledge and data-driven techniques. The goal of this approach is to combine the accuracy and physical insight provided by physics-based knowledge with the flexibility and scalability of data-driven models.

To achieve this goal, we combine a deep neural network with a genetic algorithm to determine the existing physical relationships between the data and then estimate the final model for the system. More precisely, we set out to determine the symbolic expression for an unknown function f using a genetic algorithm. To do this, we created a table of data consisting of rows in the form {x1, ..., xn, y}, where y = f (x1, ..., xn). We first attempted to simplify the data by analyzing it and identifying dimensionless parameters. Next, we utilized a neural network to search for any underlying physical properties within the data. Finally, we employed the genetic algorithm to generate various symbolic functions, selecting the most accurate one as the final expression. The resulting function was then applied as a white-box model to predict the behavior of our system.
This hybrid model allows for a more comprehensive and accurate prediction of the performance of the battery electrode and thus can be used to optimize the production process and improve the performance of the battery.

ON THE NUMBER OF SUBPROBLEM ITERATIONS PER COUPLING STEP AND MONITORING CONVERGENCE IN PARTITIONED FLUID-STRUCTURE INTERACTION SIMULATIONS

Norbert Hosters[*1], Thomas Spenke[1], Nicolas Delaissé[2] and Joris Degroote[2]*

[1]*RWTH Aachen University*
[2]*Ghent University*

ABSTRACT

In literature, the costs of strong (implicit) coupling schemes for fluid-structure interaction are typically assessed by the number of coupling iterations required per time step, while ignoring the internal iterations within the nonlinear subproblems. We demonstrate that the internal iterations have a significant influence on the computational cost of the coupled simulation. Particular attention is paid to how limiting the number of iterations within each solver call can shorten the overall run time, as it avoids polishing the subproblem solution using unconverged coupling data. Specifically, it is demonstrated that performing subproblem iterations until the solver is fully converged in each call does minimize the number of coupling iterations but does not lead to minimal computational time. Instead, under the assumption of constant subproblem iteration cost, the optimum is found by minimizing a weighted sum of both coupling and subproblem iterations.

When analysing the optimal choice of the coupling steps and the internal iterations of the non-linear solvers, the question automatically arises as to when a time step can be considered converged. A variety of convergence criteria exists, but they all compare a quantity representative of the change in interface data between successive coupling iterations, e.g., the interface residual, to a prescribed tolerance. The choice of this tolerance value is often ad hoc and based on experience. Moreover, its relationship to the tolerances of the subproblems is unclear and often not considered, even though the accuracy of the coupled simulation is inherently linked to that of the solutions of the subproblems. We address this shortcoming by discussing a newly introduced criterion that does not require the choice of a coupling tolerance but bases the convergence of the time step on the number of subproblem iterations to reach convergence. This not only eliminates the inconvenient choice of a coupling tolerance but also allows one to better judge the accuracy with which the subproblems should be solved. The new criterion can be applied to black-box solvers under the condition that they provide information on whether they have converged and on how many subproblem iterations have been run. Although the focus of this work is on fluid-structure interaction simulations, the criterion applies to any type of coupling of black-box solvers under the given minor condition.

OVER-DETERMINISTIC METHOD AND ITS APPLICATION IN FRACTURE MECHANICS

Cheng Hou[*1], Xueling Fan[1], Xiaochao Jin[1] and Jingjing Yang[1]*

[1]*Xi'an Jiaotong University*

ABSTRACT

The over-deterministic method (ODM) is dedicated to calculate a small set of unknown coefficients from a large system of equations, by making use of a large number of data points. A displacement over-deterministic method (DODM) developed by Ayatollahi et al. has been employed by for calculating the stress intensity factors (SIFs) as well as the coefficients of the higher-order terms in the Williams' series expansions for cracked bodies. The ODM provides a great idea to easily obtain fracture parameters, combine with finite element method (FEM).

In our work, a stress over-deterministic method (SODM) has been proposed for calculating the SIFs and T-stress at the crack tip for pure mode I, pure mode II and I-II mixed-mode cracks under static and dynamic loads. The effectiveness and computational accuracy of the SODM are verified using static and dynamic numerical examples. The effects of the number of terms in Williams' series expansion, the number and location of the nodes selected around the crack tip, and the mesh around the crack tip on SIFs and T-stress are discussed in detail. Results indicate that the SODM is simple and efficient in calculating the SIF and T-stress at the crack tip under static and dynamic loads.

Moreover, benefiting from the core idea of the ODM, a generalized over-deterministic method (GODM) is proposed to determine the Young's modulus and Poisson's ratio of materials through cracked specimens. A number of numerical examples of specimens with pure mode I, pure mode II and I-II mixed-mode cracks are carried out to verify the effectiveness and feasibility of GODM. The accuracy between the GODM and the traditional uniaxial tensile method for obtaining Young's modulus and Poisson's ratio of materials is verified by experiments using 2024-T3 aluminum alloy. The effects of the term number of Williams' series expansion, the number and location of selected nodes near the crack tip on results are discussed in detail. Results show that the GODM method can effectively and accurately determine the Young's modulus and Poisson's ratio of materials through the cracked specimens.

UNCERTAINTY QUANTIFICATION FOR MULTIFIDELITY OPERATOR NETWORKS

Amanda Howard[*1] and Panos Stinis*[1]

[1]*Pacific Northwest National Laboratory*

ABSTRACT

We will look at multifidelity Deep Operator Networks (DeepONets) as a way to improve the accuracy of DeepONet training when faced with a dataset with high uncertainty. Training DeepONets requires large amounts of data, and noisy data can decrease the accuracy of the training. One solution is to use multifidelity DeepONets, which use two different datasets simultaneously to train more accurately. We will show that using multifidelity DeepONets to add a small amount of high fidelity data, or using physics-informed training, can provide more robust answers than using the high fidelity data, physics, or low fidelity data alone, and can overcome noise in the low fidelity data when accompanied by high fidelity physics.

Quantifying epistemic uncertainties for computational predictions

BACKCALCULATION FOR DESIGN UNDER GENERAL UNCERTAINTY: AN INTRODUCTION AND A TUTORIAL

Peter Hristov[*12] and Scott Ferson[2]*

[1]GATE Institute
[2]University of Liverpool

ABSTRACT

Uncertainty surrounds the design of engineered systems. Two main contributors to this uncertainty are the as-yet unfinished decision making the system's design and variation in the operational environment of the system. Engineering design has evolved from using deterministic rules and safety factors, which can often result in grossly overengineered systems, through designs based on worst-case scenarios, which treat catastrophic events as having high likelihood of occurrence, to robust and reliable design, which uses probability theory to minimize the risk of arriving at an unwanted outcome during the deployment of the system.

Despite providing a sound framework for the treatment of random variations, which constitute aleatory uncertainty, traditional probability theory has been repeatedly shown to be an inadequate tool for the characterization and management of epistemic uncertainty. This is just uncertainty from the lack of knowledge, which abounds in design, especially in its conceptual and preliminary (C&P) stages. Real-world uncertainty requires a more general class of uncertain numbers, such as the mathematical interval, characterizing epistemic uncertainty and the probability box characterizing mixed epistemic-aleatory uncertainty.

During C&P design engineers must come up with a robust and safe product, despite sometimes massive uncertainty. This task is most commonly formulated as an inverse problem, that is, candidate designs are evaluated against a set of criteria, which may also be uncertain, and the ones meeting the criteria are admitted for further evaluation. Most of the computational tools used in C&P design are fast, parametric models with open code, which is amenable to dissection and alterations. Engineers may find it tempting, therefore, to use deterministic arithmetic rules to invert the computations and project backward the uncertain numbers. Such projections, however, lead to systematic violation of design targets.

To ensure systems designed under general uncertainty respect the safety and performance limits, engineers can use backcalculation. In this talk we present the principles of backcalculation and controlled backcalculation for general uncertain numbers. We provide a demonstrative case study and draw attention to some outstanding problems as future directions of research.

POINT CLOUD-BASED IMMERSOGEOMETRIC FLOW ANALYSIS

Ming-Chen Hsu[*1], Monu Jaiswal[1] and Ashton Corpuz[1]*

[1]*Iowa State University*

ABSTRACT

In this talk, a new point cloud-based immersogeometric flow analysis framework will be presented. This framework is designed for simulating structures whose design models and analysis meshes are difficult to obtain. The proposed framework utilizes photogrammetry to reconstruct 3D point clouds of structures from 2D images captured by portable devices such as cell phones and drones. Additionally, it employs an immersogeometric approach that can directly carry out flow analysis on the reconstructed point clouds. New stabilization and regularization approaches that improve the solution quality will be discussed.

INTEGRATING FIRST-PRINCIPLES CALCULATIONS AND EMPIRICAL STUDIES FOR EXPLORING MECHANICAL, ELECTRICAL, AND OPTICAL PROPERTIES OF HIGH-ENTROPY MATERIALS

Wen-Dung Hsu[*1], Kai sheng Huang[1], Chen-Yun Kuan[1] and Yuan-Chun Chang[1]*

[1]National Cheng Kung University

ABSTRACT

This study explores the dynamic realm of high-entropy materials, known for their diverse and nearly equiatomic composition. Departing from traditional materials with variable chemical makeup, the adjustment of components in high-entropy materials offers a wide spectrum of possibilities for tuning their physical and chemical properties, marking an innovative trajectory in material development. Our investigation specifically delves into the phase stability and mechanical properties of high-entropy alloys and high-entropy carbon nitrides. Additionally, we address the often-overlooked electrical and optical properties in existing literature on high-entropy alloys. In semiconductor applications, the interplay between metallic materials and their electrical and optical characteristics is pivotal. Embracing the high-entropy concept allows for the identification of superior metallic thin film materials, exemplified by reflective coatings typically utilizing aluminum or gold layers. While aluminum faces challenges with oxidation and gold proves expensive, high-entropy alloys emerge as promising alternatives, providing materials for reflective coatings that are both oxidation-resistant and cost-effective. Shifting focus to wear-resistant coatings, conventionally reliant on metal carbides or nitrides to enhance mold durability, we introduce high-entropy carbon nitrides as potential game-changers in this domain. Strategic use of different metals to govern bonding characteristics between metal-carbon or metal-nitrogen enables the fine-tuning of their mechanical properties. This adjustment facilitates the customization of coating characteristics to suit diverse applications, highlighting a compelling frontier for development in the wear-resistant coatings landscape. In summary, this study illuminates the multifaceted nature of high-entropy materials and their potential applications. By navigating beyond the constraints of traditional materials, we unlock avenues for tailoring properties in high-entropy alloys and carbon nitrides. This research contributes to the broader understanding of the intricate interplay between composition and properties, offering insights that may reshape material development strategies in fields ranging from semiconductors to wear-resistant coatings.

BATTERY DEGRADATION DIAGNOSTICS: CHALLENGES, METHODOLOGIES, AND TESTING CAMPAIGNS

Chao Hu[*1]*

[1]*University of Connecticut*

ABSTRACT

Battery degradation diagnostics is focused on continuously monitoring lithium-ion batteries' state of health (SOH), encompassing the estimation of capacity and degradation parameters throughout the service life. The insights derived from SOH estimation are crucial in guiding health-aware maintenance and control decisions. This presentation will start with an overview of battery degradation diagnostics, followed by a tutorial-like discussion of state-of-the-art methodologies, and conclude with a review of long-term testing initiatives led by a collaborative team from Iowa State University and the University of Connecticut. Special attention will be given to applying physics-informed machine learning to automate degradation diagnostics for in-line inspection and online battery management system (BMS) applications. The methodologies will be illustrated through practical demonstrations using a long-term aging dataset from implantable-grade lithium-ion batteries.

CRYSTAL PLASTICITY MODELING OF RESIDUAL STRESS, DISLOCATION DYNAMICS AND CRACKING IN ADDITIVE MANUFACTURING

Daijun Hu[*1], Nicolò Grilli[2] and Wentao Yan[1]*

[1]*National University of Singapore*
[2]*University of Bristol*

ABSTRACT

In metal additive manufacturing (AM), complex thermal histories, large temperature gradients, and rapid cooling rates can lead to high residual stresses, distinct dislocation structures and even cracks. The generation and evolution phenomena during the AM process are not fully understood due to experimental challenges. In our study, we develop a multiscale modeling approach to investigate thermal and residual stress formation at the grain scale during the laser powder-bed fusion process. This approach integrates temperature profiles from thermal-fluid flow simulations and polycrystalline structures from phase-field grain growth simulations into a thermal-mechanical crystal plasticity finite element model. This framework allows for detailed observation of microscale thermal and residual stress evolution in AM materials. Based on this modeling framework, the deformation and temperature histories can be extracted to observe the dislocation dynamics in AM process. We then apply a continuous dislocation dynamics (CDD) model within a dislocation-based crystal plasticity framework to simulate the dislocation behavior under thermal stress in representative grains. Additionally, we extend our research to investigate the origins of strain localization phenomena in AM materials under loading at the grain scale, which is associated with the dislocation density and residual stresses induced by the AM process. This model can also be further coupled with phase-field fracture method to investigate the causes of crack formation during the AM process, reflecting the effect of thermal stresses during solidification and cooling. This modeling framework emerges as a powerful tool for the microscale mechanical analysis of AM materials and lays the groundwork for future multiscale process-structure-property investigations.

ON EFFICIENT SOLVERS IN DENSITY FUNCTIONAL THEORY AND THEIR APPLICATIONS

Guanghui Hu[*1]

[1]*University of Macau*

ABSTRACT

Density functional theory has been playing an important role in numerical simulations of nano materials etc. In this talk, towards the efficiency of the numerical simulations, several novel numerical methods such as multi-mesh method, multiple-precision method, as well as mesh adaptivity techniques will be introduced based on a finite element framework. More specifically, in the multi-mesh method, two different approximate spaces are designed for the wavefunction and the Hartree potential, respectively. Such a technique can reduce the requirements for both the memory and CPU time simultaneously. In the multiple-precision method, the calculation on the Hartree potential will be implemented in the single precision first to speedup the simulation, and the double precision calculation will be implemented in the last round SCF iteration to guarantee the accuracy. The mesh adaptivity is an effective approach for the acceleration, we will introduce the progress on the error estimation technique. Plenty of numerical results would show the effectiveness of proposed techniques. We finally will discuss the potential application of our solver in the material simulations.

STRUCTURE-PRESERVING DISCRETIZATION OF INCOMPRESSIBLE MHD SYSTEMS AND IDEAL MAGNETIC RELAXATION

Kaibo Hu[*1]

[1]*University of Edinburgh*

ABSTRACT

The magnetohydrodynamics (MHD) systems have several important conservative properties, e.g., the magnetic Gauss law and the conservation of energy and (magnetic, cross, hybrid) helicity in the ideal limit. These conserved quantities encode various kinds of intrinsic symmetry of the equations. To achieve physical fidelity and numerical stability, it is desirable to preserve these conditions precisely in the numerical discretization (up to the machine precision). In this talk, we first review the conservative properties of continuous MHD systems and the idea of Finite Element Exterior Calculus. Then we construct finite element methods that precisely preserve these properties. Discrete de Rham sequences play a vital role in the study. We also apply the idea to ideal magnetic relaxation.
