Abstract

In this paper we show that the recent model by Gilles Duranton [Duranton, G., 2007. Urban evolutions: The fast, the slow, and the still. *American Economic Review* 97, 197–221] performs remarkably well in replicating the city size distribution of West Germany, much better than the simple rank-size rule known as Zipf's law. The main mechanism of this theoretical framework is the “churning” of industries across cities. Little is known in urban economics about the determinants of local industry turnover so far. We present an empirical analysis of the excess churning index for West German cities, which describes the strength of intra-city industry reallocations over time. We find that urban growth and industry turnover are not notably correlated: Some, but not all fast-growing cities have notably changed. Secondly, human capital is positively related to growth and turnover, but only among successful cities. Industrial change within unsuccessful cities is driven by the disappearance of old-fashioned and declining sectors such as agriculture or mining. On a more general level our results suggest that the recent model by Duranton is a powerful description of the urban growth process. Still there are some aspects that are not captured by that model, which are at the core of other theories of urban growth.

1. Introduction

Due to various forms of localized increasing returns, most economic activity is concentrated in cities and cities are the main engines of economic growth. Yet, there is no evidence that all economic activity within a country will eventually end up in one or a few large metropolitan areas. The data rather suggests that the distribution of city sizes remains remarkably stable over time, and is at least close to the famous rank-size rule known as “Zipf's law.” Successful theories of urban growth all come to grips with this basic fact.¹ A limitation

of most existing approaches, however, is that they have little to say about how cities change their face—i.e., their industry composition—during the growth process, and how urban growth is related to (changes in) local economic structures. Cities are to a large extent characterized by their economic structure, and urban growth depends on the performance of the local industries of which the city is composed (Simon, 2004; Combes et al., 2004). Case studies like those by Glaeser (2005) in fact suggest that the success of cities can be well understood by their ability to adapt and to change (“re-invent”) their industry structure.

These issues have recently been taken up in an article by Gilles Duranton (2007). Three facts about local growth and industrial change are the starting point of his contribution. First,

¹ Zipf's law implies that the country's largest city has twice the size of the second largest city, three times the size of the third largest, etc. Theories of urban growth that generate such or a similar equilibrium city size distribu-

tion include, e.g. Eaton and Eckstein (1997), Black and Henderson (1999), Gabaix (1999), Eeckhout (2004), Rossi-Hansberg and Wright (2007) or Córdoba (2008). A survey of this literature is provided by Gabaix and Ioannides (2004).

Duranton shows that there is considerable “churning” of industries across cities. Single industries grow or decline relatively quickly in cities and cause rapid changes of the local industry compositions over time. Second, entire cities move relatively slowly up or down the country’s urban hierarchy. The speed at which some cities take over others in the distribution of total city sizes is low compared to the frequent changes in the location hierarchy for single industries. Finally, these processes occur within a distribution of city sizes that is stable over time. Duranton develops a theoretical framework—based on a spatial version of the quality-ladder growth model by Grossman and Helpman (1991)—that accommodates all three facts. Industries move across cities following endogenous cross-sector innovations. Cities experience gains and losses of industries, which partly offset each other, so that entire cities “churn” less than single industries, and urban growth goes along with industry turnover. Finally, the model generates a concave distribution of city sizes in the steady-state, where individual cities are mobile within the distribution due to the endogenous industrial relocations. Using US and French data, Duranton finds that this steady-state city size distribution of his model matches the actual distributions in these two countries quite closely, actually better than Zipf’s law.

The purpose of our paper is twofold. In a first step we use data on West German local industries over the time period 1977–2002 to study the robustness of Duranton’s recent results. We find support for considerable industry churning in Germany, even after controlling for structural change. When calibrating the model using our data, we obtain the result that the simulated city size distribution resembles the actual West German distribution very closely. The model is a much more accurate description than Zipf’s law, and it even achieves a better fit for West Germany than for France or for the US.

The second and main aim of this paper is to provide new insights about the determinants of churning and industry turnover in cities, which are the central mechanisms of the Duranton-model. We make use of an “excess churning index,” which summarizes the strength of intra-city industry reallocations corrected for overall changes in total local employment.² The larger the value of this index is, the more change in the local industry composition has occurred over time. We provide an empirical analysis on the determinants of industry turnover at the local level, as measured by the excess churning index, and we address the following questions: What are the characteristics of cities that have exhibited the most rapid change, and how are industry turnover and growth related on the local level?

This exercise is important for at least two reasons. First, little is known about the determinants of industry turnover in urban economics so far. Substantive empirical contributions have analyzed the performance of metropolitan areas or single industries, and addressed the question which local economic structure is most conducive to growth (see e.g., Glaeser et al., 1992, 1995; Henderson et al., 1995; Combes et al., 2004;

Simon, 2004). But the equally important issues, which type of cities exhibit the most rapid overall change in their industrial structure over time, and how the intensity of industry turnover is related to long-run city growth, have not been analyzed so far.

Second and even more important, we hope to inspire further theoretical work with our empirical results. Even though the model by Duranton matches several stylized facts very closely, it neglects other aspects of urban growth that have been emphasized elsewhere. In particular, it leaves aside human capital as an engine of growth, which is the central driving force, e.g., in Black and Henderson (1999) and in Eaton and Eckstein (1997). Below we will analyze, among other things, if skilled cities with a large employment share of university-trained workers exhibit more change over time than unskilled cities, as skilled Schumpeterian entrepreneurs may speed up the process of creative destruction of old-fashioned local industry structures. Furthermore, industries in the Duranton-model are inherently symmetrical. Thus, there is no special role assigned to local specialization patterns, even though Simon (2004) and Combes et al. (2004) convincingly argue that the initial structure is likely to influence a city’s subsequent development. We will analyze if cities are more likely to change if they are initially specialized in certain industries, and if yes, in what type of industries.

We find that growth and churning are not notably correlated at the local level. Among the fastest growing cities there are some that have witnessed considerable churning of their industries. Following Glaeser (2005), we see those as examples of “reinvention cities” which are successful because of a rapid change (“reinvention”) of their industrial structure. Yet, some other fast-growing cities have seen very little churning of their industries. Performing several estimations using different subsamples of cities, we find that human capital is the key engine of growth and industrial change in successful cities, but not in declining ones. In the latter group industry turnover is strongly driven by the disappearance of old-fashioned and declining industries such as agriculture or mining. Taken together, our empirical findings suggest that the model by Duranton (2007) is a powerful description of the urban growth process. Still there are some aspects that are not captured by that model, which are at the core of other theories of urban growth. In the light of our results, a combination of these different approaches seems to be a very promising agenda for further research.

The rest of this paper is organized as follows. In Section 2 we briefly review the main features of the Duranton model and simulate it using German data. Section 3 presents the empirical analysis on the determinants of local churning and growth. Section 4 concludes.

2. Brief review and replication of Duranton’s approach

2.1. The model

Duranton (2007) embeds the quality-ladder growth model by Grossman and Helpman (1991) into a spatial framework. The economy consists of a large (discrete) number of industries (n), each producing a specific commodity of a certain quality at any point in time. Consumer preferences are symmetrical over the

² Churning indices have been used before by labor economists (see Davis and Haltiwanger, 1998), but detached from any spatial or urban dimension of employment.

n goods, and households only demand the brand with the best price-quality ratio from each industry. There is, thus, a unique quality leader in each industry, which is the only active firm that produces output. This quality leader holds a patent for its specific brand, which only expires when another firm innovates this industry and climbs up the next step on the quality ladder. The R&D sector is competitive and features free entry. A research firm is specific to some industry z and invests in R&D. It innovates the own industry with some probability β , yet with some lower probability $\gamma < \beta$ the research effort targeted at industry z actually leads to an innovation of some other industry z' . This possibility of cross-sector innovations is crucial for the working of the model.

A spatial structure is introduced by assuming that the economy is divided into m locations, with $m < n$, across which workers and goods can move freely at no costs. It is assumed that research labs from industry z must engage in R&D in the same city where the active quality leader of industry z is located, i.e., research is geographically tied to production. Total employment of industry z consists of the production workers and the workers engaged in R&D, and the split between the two activities is determined endogenously by equating marginal costs and benefits of doing research, which are the same across all industries. Since all industries are symmetrical, they employ the same number of homogeneous workers in equilibrium. As a result, the size of some city c can be identified by the number of active industries it hosts.

Cross-sector innovations are the mechanism by which industries move across cities and by which city sizes can change in the model. If a research lab from z happens to innovate a different industry, production of that sector moves (at no cost) from the previous location to the city of the successful innovator.³ Locations gain or lose industries due to cross-sector innovations, but since these gains and losses partly offset each other, the model directly predicts that industries exhibit stronger churning than entire cities. City sizes change relatively slowly over time, whereas industries change their location fairly frequently in comparison.

Notice that larger cities are more likely to gain, but also to lose industries: More research labs are located in large cities that can successfully innovate and, thus, attract industries. At the same time, more local industries can be innovated from somewhere else. Hence, there will be stronger gross industry churning in large cities, but an important property of the model is that churning increases *less than proportionately* with city size. If a city already hosts many industries, it becomes less likely that the next innovation actually attracts a new industry, because the innovated sector is more likely to be already lo-

cated there.⁴ Larger cities are more likely to lose an existing second-nature industry than to gain a new one, i.e., they have a lower expected growth rate. The endogenous mechanisms of the model do, therefore, imply mean reversion across cities. The model furthermore generates a steady-state city size distribution that can be represented by a strictly concave curve when plotting log city sizes against the log of the ranks in the country's urban hierarchy, rather than a straight line as suggested by Zipf's law (see Section 2.3 for further details).

2.2. Stylized facts

Before continuing with a more formal analysis of the steady-state properties of the model, we present a few stylized facts in this sub-section which verify some of the model's basic predictions for the case of West Germany. Our data basis is the official employment statistics of the Institute of Employment Research (IAB). This data set is a balanced spatial panel of local industries covering the time period 1977–2002. It encompasses all 326 Western German districts (= NUTS3 regions) except West Berlin, and 28 different industries representing the complete range of economic activities.⁵ Further details about the data set can be found in Appendix A. First we compute the following raw churning index for every city

$$\text{Churn}_c = \frac{1}{25} \cdot \left(\sum_{t=1977}^{2001} \sum_{z=1}^n \frac{|e(z, c, t+1) - e(z, c, t)|}{e(c, t)} \right) \quad (1)$$

for $c = 1, \dots, 326$,

where $e(z, c, t)$ is the employment level of industry z in city c and at time t . This index measures the average gross industry turnover in city c over the observation period $t = 1977, \dots, 2001$.⁶ This number can be compared to the yearly average aggregate change in each city's total employment:

$$\Delta \text{EMP}_c = \frac{1}{25} \cdot \left(\sum_{t=1977}^{2001} \frac{|e(c, t+1) - e(c, t)|}{e(c, t)} \right) \quad (2)$$

for $c = 1, \dots, 326$.

⁴ The most extreme constellation is that all second-nature industries are concentrated in a single city at some point in time. In that case there is no industry left to be attracted from somewhere else. However, the "mega-city" can still lose industries due to cross-sector innovations from one of the immobile "first nature" industries. This intuition applies more generally and illustrates the mean reversion property.

⁵ It should be noted that our data set covers all regions of West Germany, including the rural areas. The West German districts are roughly comparable to US counties. This is one difference with the US and French data used by Duranton (2007), which cover only metropolitan areas. This difference does not appear crucial, however, since the theoretical framework is more generally about "locations" rather than "cities" with typical urban features such as an explicitly modeled CBD or an endogenous city fringe. In the remainder of this paper we will only use the term "city" for the West German administrative units.

⁶ By construction this index is equivalent to an arithmetic mean of annual growth rates of all local industries $z = 1, \dots, 28$ in city c over all time periods t when growth rates are measured in absolute terms, and when the "change rates" of the single industries are weighted by the local employment shares of z in period t , $e(z, c, t)/e(c, t)$.

³ To prevent cities from disappearing, Duranton assume that each city hosts exactly one "first-nature industry" where production is always tied to that particular location. In the event of a cross-sector innovation from somewhere else, the innovator must relocate (also at no cost) to the location of production. This is different in the remaining $(n - m)$ "second-nature industries," where production moves in case of a successful cross-sector innovation from a different city. Only these "second-nature" industries drive changes in city sizes.

Table 1
Churning in Western Germany, USA and France

	$Churn_c$	ΔEMP_c	$Churn_c/\Delta EMP_c$	$\Delta SecEMP$
West Germany	4.98%	2.29%	2.17	2.62%
USA	8.26%	4.10%	2.01	~5%
France	11.40%	5.20%	2.19	~5%

Source: Numbers for USA and France from Duranton (2007), numbers for Germany own calculation.

There are exactly two cases when Eqs. (1) and (2) are equal: Either *all* industries z in city c exhibit positive growth rates in a given time period, or all have a negative growth rate. Whenever some industries grow while others decline, industry turnover is stronger than the aggregate change in city employment.

In fact, Table 1 shows that, on average across the 326 West German cities, $Churn_c$ is more than twice as large as ΔEMP_c . I.e., the average city saw its industries changing twice the amount necessary to accommodate aggregate employment changes. The average amount of raw churning, roughly 5% p.a., is also decisively higher than the average industry turnover at the national level, as measured by $\Delta SecEMP = (1/T) \times \sum_{t=1}^T \sum_{z=1}^n (|e(z, t+1) - e(z, t)|/e(t))$, which ranges around 2.62% p.a. This variable is a measure for the general structural change that has occurred in West Germany.⁷ The comparison between $Churn_c$ and $\Delta SecEMP$ should be interpreted as follows: the average industry turnover at the local level is almost twice as strong as the amount of industrial change that would be observed, if all regions would mimic the sectoral employment changes that occur at the national level. Since the national industry turnover is composed of the turnover in the single locations, this implies that some cities must have changed considerably stronger than the national average, while the turnover speed in other cities has been lagging behind the national average.⁸

Turning to a cross-country comparison we find that the observed strength of raw churning in West Germany is somewhat lower than in the USA and in France. This is due to the fact that the industry classification in our data set is not as disaggregated as in the US and French data. Hence, the data will indicate less employment turnover *between* industries, since there is more change *within* the broader classified industries. Furthermore our data set of administrative regions indicates

⁷ In the theoretical model by Duranton (2007) there is no “structural change” at the national level, because all industries are identical and share the same expected (quality-adjusted) growth rate in the steady state. An interesting model where a particular form of structural change arises as an equilibrium outcome, namely the transition from sectoral to functional specialization of cities, has been presented by Duranton and Puga (2005).

⁸ Notice that if a particular city has a churning rate $Churn_c$ that is equal to $\Delta SecEMP$, this implies that the overall turnover *speed* in that city is the same as in the national average, but not necessarily the *direction* of the industrial change as single regions might develop their structure against the national trend. One could try to neutralize raw city churning from the national component of structural change. This would possibly lead to an identification of different types of cities: Those which exhibit a turnover pattern with a similar direction as the national average (yet, possibly at a different speed), and those which develop against the average national trend. A more detailed inspection of these issues is beyond the scope of this paper, however.

less average change in total local employment as compared to American or French metropolitan areas. Total local employment, thus, appears to be more volatile across economically defined metropolitan areas than across administrative regions. However, even if the absolute numbers for West Germany are lower, when comparing the intensity of industrial churning in relative terms ($Churn_c/\Delta EMP_c$) across countries we obtain numbers that lie in the same ballpark as in France and in the United States.⁹

The other two basic predictions from the model are that large cities churn more than small cities, but at a decreasing rate, and that there is mean reversion across cities. Both predictions can be addressed in a straightforward way. When regressing $\log(Churn_c)$ on the log of total city employment in the base year period $t_0 = 1977$, $\log e(c, t_0)$, we obtain a coefficient equal to -0.13 with standard error 0.01 (the French and US estimates are -0.20 and -0.21 , respectively). Since the churning index (1) is normalized by total city employment, these results suggest that churning increases less than proportionately with city size. Secondly, when regressing the long-run city employment growth rates over the period 1977–2002 on $\log e(c, t_0)$, we obtain a coefficient of -0.099 (std.error 0.015). This is consistent with the literature on mean reversion across cities (e.g., Glaeser et al., 1995) and also compares to the coefficient -0.11 for France as reported by Duranton.

In sum, the basic stylized facts about industry churning and city growth in West Germany appear to be very similar as in the USA and in France.

2.3. Simulation of the steady-state city size distribution

In this sub-section we describe the steady-state city size distribution of Duranton’s theoretical model, and we calibrate it using our data. Recall that cross-sector innovations of second-nature industries are the only way by which city sizes can change in the model. Let i denote the number of industries a city hosts. As explained in Section 2.1 this number is a sufficient statistic to describe the city size, since all industries in the model are symmetrical and employ the same number of workers. Due to the presence of the city-specific first-nature industries, $i = 1$ is the minimum city size.

Let m_i be the number of cities of size i . In the steady state, the number of cities of any size i must be constant over time. More formally, it is required that $E[m_i(t + dt)] - m_i(t) = 0$ holds for any arbitrarily small time interval dt . Hence, the probability of having one more city of any size i must be equal to the probability of having one less city of that size, conditional on the event of a cross-sector innovation. This reasoning can be illustrated for the case of cities of size one ($i = 1$). The probability that m_1 increases is equivalent to the probability that a city

⁹ To complement this analysis we have also performed a Markovian analysis of mean passage times for industries and cities. Consistent with Duranton’s results we find that mean passage times to move from the lowest to a highest quartile in the respective location ranking are much faster for single industries than for entire cities. More detailed results are available upon request from the authors.

of size $i = 2$ loses its second-nature industry due to a cross-sector innovation from a research lab that is located in a city which has at least the size $i = 2$.¹⁰ There are m_2 cities of size $i = 2$, and $(n - m_1 - 2)$ research labs that are neither located in cities of size one, or in the city that loses the industry itself. The number of all possible cross-sector innovations in the economy is given by $n(n - 1)$. Hence, the conditional probability that m_1 increases can be expressed as $m_2(n - m_1 - 2)/n(n - 1)$. In a similar vein, the conditional probability that m_1 decreases is equivalent to the probability that a research lab from a city of size $i = 1$ successfully attracts an industry from a city that is strictly larger than $i = 2$: $m_1(n - m - m_2)/n(n - 1)$. In the steady state, these two conditional probabilities must be equal, hence, the condition $m_2 = \frac{n-m}{n-2} \cdot m_1$ must hold.

Generalizing this reasoning, Duranton shows that the steady-state city size distribution of the model can be described in terms of the parameters n and m only, whereas the other parameters of the model (e.g. β , γ) only affect the aggregate growth rate of the economy. The city size distribution can be expressed by the following equation (see Eq. (28) and the Appendix in Duranton, 2007):

$$m_i = \frac{m(m-1)}{n-1} \cdot \prod_{j=1}^{m-2} \frac{n+1-m-i+j}{n-m+j}, \quad (3)$$

and it is monotonically decreasing in i . That is, there are strictly more cities of size one than of size two ($m_1 > m_2$), more cities of size two than of size three ($m_2 > m_3$), etc. This in turn implies that larger cities are more likely to lose one of their existing industries than to gain an additional one.

We can readily use our data on West German local industries to simulate the city size distribution that is generated by the model. The simulation procedure stays as close as possible to the original approach used by Duranton (2007) and is described in greater detail in Appendix B. In each run of one simulation, 10,000 cross-industrial innovations are randomly drawn.¹¹ Each run yields one fictitious distribution of city sizes, after which cities are ranked by the natural log of their simulated size. We repeat this procedure 1000 times and compute the average of the fictitious natural log size for each rank. This outcome, the simulated city size distribution, is then compared to the actual city size distribution of West Germany in the following fashion: $msd = \frac{1}{326} \cdot \sum_{j=1}^{326} [Actual \ln size_j - Mean \ln simulated size_j]^2$. We construct the simple efficiency criterion $R^2 = 1 - msd/var$, where var is the variance of the actual (log) city sizes. This R^2 -measure depicts how much of the sample's variation can be explained by the model.

¹⁰ If the second-nature industry from a city of size two gets innovated by a research lab from a city of size one, there would be no net increase in m_1 . The possibility that a city of size $i = 3$ loses two industries at the same time, etc., can be neglected since the time interval dt in which innovations occur can be made arbitrarily small.

¹¹ We experimented with more simulated innovations, but in general 10,000 were sufficient for convergence. Additionally, we simulated a scenario where initially industries are uniformly distributed across cities. Similar results were obtained with one million innovations in each run.

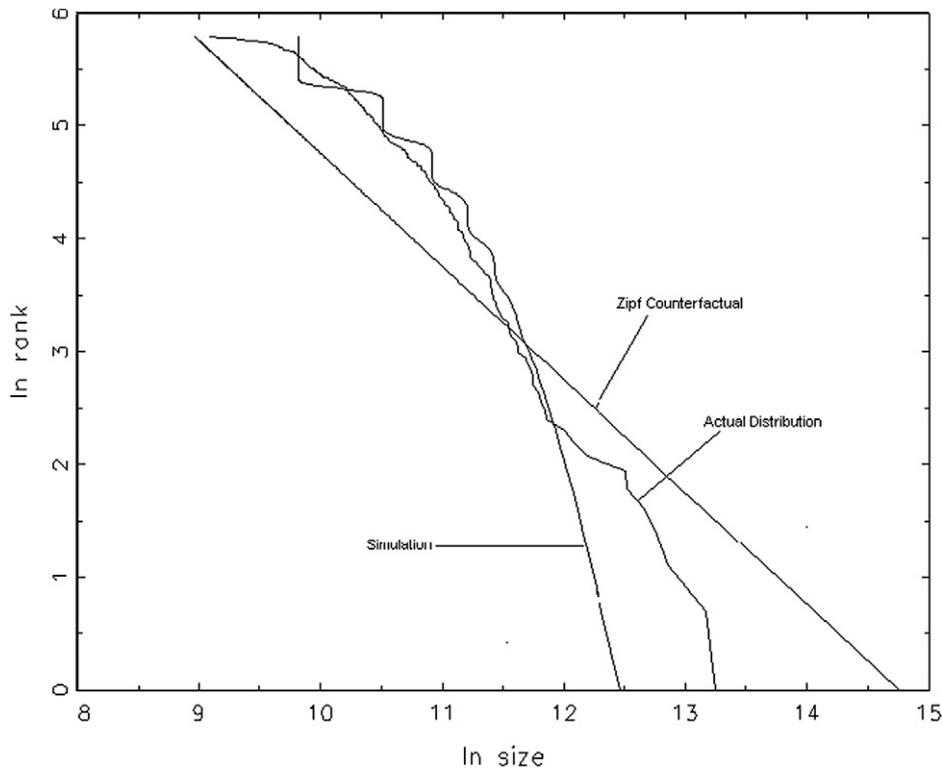

Results are very encouraging. The R^2 of the benchmark model is 92% for West Germany (the numbers for France and the US are 91% and 85%, respectively). To set these results into perspective, we have also constructed a Zipf counterfactual. We compute how the employment distribution across cities would look like if Zipf's law held perfectly, and compare this fictitious city size distribution to the actual one.¹² The respective R^2 for the Zipf scenario is a meager 23%.

To further evaluate the model's performance we have plotted the actual rank-size distribution of West German cities, the rank-size relationship that is generated by the model, and the simple Zipf line with slope -1 in Fig. 1. The concave relationship that is generated by the model fits the actual distribution in Germany fairly closely. In fact, the model performs even better for Germany than for France or for the US. Despite the lumpiness of industries (this is why the simulations look stepwise in the lower tail), the model still replicates the lower tail better and underestimates the size of the bigger cities with lower rank. The simulated rank-size curve even moves a bit closer to the actual city size distribution when we introduce ad-hoc agglomeration effects in the R&D sector (see also Appendix B). This assumption implies relatively more successful innovations, and thus more industries that are attracted by large cities. The performance of the model mildly increases to 0.922, and the fit in the upper tail is improved since large cities will be relatively larger the stronger the agglomeration effects are.

3. Empirical analysis

The previous section indicated that the churning of industries shows up as a pervasive fact in the data, creating considerable turbulence from the perspective of cities. As a consequence, in the last three decades, an average German, French, or US city faced changes in its industrial employment composition that have been more than twice as large as its (aggregate) employment change. Moreover, we observe considerable variation in the magnitude of excess churning across cities in the data: the city with the strongest industry turnover has a churning rate around four times as large as the city with the least change in its industry composition. Naturally, cities are heterogeneous in a variety of other dimensions as well: some are considerably more human capital intensive than others; some cities are strongly specialized in particular industries whereas other cities have more balanced industry compositions, etc. Most of this heterogeneity refers to characteristics that are not directly part of the Duranton-model. For example, workers in the model are assumed to be homogeneous, industries are assumed to be symmetrical, and cities are not inherently different. From an empirical point of view and as a direction for further theoretical extensions it is crucial, however, to understand if certain city characteristics are robustly related to churning patterns.

¹² Two conditions must be met to compute the Zipf counterfactual: First, the \ln rank- \ln size relationship must hold perfectly, with the Zipf coefficient equal to -1 . Second, the sum of the implied city sizes must be equal to the sum of the real world city sizes. Given that there are 326 cities in the data set, there is precisely one city size distribution that satisfies both conditions.

Note. On the vertical axis we plot the natural logarithm of the rank of cities in the urban hierarchy. On the horizontal axis we depict the corresponding total local employment level of the respective city c (also in natural logarithm). The three curves refer to the actual size of the city of the respective rank, the predicted size according to the simulation of the Duranton-model, and the hypothetical city size if Zipf’s law would hold perfectly.

Fig. 1. Simulation results.

Two issues immediately come to mind on which we will put our main focus in this paper. First, do “skilled cities” with a large local share of university-trained workers exhibit more rapid industry turnover than “unskilled cities”? This may be possibly due to the fact that the R&D process that is needed to attract footloose second-nature industries is skill-intensive. Second, what is the role of the initial industry composition for subsequent churning and growth? Do cities with an idiosyncratic initial specialization pattern exhibit different turnover patterns than cities with an average initial industry mix? This issue appears to be quite complex. A city that is initially specialized in the “wrong” industries may be interested in changing considerably, whereas a high concentration of the “right” industries may be an indicator that the city is less likely to change in the future. In the empirical analysis in this section we will analyze, in particular, the effect of human capital and initial industry structure for subsequent city churning and city growth.

3.1. Churning in cities

As the dependent variable we use the average annual excess churning rate of city $c = 1, \dots, 326$

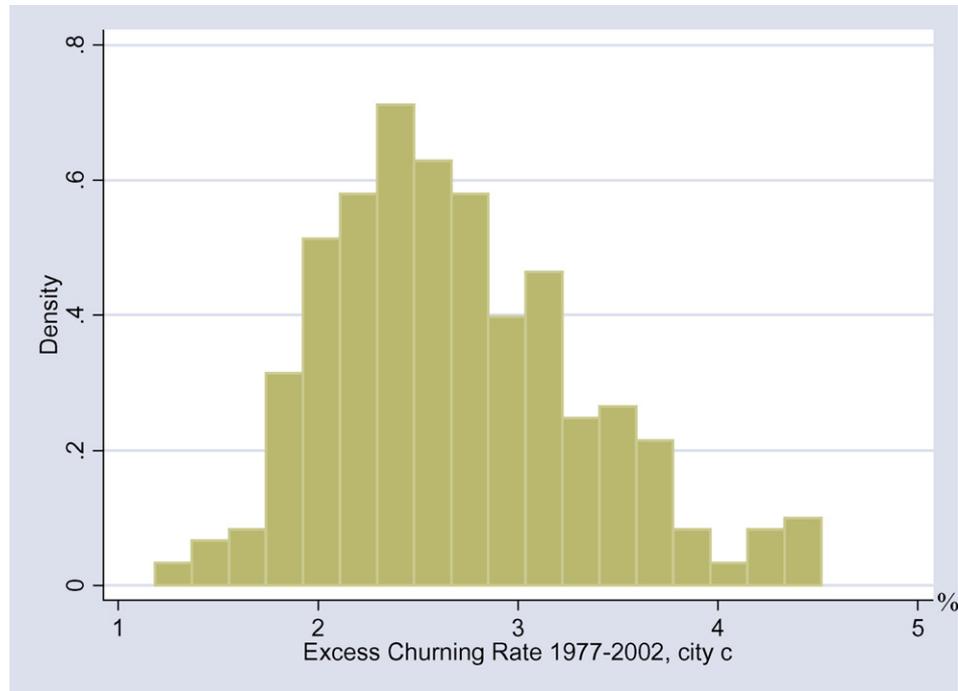

$$ExcChurn_c = Churn_c - \Delta EMP_c$$

$$= \frac{1}{T} \cdot \sum_{t=1977}^{2001} \left[\frac{(\sum_{z=1}^n |e(s, c, t+1) - e(s, c, t)|) - |e(c, t+1) - e(c, t)|}{e(c, t)} \right] \times 100. \quad (4)$$

This index has a straightforward interpretation: The larger $ExcChurn_c$ is, the more has the industrial composition changed over the years, in excess of the overall change in the city’s total employment level. The index has some notable properties: It is non-negative by definition and equal to zero if *all* industries z within the city exhibit growth rates with the same sign. Notice that $ExcChurn_c = 0$ by no means requires uniform growth rates across industries in c , but only that all industries grow or all shrink. If some industries grow and others decline in employment terms, the index $ExcChurn_c$ is positive, and increasing in the degree of industrial reallocation.¹³

Fig. 2 presents a histogram of the excess churning rates across West German regions. The index $ExcChurn_c$ ranges from 1.2% to 4.5% p.a. in West Germany (with mean 2.7% and std dev. 0.6). A look at simple correlation tables reveals that $ExcChurn_c$ is strongly negatively correlated with initial total city size in the base period $t_0 = 1977$ ($\rho = -0.6114$). When running a simple bi-variate OLS regression, as reported in column (1) of Table 2, we find that (log) total employment in t_0 is highly significant and explains nearly 40% of the variation of excess churning rates. This high explanatory power is reassuring of the theoretical model, which precisely predicts such a

¹³ Alternatively we could have used the ratio $Churn_c / \Delta EMP_c$, which has a similar interpretation. Furthermore we could have specified the dependent variable in logs, in order to take into account that excess churning rates are truncated at zero. We have performed such regressions as well and obtained results that were qualitatively very similar to those reported below.

Note. This figure illustrates the distribution of the variable $ExcChurn_c$ as defined in Eq. (4) across the 326 West German NUTS3 regions (in % p.a.).

Fig. 2. Histogram of excess churning rates across cities (1977–2002).

Note. dep. var. is the excess churning rate given in Eq. (5). The estimation method is OLS with robust standard errors reported in parentheses. Further control variables in the 4th–6th specification (coefficients not reported for brevity): local employment shares of all other industries. Full details about all results are in Appendix C, columns (1), (3), (5).

* Significant at 10% level. ** Idem, 5%. *** Idem, 1%.

negative relationship between city size and industry churning.¹⁴ Starting from this benchmark specification, we have performed several regressions to find out which characteristics are robustly related to excess churning rates. All controls are measured for the base year period $t_0 = 1977$. Of particular interest are skill-related variables, as well as variables that describe the initial industry composition of the cities.

The first basic conclusion that we draw is that human capital does not have an obvious and robust effect on churning patterns. When we only include the local share of high-skilled workers in the regression (see second column), we do in fact find a positive and significant effect on city churning. This result is not robust, however. Controlling for further city characteristics with which human capital is likely to be correlated, such as the share of workers in large firms, it turns out that the positive impact of high-skilled workers on churning is no longer significant (see third column). This indicates that the specification in the second column suffers from a basic omitted variable bias.

When looking at the full sample we find that “skilled cities” with a large employment share of university-educated workers did not exhibit notably stronger industry turnover than “unskilled cities” over time. We will come back to the role of human capital below when we present more detailed results for different sub-samples of cities.

Further controls included in the third column, such as the age and gender structure or the average city wage, do not seem to play a role either. The only characteristic that is related to churning patterns is the regional firm-size composition. Cities face less churning if a large share of the employees work in medium-sized firms (with 20–100 employees), which suggests that employment in such firms is relatively stable. All in all, it turns out that total city size remains the only highly significant explanatory variable. The other characteristics do not add much to the understanding of excess churning rates. The regression R^2 increases only mildly from the first to the third specification.

Moving to our second main focus, the role of the initial industry composition for subsequent turnover, we control for a city’s initial structure by adding the employment shares of 27 of the 28 industries (leaving the public sector as the excluded reference category) in the baseline period 1977 to the regressions. For expositional purposes we only report the main results in the fourth column of Table 2 (the complete tables are relegated to Appendix C).

The most important insight from this exercise clearly is that cities with a large initial employment share in agriculture and (metallic and non-metallic) mining have experienced significantly stronger industry turnover.¹⁵ Like in most developed countries, these traditional sectors have been on a steady down-

ward trend during the last decades in Germany. Of course, cities initially specialized in these sectors are dis-proportionally affected by these general trends of structural change. Consequently, their legacy of a disadvantageous economic structure is a good predictor for their subsequent change in terms of industrial composition.¹⁶

We run the same specification on the two sub-samples of growing and declining cities with above-average and below-average total employment growth rates over the period 1977–2002, respectively. Results are reported in the 5th and 6th column of Table 2 and in Appendix C (columns (3) and (5)). We find that the positive effect of the initial agriculture or mining share on excess churning is driven by the declining cities. Among the growing cities a high concentration of certain industries (like optics and the IT-sector) leads to *less* subsequent churning, i.e., cities specialized in these fairly “modern” sectors are less likely to change afterwards. Yet, there is no notable impact of agriculture or mining on churning patterns in this group of regions. In contrast, among the declining cities we find a significantly positive effect of these initial industry shares.

3.1.1. Robustness checks

The regressions on the two sub-samples of growing and declining cities are less efficient than the regression on the full sample of cities, since the number of observations is lower. Furthermore, the coefficient for the central significant explanatory variable (log total employment) appears not to differ across sub-samples. Therefore, we performed a robustness check of our result that the initial industry composition drives churning in the declining regions only. We ran a regression on the full sample of cities, and included the initial industry shares and interaction terms of these shares with a dummy variable that indicates whether the city is a growing or a declining one. Consistent with the results reported above, we obtain significantly positive coefficients of the agriculture and mining share on city churning. The interaction terms are negative and significant (strongly significant at the 1% level for mining, at the 10% level for agriculture). These findings verify that city churning is associated with the disappearance of old-fashioned industries, yet only among declining cities.

Secondly, one might wonder how the fact that our data set includes all West German locations (including rural areas) affects our results. We have repeated the comprehensive specification in column (4) of Table 2 and excluded all rural areas. Furthermore we ran this specification on the rural areas only. It turns out that the qualitative results are very similar across samples: the coefficient for the high-skilled employment share is insignificant, and the coefficients for the initial agriculture and mining shares are positive and significant in all regressions. Our

¹⁴ This property can be seen even more clearly when re-estimating the first specification as follows: $Churn_c = 7.62 + 1.092\Delta EMP_c - 0.49\log(emp_{c,t_0})$, where all estimated coefficients are highly significant. The coefficient on ΔEMP_c , which is larger than one, is also consistent with the property of the theoretical model that industries churn more than entire cities.

¹⁵ There are only two additional significant coefficients for the other initial industry shares when looking at the full sample of regions (gastronomy and health care, see column (1) of Appendix C).

¹⁶ Notice, as obvious these results appear they were by no means so clear a priori. Since $ExcChurn_c$ measures the industry turnover *in excess of a city's aggregate employment change*, it might still have been the case that no correlation between the initial employment shares in declining industries and $ExcChurn_c$ shows up in the data. This would have been the case, if on average cities initially specialized in those declining industries had not gained employment in other rising industries.

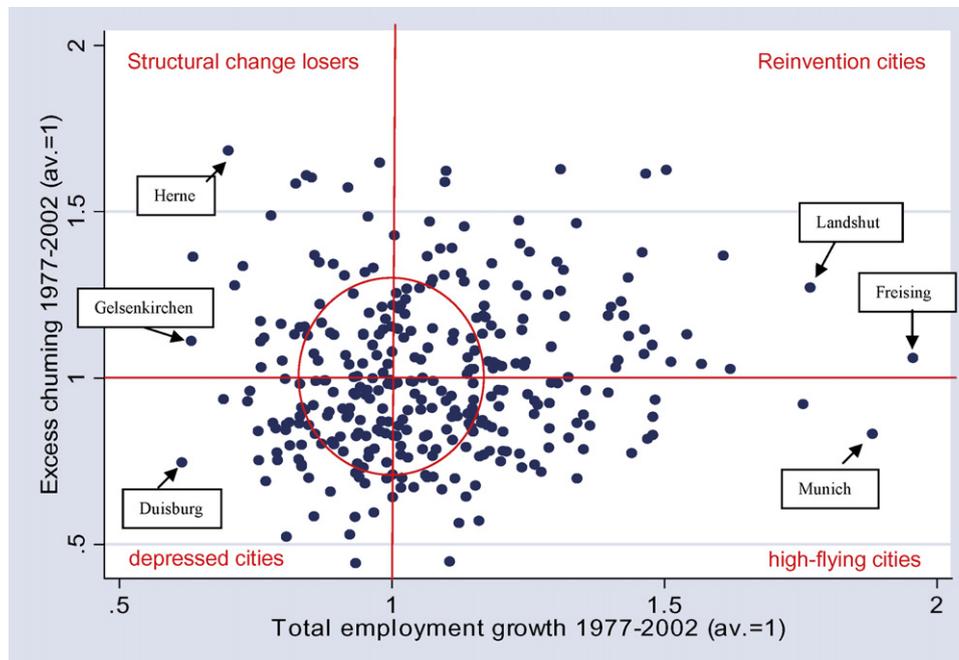

Fig. 3. City growth and industry churning.

findings, thus, appear to be robust to different definitions of “locations”.¹⁷

3.2. Churning versus growth: A classification of four different types of cities

How are the growth of a city and the excess churning of industries it faces interrelated? A priori, it is not clear if one should expect a positive or a negative correlation, if any at all. Strong urban growth may go along with strong urban change: The success of a city may be due to the fact that it has modernized its economic structure and outpaced other regions in terms of industry turnover and structural change. On the other hand, urban growth may also result from factors that are essentially unrelated to industrial change, i.e., some cities may grow without exhibiting notable industry turnover over time.

Indeed, plotting the cities’ excess churning rates against the standard employment growth rates (as in Fig. 3) we only find a slightly positive correlation ($\rho \approx 0.1$) between the two variables. City growth rates and excess churning rates are both measured relative to the respective sample average. Regions to the right (left) of the vertical solid line have grown faster (slower) than the West German average over the years 1977–2002. Regions above (below) the horizontal line have seen more (less) industry turnover than the average region over the same time period.

The emerging picture allows a stylized classification of cities into four types. In some cities, located in the north-east corner of the figure, high growth rates coincide with a strong churning of industries. Yet other growing cities, located in the south-east corner, have seen relatively little change in their industry composition. A similar distinction can be made for the group of declining regions. Those in the north-west corner exhibit above-average excess churning rates, whereas those in the south-west corner rank below the average both with respect to growth and churning.

Following Glaeser (2005), we think of the regions in the north-east corner as examples of successful “reinvention cities.” The above-average values of the growth rate and the $ExcChurn_c$ -index imply that these regions have seen considerable industry turnover, such that the employment losses in the declining sectors were more than compensated by the gains in the growing industries. Many of these cities are rather small and located in the state of Bavaria (like Freising or Landshut), which has been dominated by traditional industries but then developed rapidly over the 1970s and 1980s to become one of Germany’s leading high-tech states. Growth in these regions coincides with rapid change, which suggests that they have successfully “re-invented” themselves fairly quickly.

Yet, there is also a huge group of regions where high growth coincides with relatively low excess churning rates. This coincidence indicates that, by and large, all local industries have exhibited positive growth rates. The best example of such a city is Munich. Of course, even in Munich some industries grew stronger than others. Hence, relative industry shares have changed over time, but very few industries actually shrank in absolute terms. In view of this, we call the cities in the south-east corner of the figure the “high-flying cities” which generally grow without exhibiting strong industrial change.

¹⁷ For the definition of “rural areas” vs. (non-rural) “cities” we adhered to the different area types defined by the German Federal Agency of Building and Planning (BBR). Regions not belonging to area types 1 and 5 were defined as “rural” in this robustness check. Of course, the agricultural employment shares in non-rural cities are now much lower, but the variation was still sufficient to identify all coefficients.

As for the declining cities, those in the north-west corner still have above-average excess churning rates. At least some industries have grown in these cities, even though this growth was not sufficient to compensate the employment losses of the declining sectors. Many large cities from the coal & steel dominated Ruhr area (like Herne, Gelsenkirchen, Dortmund) belong to this group. These cities launched a process of change, but what has been achieved was not sufficient to compensate the losses in the declining traditional sectors. We therefore call these regions the “structural change losers.” Finally there are some cities, where most industries shrank over time, so that low city growth coincides with a low excess churning rate. We call these regions in the south-west corner the “depressed cities,” since encouraging experiences of at least some growing industries appear to be absent.

3.3. Determinants of churning and growth in the different types of cities

In Section 3.1. we have investigated the determinants of excess churning rates for all cities in the sample. In this section we present similar regressions for the different types of cities. More precisely, we re-estimate the comprehensive specification (4) of Table 2 on the four sub-samples (reinvention cities, high-flyers, structural change losers, depressed cities). Furthermore, we conduct all regressions not only with $ExcChurn_c$ as the dependent variable, but also with the standard long-run employment growth rate of cities over the period 1977–2002. The selection of a city into one of the sub-samples is of course not random. However, our aim in this paper is not to uncover causal mechanisms that determine the success of cities *ex ante*, but we try to develop new stylized facts about the processes of industry turnover and growth *ex post*. What have been the main characteristics of the cities in the four respective groups that are notably correlated with their growth performance and their turnover pattern? In particular, we are interested in whether the effects of human capital and the initial industry composition on churning and growth have been different in the different types of cities.

Table 3 highlights the most important results.¹⁸ Columns (1) and (2) present the results for excess churning and growth using the full sample of cities. The share of university-educated workers is insignificant in the estimation of the excess churning rate, as argued above. Yet, it is positive and highly significant in the standard employment growth regression. The important role of human capital as an engine of local growth is well documented in several previous studies that find that “skilled cities” exhibit faster employment/population growth than unskilled cities (see Simon, 1998 and Glaeser and Saiz, 2004 for the US; Südekum, in press for West Germany). We obtain consistent results. Yet, there is no evidence that the faster growth of skilled cities is accompanied by more industrial change in general. A more complex picture emerges, however, when repeating the regressions

for the group of growing cities only, and for the two sub-groups of growing cities (specifications (3)–(8)).

First of all we find that human capital is even stronger correlated with city growth within growing cities than in the full sample (compare specifications (2) and (4)), yet the correlation is again even stronger among the fast growing and quickly changing “reinvention cities.” Among those cities which grow *and* churn, the skill-intensive ones have grown *much* faster although they were not the ones that exhibited the fastest turnover within the group of fast churners. Interestingly, when looking at the “high-flying cities” which grow fast but churn relatively little, the results are reversed. Within this group we find that the skill-intensive cities have not grown faster, but instead they have exhibited a somewhat stronger turnover. Furthermore, the association between the initial industry composition and subsequent growth seems to be quite different between the two types of growing regions (see in particular Appendix C, columns (8) and (10)). For both, the re-invention and the high-flying cities, we find that the initial mining and agricultural employment share are not significant in the churning and growth regressions. Yet, growth among the high-flying cities was notably positively correlated with the initial employment shares of 13 out of 27 industries (e.g., education or automobile production). In contrast, the initial industry composition played a much lesser role for growth among the reinvention cities.

These empirical findings suggest that there have been two different profiles of urban success. In the *first type* of successful cities, the “reinvention cities,” there is a principal association of growth with human capital. The reinvention cities must exhibit declining employment in a notable number of industries, but this decline has been dominated by the growth of rising industries. This growth of the rising industries appears to be strongly associated with human capital.¹⁹ In the *second type* of successful cities—the “high-flyers”—growth was not significantly associated with human capital. We believe that this result is due to the fact that this group entails some successful cities, where growth is due to fortunate circumstances such as location or market potential, which are detached from skill intensity. These cities have been specialized in the “right” industries already in the beginning of the observation period, as suggested by the positive effects of several industry shares on growth (see Appendix C). These cities have, thus, experienced a growth process that did not require the city to change constantly. Yet, even within this group of “high-flyers” we still find that the most skill intensive ones showed the relatively most rapid industry turnover. This may indicate that the most skilled “high-flyers” realize that a strategy of change may be needed in the longer run to complement the fortunate development that is common to these cities.

In declining cities, churning and growth seem to have quite different characteristics. Most importantly, we find no significant effect of human capital, neither on churning nor on growth. This is true for the group of declining regions altogether, but

¹⁸ Some coefficients are omitted in Table 3 for expositional purposes. The complete set of results is reported in Appendix C.

¹⁹ This finding is nicely consistent with Glaeser’s study on Boston (see Glaeser, 2005), where he argues that the city’s success in “reinventing itself” was essentially due to its human capital.

also for the two-subgroups of declining regions with above-average and below-average industry turnover, respectively. This suggests that human capital is associated with local growth and change only within the group of successful cities. Within the group of unsuccessful cities we do not find that the skill-intensive ones are relatively less unsuccessful. What stands out for the group of declining regions is the effect of the initial agriculture and mining share.

Among the declining cities we find that those with large initial shares in agriculture and mining had stronger turnover, but grew less over the years. Industries other than mining or agriculture show no significant correlation with churning among the declining regions, which points at the special role of these two sectors for the declining cities.

To sum up, our empirical findings point at two important characteristics of the processes of local growth and churning that have been neglected in the Duranton-model. First, human capital matters, at least in successful cities. In the “reinvention cities” human capital particularly boosts the growth of the rising industries, and it accelerates industry turnover in the “high-flyer” cities. Second, initial industry composition also matters for the subsequent turnover pattern of cities, particularly among declining cities. Cities that are initially specialized in declining industries, such as agriculture or mining, are more likely to change afterwards, as an industry turnover is needed to cope with their initial structural problems.

4. Conclusions and outlook

In this paper we have shown that the recent model by Duranton (2007) is successful in explaining a variety of facts about industry turnover and growth in West German cities and local industries. The steady-state city size distribution of that model comes very close to the actual distribution, and the model clearly outperforms Zipf’s law. These results are reassuring of the importance of Duranton’s approach, since all essential results can be confirmed for the case of West Germany in our independent study. Secondly, we have established several new facts and insights about industrial churning in cities, which is the central mechanism of that model. In particular, we have investigated the effect of human capital and the initial industry composition on industry turnover in different types of cities.

Our empirical findings point at some aspects of the urban growth process that are not fully captured by the Duranton-model. The prominent role of the skill structure for local growth among successful cities is strongly in line with theories in the spirit of Black and Henderson (1999), which relies on human capital accumulation with knowledge spillovers as the main growth engine. Worker heterogeneity is neglected as an integral part of Duranton (2007), however. Urban growth appears to carry facets of both theories. Both, industry reallocations and human capital play important roles in reality. It seems to be an exciting area for further research to combine these two views of the urban growth process in a unifying framework, possibly by being more explicit about the role of human capi-

tal for the endogenous R&D process that drives local industry turnover.

A second feature that is not captured by Duranton (2007) concerns the fact that the development of cities sometimes cannot be detached from long-run trends of structural change. Following Duranton we consistently find strong spatial mobility of industries in general, which causes rapid industry turnover at the local level in West Germany. Yet, the evidence also suggests that not all cities and industries are symmetrical in this respect. At least for some cases we find fairly persistent local specialization patterns in the data, so that the fate of a city is closely tied to the fate of a particular sector. Some sectors, such as agriculture and mining, are on a long-term trend of decline. Cities with a high concentration of those sectors are stuck with a structural problem, which is resolved only slowly over time. Consistent with this view, we find that a large initial employment share of agriculture and mining is associated with more rapid subsequent industry turnover but with lower growth. Coming to grips with these observations will probably require including aspects of inertia in local economic structures as well as industry-specific growth trends into the model.

Acknowledgments

The authors thank Gilles Duranton for several extremely helpful comments and suggestions on an earlier draft of this paper. We are also grateful to Stuart Rosenthal, Markus Jochmann, Kristian Giesen, Florence Bouvet and seminar participants in Savannah and Halle. All remaining errors and shortcomings are, of course, our responsibility.

Appendix A. Details about data set

The data is a balanced spatial panel, with annual observations for the time period 1977–2002. Data is not subject to any censoring. For each local industry and year the following information is available:

- *SIZE*: the total employment level of full-time employees (≥ 35 working hours per week) referring to workplace location.
- *MEDIUM*, *LARGE*: the employment shares in medium-sized (20–99) and large (> 100) firms. Residual share is employed in small firms (< 20 workers). Data for firms refer to the headquarter location, i.e., the data does not refer to establishment sizes.
- *HQ*, *MQ*: employment share of workers with completed tertiary education, respectively with completed apprenticeship. Residual share: Workers without formal vocational qualification.
- *AGE*: average age of all employees in the respective local industry.
- *MEN*: fraction of men among all employees in the respective local industry.
- *WAGE*: the average wage income per employee per calendar day, including all bonuses and extra payments subject to social security.

Note: Standard errors omitted for expositional purposes. Variable abbreviations are explained in Appendix A.

* Significant at 10% level. ** Idem, 5%. *** Idem, 1%.

The 28 different industries that are distinguished in the data set are: Agriculture, Mining, Electronics, Chemical Industry, Synthetic Material, Non-metallic Mineral Mining, Glass & Ceramics, Primary Metal Manufacturing, Machinery, Automobile, Office Supplies & IT, Toys & Jewellery, Wood-working, Paper & Printing, Leather & Textile, Food & Tobacco, Building & Construction, Transportation, Banking & Insurance, Hotels & Gastronomy, Health Care, Business-Related Services, Education, Leisure-Related Services, Household-Related Services, Social Services, Commerce and the public sector. Data for the public sector contains only public employees with social security contributions but no civil servants, who are exempted from the social security system.

The abbreviations of variable names refer to the full results tables presented in Appendix C.

Appendix B. Simulation of the steady state city size distribution

The number of cities in the simulations is equal to the number cities in our dataset, hence $m = 326$. The derivation of n relies on the assumptions that all industries are homogeneous in size, and that the smallest cities in our model host one industry. The number of the smallest cities can be shown to be

$$m_1 = \frac{m(m-1)}{(n-1)}, \quad (\text{B1})$$

see Duranton's Appendix A, Eq. (A12). Since m_1 cities host one industry, it must hold that the average size of the m_1 cities times n must equal the sum of all employed people in the economy, defined as POP:

$$POP = \frac{1}{m_1} \cdot \sum_{c=1}^{m_1} e(c, t) \cdot n. \quad (\text{B2})$$

Solving (B1) for n and inserting this into (B2) with $m = 326$ yields:

$$POP = \frac{1}{m_1} \cdot \sum_{c=1}^{m_1} e(c, t) + \frac{326(326-1)}{(m_1)^2} \cdot \sum_{c=1}^{m_1} e(c, t). \quad (\text{B3})$$

Using the most recent year in our panel $t = 2002$, we have $POP \approx 16.28m$. Then the best "fit" for Eq. (B3) is achieved with a value of $m_1 = 115$, which in turn implies a fixed industry size of approximately 18,400 employees and $n = 885$ industries. These industries are then assigned to the 326 cities in proportion to their relative size in 2002.

In the first step of each simulation, one "innovator" of the $n = 885$ industries is randomly picked from a discrete uniform distribution. The "innovated" industry is then drawn from the remaining pool of $n - m = 559$ second-nature industries. The

"innovated" industry moves to the city of the "innovator" (or stays if already located there).

In the benchmark model every city faces a probability of being home to an "innovator" of i_c/n , where i_c denotes the number of industries in city c . In an extension, we also consider ad hoc agglomeration benefits to R&D (yet, not in production) in the simulations. This is done by assuming that the probability for a city to innovate increases to $i_c^{1+\phi}/n$, where $\phi \geq 0$ captures the scale economies in R&D. Like Duranton (2007) we allow ϕ to vary over the 0.00–0.05 range in different simulations. Fig. 1 refers to the set of simulations with $\phi = 0.01$.
